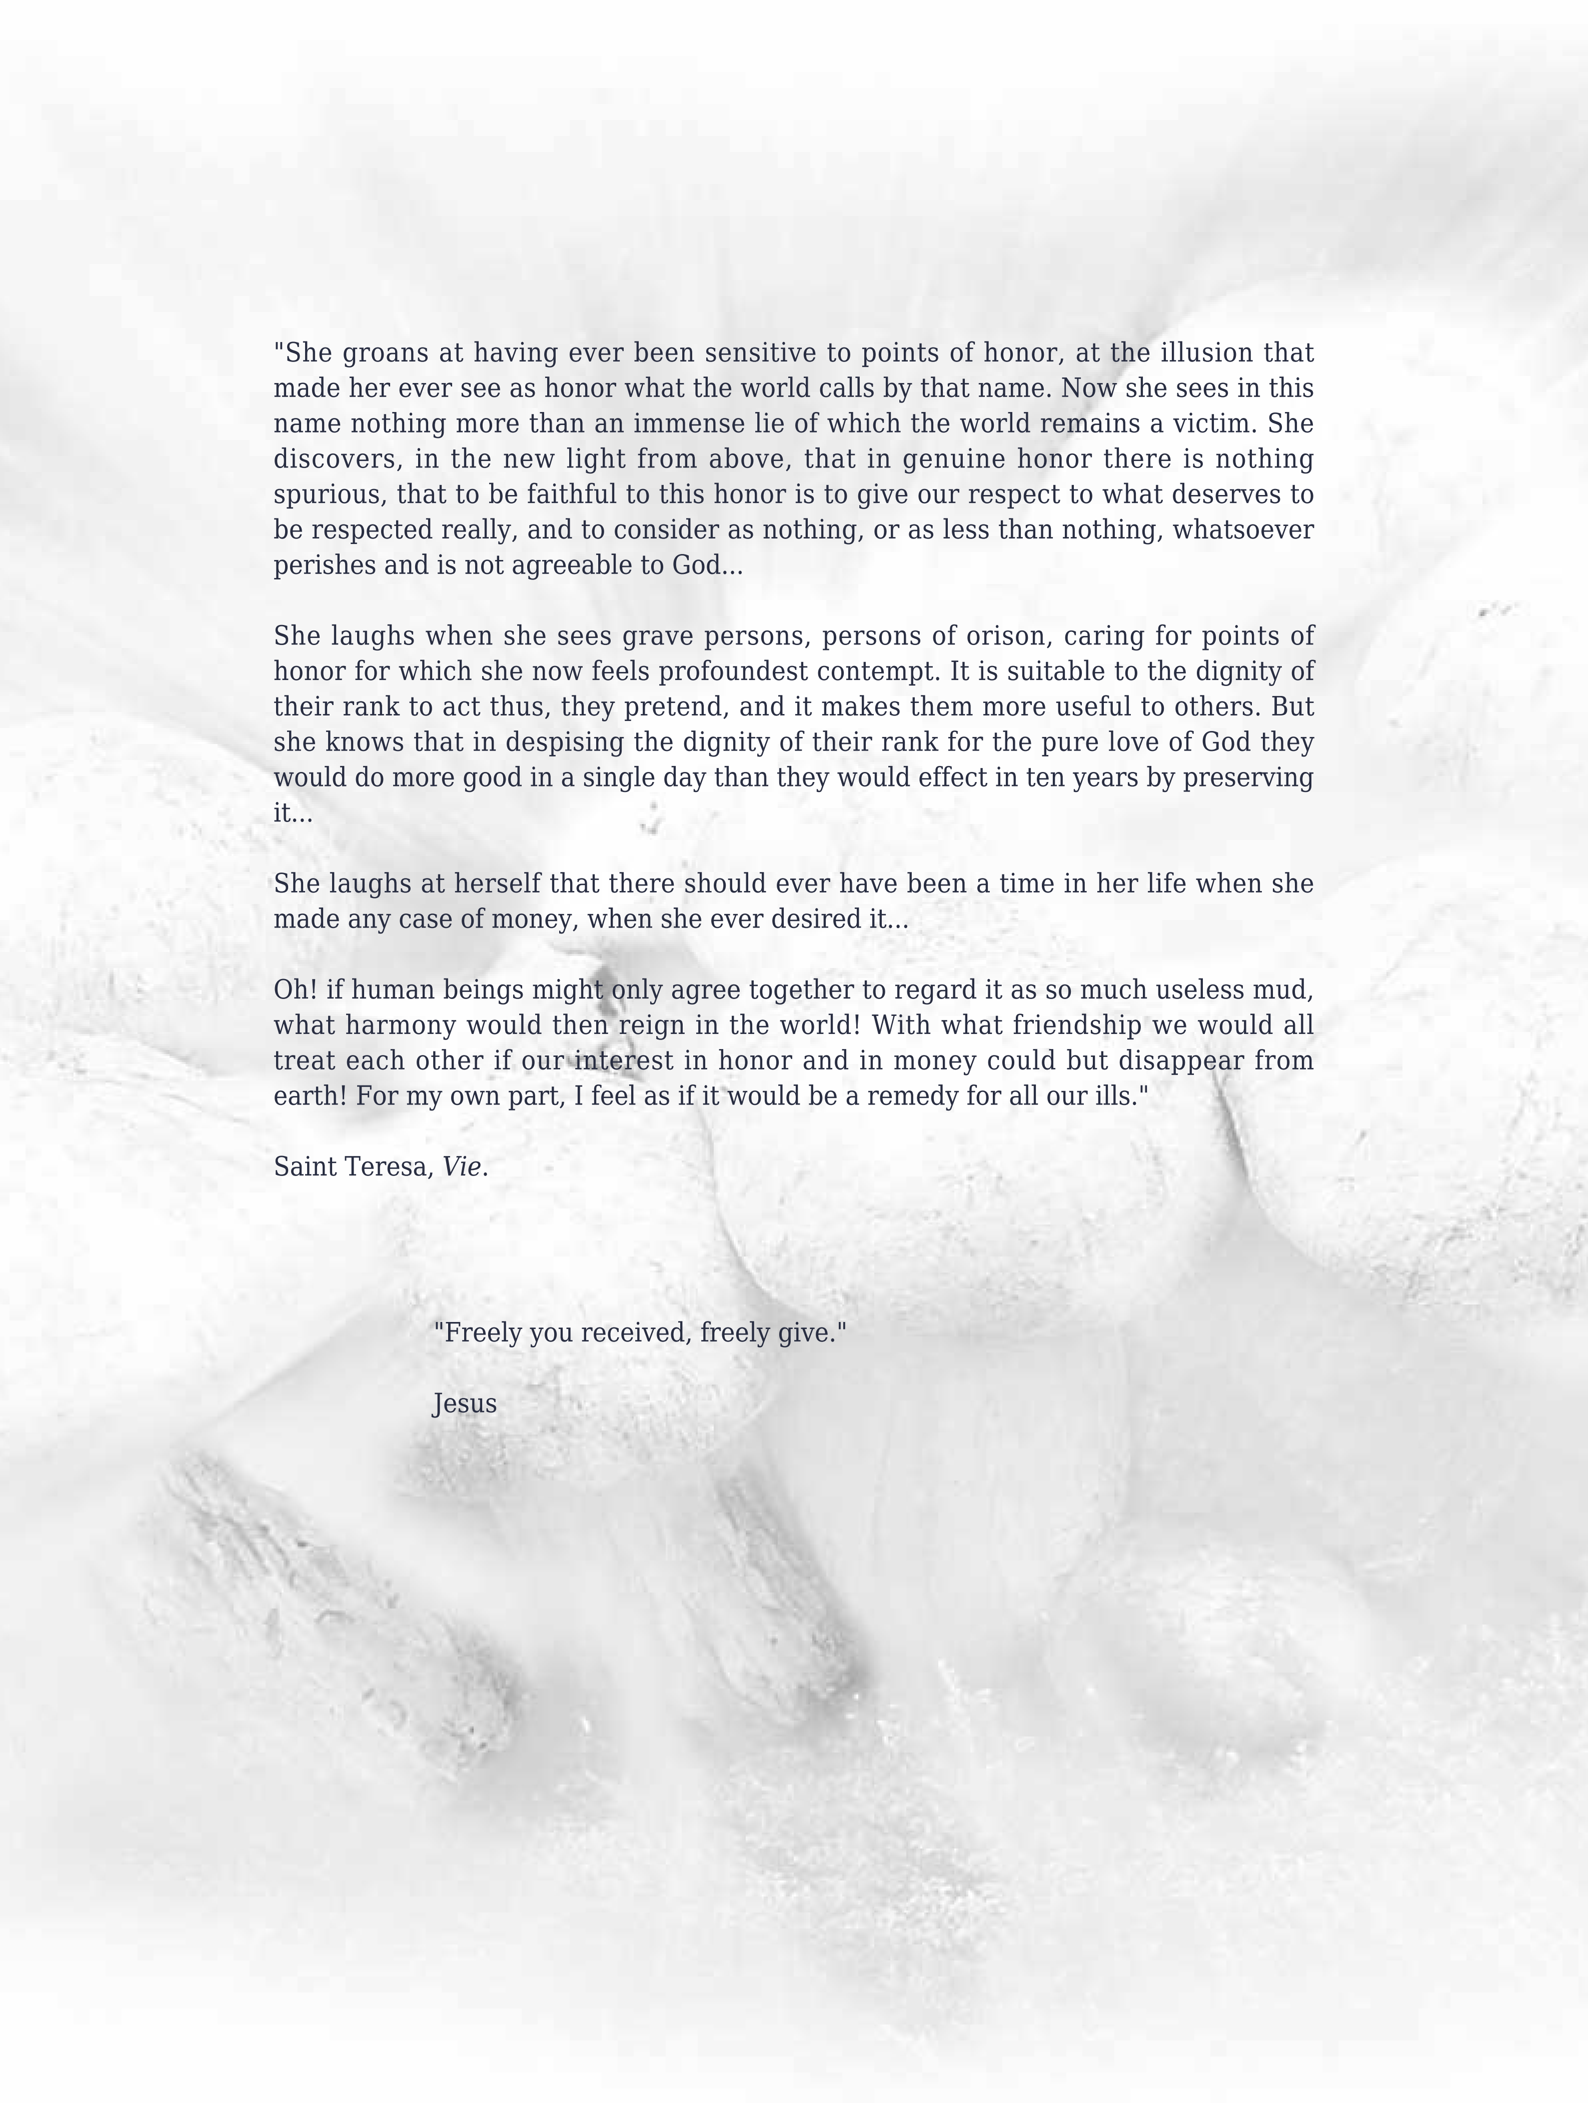
highness in a Holt by May.

Fungate fungatorum exorte Popule Libri…

…et cave, vos qui huc intratis, quoniam relinquetis tinctus litteris.



"She groans at having ever been sensitive to points of honor, at the illusion that made her ever see as honor what the world calls by that name. Now she sees in this name nothing more than an immense lie of which the world remains a victim. She discovers, in the new light from above, that in genuine honor there is nothing spurious, that to be faithful to this honor is to give our respect to what deserves to be respected really, and to consider as nothing, or as less than nothing, whatsoever perishes and is not agreeable to God...

She laughs when she sees grave persons, persons of orison, caring for points of honor for which she now feels profoundest contempt. It is suitable to the dignity of their rank to act thus, they pretend, and it makes them more useful to others. But she knows that in despising the dignity of their rank for the pure love of God they would do more good in a single day than they would effect in ten years by preserving it...

She laughs at herself that there should ever have been a time in her life when she made any case of money, when she ever desired it...

Oh! if human beings might only agree together to regard it as so much useless mud, what harmony would then reign in the world! With what friendship we would all treat each other if our interest in honor and in money could but disappear from earth! For my own part, I feel as if it would be a remedy for all our ills."

Saint Teresa, *Vie*.

"Freely you received, freely give."

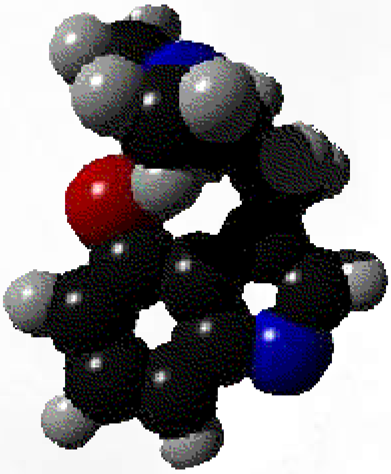
The Magic Mushroom Growers Guide

Version 3.2 (3.22 by Erowid)

Widely acclaimed as the best and most comprehensive growing guide for the first time cultivator anywhere on the web. You be the judge!

original source: https://www.erowid.org/plants/mushrooms/mushrooms_mmgg.shtml



This document may be freely copied and distributed so long as the following conditions are met:

- *Any copies of this document must include this notice.*
- *This document must only be distributed in an unaltered and complete form.*
- *This document can not be distributed for profit.*

This document provides complete directions for cultivating psilocybin mushrooms in your home. The strain this guide is intended to help you grow is Psilocybe cubensis (Amazonian strain) mushrooms. It is the intent of this document to enable the first time grower to succeed at a minimal cost and with a minimal amount of effort. This growing guide is the only reference you will need. After a person has completed the entire cycle successfully, later generations of mushrooms can be grown with even less cost and effort. The initial cash outlay will be well under $100 for a fully automated shroom factory. Subsequent crops can be produced for several dollars with expected yields of several ounces of dried mushrooms.

Revision History

What has changed since version 3.1

Following is a list of changes made to the document.

3.22 : 2005 Dec : by Erowid.org :

- Typo fixes on suggestion of reader.

3.22 : 2005 Nov : by Erowid.org :

- Removed PF address on suggestion of reader. PF's arrest and guilty plea suggests it is no longer appropriate to send money to the old PF address.

3.2 : 1996 : Primary Author

- Version number was changed from 3.1 to 3.2
- Change pictures in opening.
- Suggest ways to get help and provide PGP public key for private messages.
- Poor Man's terrarium setup.
- Bulk growing.
- Cris Clays email address and such.
- Link to http://www.xs4all.nl/~psee/ as a spore seller.
- No more packing of the substrate.
- Vacuum cleaner instead of hair dryer.
- Link to PF's pages.
- Timer stuff.
- Arrowhead Mills no longer sells brown rice flour as a mail order item.
- Caution about jars sitting flat in boiling pan.
- Low humidity cap apperance.
- Sealing a cake in a jar to reduce contamination risk when growing for spores.
- Changing plates after start of spore print for lower contamination risk.

Credits to those who have gone before us

The procedures detailed in this document borrow heavily from past innovators. In particular, much research was done by a company in Seattle, Washington called Psylocybe Fanaticus which was instrumental to the viability of this innovative and elegant procedure for the novice cultivator.

Psylocybe Fanaticus sold a Technology Report called the PF Tek. Normally, growing Psilocybe mushrooms is next to impossible for a beginner. However, the PF process is a breakthrough and virtually guarantees that the beginner will succeed.

The PF Tek is the foundation for this document. The main purpose for this document is to detail the various ways the PF Tek can be adapted to various needs of the home cultivator.

[Note: Psylocybe Fanaticus is no longer in business and plead guilty to a crime involving the possession of psilocybin-containing mushrooms. See PF's Encounter with the Law**. This section formerly requested that readers send money to PF in thanks for his work, but the address has been removed.]**. Please treat this document as you would 'shareware software'. Try it out, and if it works for you, send $10 and a thank you note to:

Psylocybe Fanaticus

Format of this Document

How to use this document

The procedures detailed in this document are a mixture of mandatory and optional steps. The core document describes the basic procedure in its simplest form and at various points there will be possible adaptations that can be incorporated. In general, the adaptations will summarize what is required and the benefit to the cultivator in the event the adaptation is implemented. You should read the entire document before you attempt to implement the procedures described in it.

The first time you use the process you should follow the directions exactly and resist the temptation to innovate. Innovation without experience is the primary cause of failure. If you must innovate because you can not find a particular item or for some other reason, first check with someone that has experience to make sure you are not doing something crazy.

It is our intent to provide the first time cultivator with the knowledge to make informed decisions about the growing process for Magic Mushrooms. The cultivator can select some adaptations that are felt to be worthwhile and reject others that don't have sufficient merit for him. It's his choice, but he is still guaranteed that if he follows the directions he will produce a crop of mushrooms.

This guide is published as a single document to make printing easy and simplify acquiring a copy to your local machine. There are several GIF files that it references in the directory that you found this document. You need these also. You might want to check and see if there is a file called MMGG.ZIP or MMGG.TAR in the directory you found this document. If so, you can just get this one file and it will contain everything you need to obtain a local copy.

If you wish to examine an adaptation, simply click on it. When you're done looking at it, there will be two links. One back to the table of contents and one back to where the adaptation is used in the procedure.

One last note. A terrarium is required to complete the growing cycle. You can perform the steps to inoculate the culture jars and over the next few weeks build your terrarium. It takes time for the cultures to grow and this should provide you sufficient time to make a suitable terrarium if you are in a hurry to get started.

Back to table of contents

Overview of the Procedure

In order to grow mushrooms, a suitable substrate must be inoculated and colonized by the fungus. This step requires sterility because the substrate contains no preservatives and can be overrun by any mold or bacteria that is present. This first step takes place in canning jars prepared in your home's kitchen. It uses brown rice flour and vermiculite which are both readily available. A substrate is prepared, placed in the canning jars and sterilized with heat. After the jars cool, they are inoculated with a spore syringe. This phase of the cycle can be completed for less than $25 and will produce enough substrate to yield many ounces of dried mushrooms.

After the substrate is inoculated, you wait until it is colonized completely by the fungus. Once the substrate is colonized completely by the fungus, sterility is less of a concern because the fungus is pretty much able to fight off invaders and the rice cake substrate can be removed from the jar. This typically takes between two and three weeks to complete. At this point, the substrate is placed in a terrarium where high humidity is available to the fungus. While waiting for the substrate to colonize completely, no effort is required.

The terrarium is kept at around 90% humidity and the carbon dioxide that is produced by the fungus is constantly eliminated. Within a week of being placed in the terrarium, the rice cakes will start growing mushrooms. Within several weeks of being placed in the terrarium, the cultivator will have numerous mature mushrooms ready for consumption. The cakes continue to produce mushrooms until either the nutrients in the rice cake are used up or the moisture in the rice cake is depleted. Depending on how the cultivator chooses to implement the terrarium, more or less attention is required at this phase in the cycle. With the fully automated terrarium setup described later in this document, attention is only required every few days. Mostly, this involves picking mature mushrooms and adding water to the humidifier used in the setup.

It is very likely that the mushrooms will be produced faster than they can be consumed by the home cultivator once the cropping phase of the cycle starts. It is fairly easy to dry the mushrooms and preserve them for many months. In fact, some people prefer the dried mushrooms to their fresh counterpart. Being the master of understatement, let me state that they do not taste as good as mushrooms available in the grocery store.
Occasionally, a sterile spore print from a mature mushroom needs to be generated if the cycle is to continue. This is used to produce a spore syringe to inoculate new culture jars. It is a little bit of effort and requires very careful, sterile procedures to be successful generating a spore print. Of course, this can be circumvented by simply ordering a new spore syringe. A 10 cc. spore syringe should be sufficient to inoculate a dozen jars of substrate. It is the cultivator's choice which path to follow for successive generations.

Back to table of contents

Preparation of the Substrate

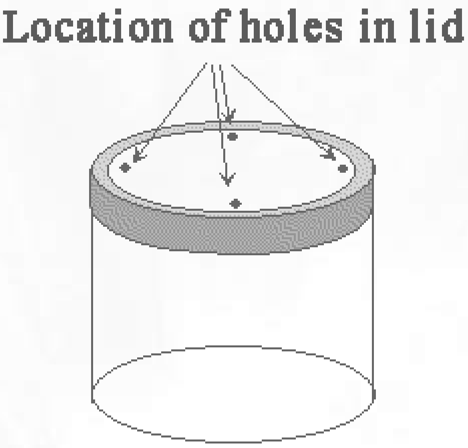
Mushrooms are grown on a substrate of nutrients. Just as a common house plant is grown in a pot of soil, mushrooms can be grown on a cake of substrate material. The big difference is that the substrate must be free of competing bacteria and molds in order for the process to be successful. Any contamination of the substrate will result in failure of the process.
Materials needed:

- 1/2 pint canning jars Adaptation-1
- Vermiculite (from any garden department. K-Mart, Target, etc.) Where to find
- Brown Rice flour Adaptation-22 (from a health food store --- No Preservatives!) Where to find
- Large pot with lid Adaptation-2
- Measuring cups
- Mixing bowl
- Hammer and small nail
- Spore Syringe (Where to get a spore syringe)

The canning jars need to be tapered. This means that the opening of the jar is wider than the body of the jar. This is important because the fully colonized rice cake needs to be removed intact from the jar. You simply want the cake to slide out when the time is right. If you use a jar that is not in the following list, check to make sure the box says it is a tapered jar. The following jars are acceptable:

- Ball 1/2 pint jelly jars.
- Kerr wide mouth 1/2 pint canning jars.
- Ball regular mouth 1/2 pint canning jars.

Step 1:
Prepare the tops of the culture jars so that they can be in place, on the jars when inoculating the jars with the spore syringe. Part of the reason this system works so well in the non-sterile kitchen environment is the fact that the sterilized substrate is never exposed to air born contaminates. Get a small nail and use the hammer to poke 4 holes in the lid of each canning jar. See the following figure:



Step 2:
Decide in how many jars you are going to initiate cultures. The average terrarium that is built will hold 6 rice cakes but you may have some jars destroyed by contamination and some jars colonize more quickly than others. It is unlikely that every jar you prepare will be ready to be placed in the terrarium at the same time. The rice flour and vermiculite are cheap enough that it makes sense to do a dozen jars.
For each 1/2 pint jar mix **2/3 cup vermiculite** and **1/4 cup brown rice flour** in a mixing bowl. Adaptation-23 When these ingredients are well mixed, add **1/4 cup of water** for each 1/2 pint jar you plan to prepare. If you are using 1 pint jars you need to double the recipe. Mix all of this stuff up well. This mixture is the substrate material that the fungus will consume and use for growth.

Step 3:
The next step is to fill each jar with substrate material. Adaptation-20 This document used to suggest gently packing the substrate into the culture jars. It has been found that keeping the substrate as loose and full of air as possible is the best way to fill the jars. The jars will colonize faster this way. Incidentally, the faster the jar colonizes, the lower the risk that some competitor contamination will get a foothold and take over the substrate. Adaptation-3 Fill each jar to within 1/2 inch of the top with substrate material. If you run out of substrate material, either mix up enough for one more 1/2 pint jar or cannibalize a jar to fill up the rest of the jars. This is important because you need to make sure the substrate is high enough in the jars for the spore syringe to inject spores into it.

Step 4:
The top 1/2 inch of the glass on each culture jar needs to be cleaned. No substrate material can be left on the glass above the compressed cake. First wipe it with your finger to get the bulk of the material off of it and then do a thorough job with a moistened paper towel. The glass needs to be spotless. The reason this is necessary is that bacteria and mold can use any material left there as a wick to infect the main substrate body.

Step 5:
Next, fill the top 1/2 inch of the each culture jar with vermiculite. This layer is pure, simple, dry vermiculite. Nothing else. Fill the jar level with the glass edge. This layer is a breakthrough pioneered by Psylocybe Fanaticus. What this layer does is insulate the sterilized substrate from any airborne contamination. This layer gets sterilized with the substrate later and airborne molds and bacteria can not (usually) get through it to contaminate the substrate. At the same time, it allows some gas exchange to occur. The fungus needs oxygen and gasses can filter through the vermiculite.

Step 6:
Now, place the jar lids in place. Normally, the jar lids have a rubber seal that is placed in contact with the glass of the jar. Traditionally the rubber seal is not placed in contact with the glass. It was placed on the upper

side of the lid. The reason was that people thought it would make too tight of a seal. This does not seem to be an issue. If you wish to follow tradition, place the rubber on the upper side of the lid. Screw the lid down tight. Note that you need to have the four holes poked in the lid in Step 1. Otherwise you can have real problems when you heat these jars up!

Step 7:
Next, place a piece of tin foil over the top of each jar and crumple it around the sides of the jar. This is to keep water drops from going in the four holes in the lid while the jar is being sterilized. If you poked your holes in the lid such that the sharp edges are pointing up, be careful not to rip or puncture the tin foil. If you need to, you can add a second or even a third piece of tin foil to make sure water will not drip into the holes in the lid.

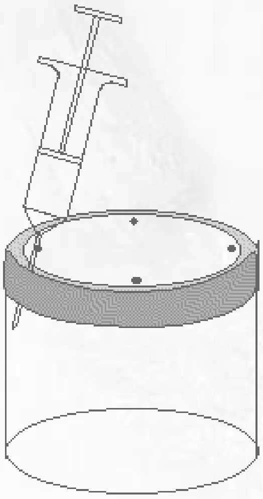
Step 8:
Now the culture jars need to be sterilized. Place the jars in a large kitchen pot/pan and add water so that water comes halfway up the side of the jars. Bring the water to a slow boil and place the lid on the pot. From the time the water starts to boil, the jars need 1 hour to be sterilized. Water should not be bubbling and splashing all over the place. The jars should not be floating around in the water. The substrate in the culture jars has the right amount of water in it already. You do not want water leaking into the jars and changing the ratio. The jars should not sit flat on the bottom of the pan. Too much heat can transfer directly to the jars and cause a loss of moisture. You can place a wash cloth inside the pan and set the jars directly on the wash cloth to help prevent too much heat from transferring to the jars.

Step 9:
Let the jars cool slowly. Leave them covered in the pot/pan that was used to sterilize them. Let them cool completely. The jars need to be at or close to room temperature in order to inoculate. The spores will be killed if the jars are not cool enough when they are inoculated. It will take several hours to cool sufficiently. You may hear sounds as the jars cool. This is normal.

Step 10:
Now comes the good part. Inoculation of the culture jars. Assuming you have a viable, sterile spore syringe, you are now in a position to inoculate the cultures and start the first phase of the growing cycle. The needle of the spore syringe must be sterile. If your fingers or anything other than the lid or contents of the culture jars comes in contact with it, assume it is no longer sterile. If there is any doubt about its condition, use a cigarette lighter to heat the entire needle. Heat it until it glows red. Let it cool for a few minutes and squirt some of the solution out of the syringe.

Shake the syringe. Make sure the spores are mixed well within the syringe. This can be accomplished more easily if you pull the plunger back on the syringe to get a little air into the syringe.

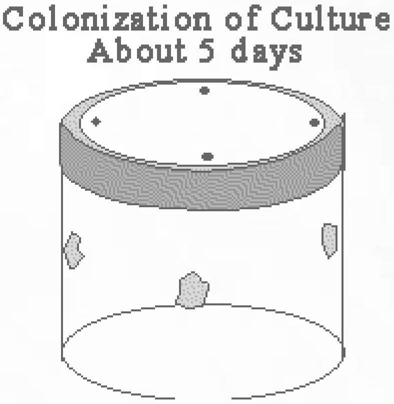
Remove the tin foil from each culture jar as you prepare to inoculate it. Insert the needle of the syringe as far as it will go into a hole in the lid of the culture jar and get the needle to press against the glass. Examine the next figure for a simple diagram of how things should look. Inject 1/4 cc of solution at a site under each hole in the lid. Adaptation-4. A total of 1 cc of solution for each jar. Adaptation-5.

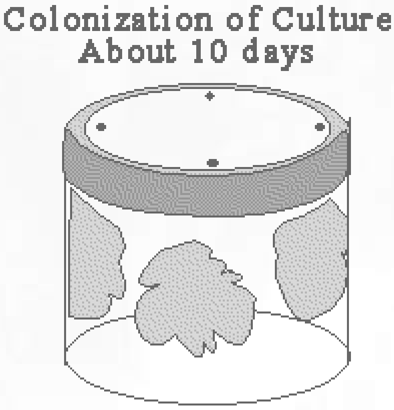


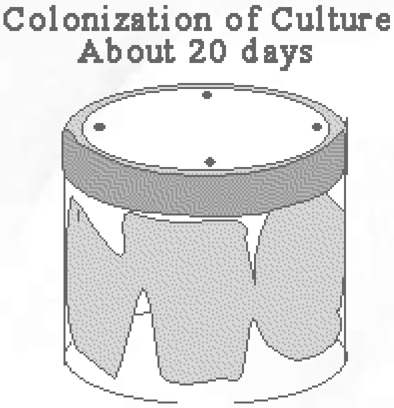
Innoculation of substrate

A 10 cc spore syringe is sufficient to inoculate a dozen jars if you inject slightly less than 1 cc in each jar.

Step 11:
This is the easy part. Put the culture jars in a dark place and wait. The fungus will first appear as little splotches of white fuzzy stuff at the inoculation sites. Adaptation-6.







As the time goes by, the fungus will spread throughout the jar. Eventually, the entire surface of the glass will be covered with fungus. Typically, the bottom of the jar is the last area to be colonized. Be on the lookout for any contamination.
Any odd colors that might appear are contamination and the jar must be thrown out. Do not take any chances. If you think the jar might be contaminated, throw it out! Some molds and bacteria produce toxins that can kill you. Just because a mushroom is growing on the opposite side of the cake from the contamination does not mean you are safe. The mycelium network carries nutrients and moisture to the mushrooms from far away and can easily pick up the toxins and bring them to the mushroom. The fact that you are using this guide means you are not an experienced mycologist. You do not know which molds and bacteria are deadly. Do not take a chance.

The one exception to the previous statements is the mycelium will some timeschange from a bright white to a very pale yellow if it has water droplets touching it on the side of the glass. It is very unusual for any area that is colonized by the mushroom fungus to become infected while in the jar. The uncolonized areas of the substrate are usually significantly more prone to infection.
The above pictures show a typical germination and colonization cycle. If your spores are old, or the temperature is not optimum, or you did not mix the substrate very accurately you can easily add a week to the above time frames.
The cake must stay in the jar until the entire surface area is covered with mycelium. As the substrate gets more colonized, the growth slows down. This is a result of CO2 building up and less oxygen being available for the fungus to consume. Adaptation-7.
The cakes can not be taken out of the jars while there is still uncolonized substrate. Adaptation-8.

Step 12:
Once a rice cake is fully colonized, it can be taken out of the culture jar. Adaptation-9 At this point, there are no areas on the substrate that can easily be infected by competitor molds and bacteria. Once the mycelium is established, it can usually prevent other organisms from gaining a foothold and destroying the rice cake.
Adaptation-10 Unscrew and remove the lid from the canning jars. Scrape all the loose vermiculite on the top of the substrate into the garbage. Take care not to gouge into the substrate material as this can leave areas open to infection. You do not need to get all the vermiculite off of the cake. In fact, the only reason to remove any of it is to keep the terrarium neat and orderly. Turn the jar up side down and slam it onto a table top. The rice cake should slide out of the jar. The rice cakes will typically shrink a little during the colonization phase of the process and will come out of the jars easily with a little tapping on a tabletop.

Step 13:
The rice cakes need to be placed into the terrarium. It is assumed that you have a fully functional and checked out terrarium setup at this point. This document contains all the information you need to prepare a terrarium. Preparation of the terrarium.

You can handle the cakes but remember that the less you handle them and the more gently you handle them, the better off they will be. Also, you should wash your hands thoroughly and be sure to rinse with water just as thoroughly to remove any soap before touching the cakes.
If you have disposable sterile gloves available, it isn't a bad idea to use them. You can get away without using them, but they are a good idea. Contamination is the mycophile's worst enemy.

Back to table of contents
The Growing Cycle
Construction of the Terrarium.

Construction of the Terrarium

The main purpose of the terrarium is to provide the high humidity required for mushroom development. The rice cakes will live inside the terrarium during the cropping phase of the growing cycle.
There are four different setups described in this document. The first one is a very simple, minimal terrarium that works well, but can only handle one rice cake. The second two are based on work done by Psylocybe Fanaticus. They will hold more cakes than the first terrarium, but they still require attention several times a day.

I encourage you to choose the last option. This one uses the same growing chamber as Psylocbye Fanaticus developed but an ultra-sonic humidifier is introduced to keep humidity up. It requires very limited maintenance and works very well.

The first terrarium, the "Poor Man's Terrarium" requires no humidification. It relies on a very small volume of air and the fact the terrarium is sealed very tightly from the outside environment.

All of the last three of the terrarium setups require the same growing chamber. The difference is the strategy for keeping the humidity high inside of the growing chamber. If you want, you can start with one of the simpler versions and switch to a different setup later if you are unhappy with it. Note that if you start with the ultra-sonic humidifier version, we don't expect that you will want to switch to one of the other two.

Poor Man's Terrarium

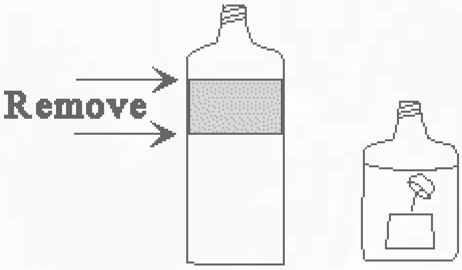
Materials needed:

- 2 liter plastic coke bottle
- razor knife

This terrarium is made by cutting a section out of a 2 liter coke bottle. This serves two purposes. First, it allows you to put a fully colonized rice cake inside the bottle. The second purpose is it allows the volume of the bottle to be reduced to the point where the moistness of the rice cake can keep it humid.

Remove a section of the bottle using the razor knife. The cut on the lower part of the bottle is not very critical. The top cut is more difficult to do correctly. It needs to be right at the point where the bottle is starting to decrease in diameter. This is because the top part of the bottle is going to be inserted into the bottom part of the bottle and the two sections need to seal tightly.

The best thing to do is start lower than the diagram indicates and cut small sections off until the top piece of the bottle fits snugly and easily into the bottom section. Once you locate the correct place to cut for the type of bottle you are using, you can simply cut at the same place and make multiple bottles to handle as many cakes as you wish to fruit at any time.



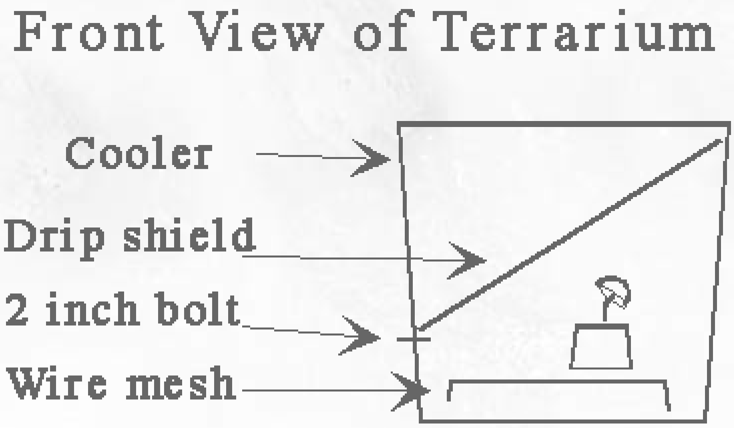
The cap for the bottle must be screwed on tightly. A damp paper towel can be placed on the bottom of the bottle to help raise the humidity inside the bottle. Twice a day the bottle should be opened to allow new air to be available for the rice cake to consume. It is best to fan the rice cake to insure new air is surrounding the cake before sealing it back in the bottle. This is the major draw back to this terrarium. If you have a dozen cakes it can become a burden to exchange the air twice a day.

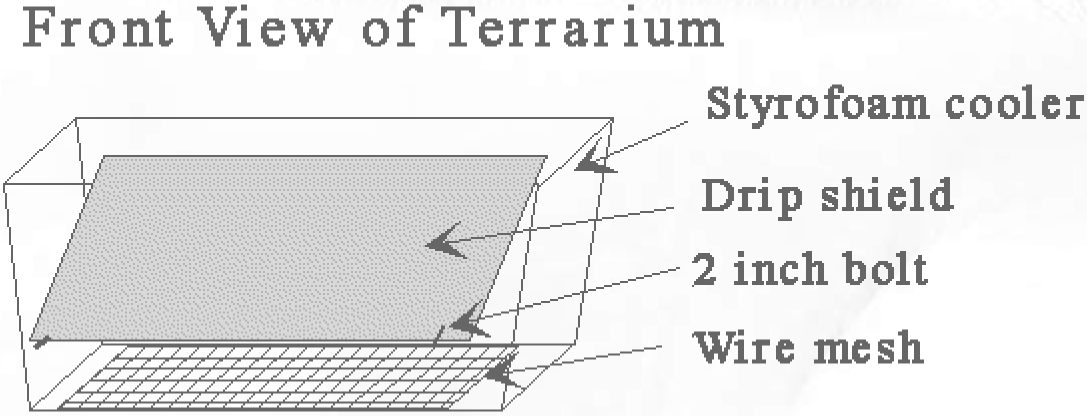
Basic Growing Chamber (Used for all other terrarium setups)

Materials needed:

- Styrofoam Cooler Adaptation-11
- Wire Mesh (1/4 or 1/2 inch is ideal)
- Plexi Glass (a 24 by 24 inch piece of window insulation or fluorescent light diffuser) Optional if using an ultra sonic humidifier.
- Silicon Glue
- Humidity Gauge Adaptation-12

The cooler needs to have a very tight fitting cover. The idea is to seal in humidity, and the looser the lid is, the more difficult this is. Except for the cooler, everything you need can be found at your neighborhood building supply store. Below are diagrams detailing the various components of the terrarium. There is no way to predict the dimensions of the cooler that you will use. You will need to use some common sense as we walk you through the steps to build your terrarium.





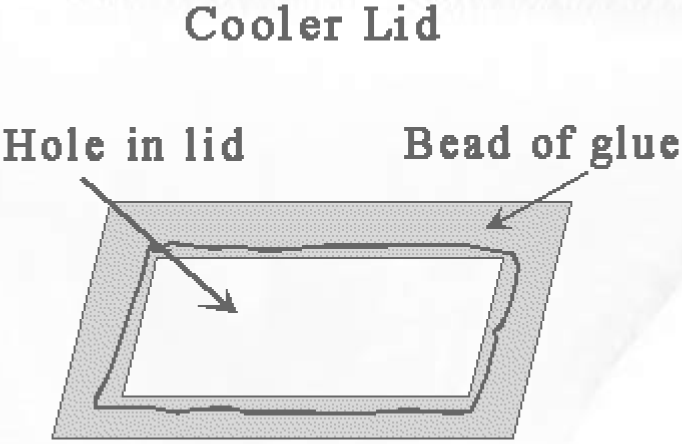
The purpose of the wire mesh is to hold the rice cakes off the bottom of the cooler where moisture will collect. The easiest thing to do is cut a piece of wire mesh an inch wider and an inch longer than the dimensions of the bottom of the cooler. Then, use a pair of pliers to bend a 1/2 inch ridge all the way around the piece of wire mesh. The piece of mesh will be held up by the bent ridge. Often times, when mushrooms are growing, space above them is at a premium. Try not to raise the wire mesh more than a 1/2 inch above the bottom of the cooler. Doing that simply wastes valuable space.

Next, if you are going to use the hand sprayer method of adding humidity, a drip shield needs to be installed. If you are using a fish tank bubblier or an ultra sonic humidifier, it is optional but still a good idea. As moisture condenses inside the terrarium, this protects the rice cakes from being 'rained' upon. Any moisture that forms on the lid of the cooler can drip and will be stopped by the drip shield from hitting the rice cakes. Any moisture that forms on the bottom side of the drip shield will form beads and run down to the side of the terrarium where it can drip harmlessly. If you use a piece of plexi-glass that is textured on one side, put the textured side pointing up. You want a smooth surface on the bottom side of the drip shield so that moisture can easily run down to the side of the terrarium.

The drip shield is held up by several bolts sticking through the side of the cooler. Depending on what size canning jars you use and the height of your wire mesh, you will need to figure out where to put them. You want the drip shield to be at as steep of angle as possible to make water run down it easily, but you want it high enough that your mushrooms have room to grow without touching the drip shield. The drip shield needs to fit well. You need a small gap on the edges to let air circulate, but keep it small. About 1/4 inch is good. In other words, the drip shield should fit pretty well to the inside of the cooler, but it is not supposed to be air tight. Also remember when shaping the drip shield that you can not go to the very top of the cooler because the lid will recess into the cooler a little ways.

If you are using a Styrofoam cooler, you should use washers on the bolts on both the inside and outside of the cooler. This will allow you to tighten the nuts on the bolts snugly to keep the bolts from tearing up the cooler as you move the drip shield during normal maintenance.

Next, the top of the cooler needs to be modified to allow light to enter the terrarium. Psilocybe Cubensis is a phototropic mushroom. It needs light to initiate pinning and to tell the mushrooms which way is up. You should have some plexi-glass left over from the drip shield that can be used for this purpose. Cut a hole in the top of cooler. Cut a piece of plexi-glass a little bit bigger than the hole in the cooler lid. Run a bead of silicon glue all the way around the hole in the cooler top. Position the plexi-glass over the hole and let the glue setup. See the following diagram:



That is it. The basic grow chamber is done. Now you need to decide which method you are going to use to keep the humidity high and the CO2 concentration low while the mushrooms are growing.

Method 1: Hand Spraying

This is the original method that Psylocybe Fanaticus recommended for the home cultivator to grow mushrooms. It is the least expensive. It is the most labor intensive and forces you to conform to a demanding schedule. The only thing you need in addition to the basic growing chamber is a spray bottle that can put out a fine mist.

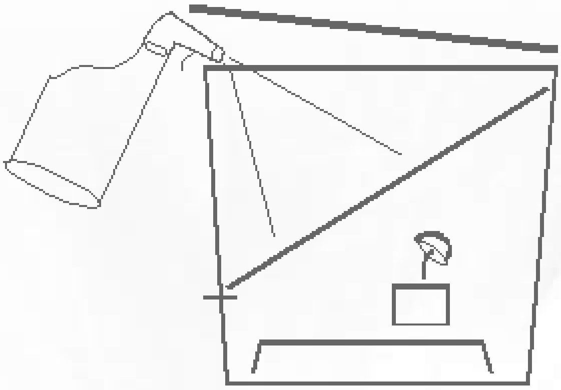
The procedure is this: At least four times a day the terrarium needs to have humidity injected into it via the spray bottle. At least twice a day the CO2 that has built up needs to be eliminated. Once a day you need to eliminate water from the bottom of the terrarium that has condensed and formed there.

Once a day, you need to remove the standing water from the bottom of the terrarium. You can use a turkey baster to suck the water out, or you can gently remove each cake and turn the terrarium up side down to drain the water out. If you remove the cakes, be very gentle. Any place you touch the cakes will not fruit. You should pick up the cakes in the same place every time.

Twice a day, the CO2 that has accumulated in the chamber needs to be removed. One method is to remove the drip shield and fan the inside of the cooler with the cover for 10 or 15 seconds. Another method that works well is to have a hair dryer next to the cooler and use it. Simply lower it into the terrarium with the exhaust jet pointing up and out of the terrarium and turn it on. It will suck all the existing CO2 out of the chamber. Be sure not to hit the rice cakes with the hot exhaust air. It will damage them. If your hair dryer has a 'cool' setting, use that instead of 'hot'. Incidentally, one cultivator recommends using a vacuum clean instead. He would simply suck the stale air out of the terrarium.

In order to create humidity in the terrarium a spray bottle that is capable of generating a fine mist is used. There are a lot of different products for use in the kitchen that have an adjustable spray nozzle, but if you choose to recycle one of these, make sure it produces a very fine mist. What ever you use, make sure it is entirely clean of the original chemicals. Let's make this perfectly clear. Make sure the bottle is clean and does not contain anything that will damage the fungus. The safest thing to do is go to the hardware store and buy a high quality spray bottle. These typically produce a finer mist than most kitchen type spray bottles. The problem is that you would not be using a spray bottle if you had a little extra cash so we are telling you that you can use a kitchen spray bottle if you are careful. In order to create the necessary humid environment in the terrarium, the nozzle is slipped under the cover of the cooler and sprayed at the center of the top side of the drip shield. See the following diagram:

Hand Spraying the Terrarium



After spraying for 5 seconds, pull the spray nozzle out of the cooler and let the lid quickly close, sealing in the vapor. The small water drops will dramatically raise the humidity of the chamber. The rice cakes can not ever be sprayed directly. The mycelium is very fragile and doing that will damage it. The terrarium needs to be sprayed at least 4 times a day. More is better.

This setup and procedure will work and is very inexpensive, but that is the only good I have to say about it. You become a slave to your terrarium. If you miss a couple sessions, your fungus will most definitely suffer because of it. Also, you can only support a few growing mushrooms at a time using this procedure. The mushrooms pull a lot of humidity out of the air and this method doesn't provide much excess.

Method 2: Using a Fish Tank Bubbler

The basic portion of this system was originally pioneered by Psylocybe Fanaticus There are several improvements and adaptations in this section that were not included in the original method. The idea is to create humidity by bubbling air through water. A small fish tank air pump and bubbling stone are used to accomplish this.

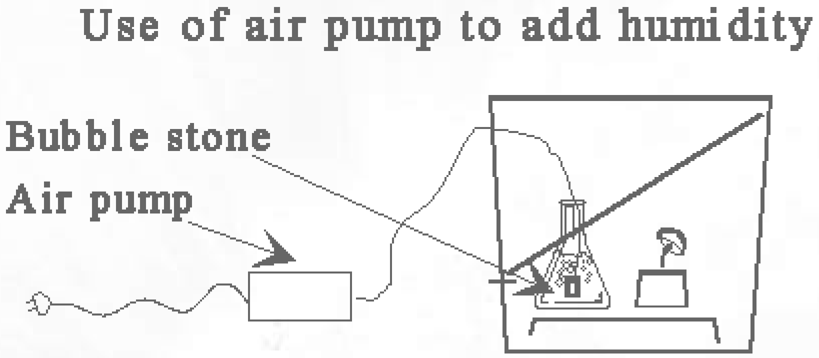
This method is inexpensive and allows the terrarium to exist without your constant attention. Its major limitation is that depending on how it is implemented, it can only raise the humidity by 15% over ambient. The minimum acceptable amount of humidity needed by the fungus is 85%. If ambient humidity is going to be less than 70% during the growing cycle, you will experience problems even with a fully optimized setup. If you have more than a few mushrooms growing, it is possible this system will fail to keep the humidity high enough. You still need to hand spray the terrarium occasionally to boost the humidity above what the bubblier can do. Several times a day is sufficient.

All of the materials needed can be obtained at any pet store or pet department in a department store.

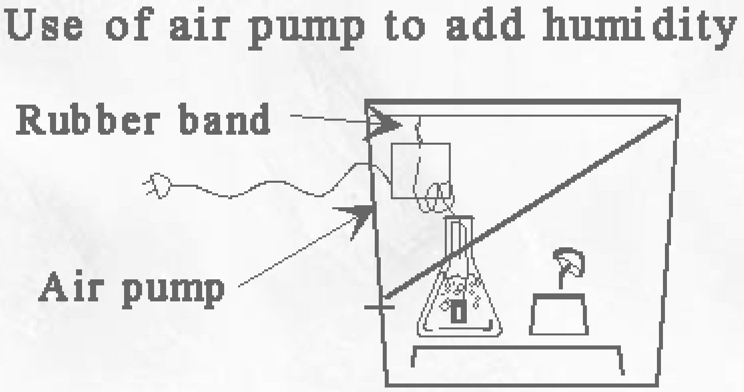
Materials needed:

- suitable container for water
- Fish Tank Bubbler
- 3 feet of 1/4 inch air line for fish tanks
- bubbler stone
- optional submersible 50 watt fish tank heater Adaptation-13
- optional Angel Hair or plastic steel wool Adaptation-14

The basic strategy is to place a container of water inside the terrarium and slowly bubble air through the water. A hole should be cut in the drip shield to allow the container to stick up through it. The top of the container should be above the drip shield to protect the fungus from water droplets that will get produced. There are several ways the system can be implemented. If the air pump is setup outside the terrarium with just an air line going into the terrarium, the humidity will be raised less than 10% over ambient. The one benefit to this setup is the fact that air is constantly being exchanged and the home cultivator does not need to eliminate CO2 every day. A small hole can be put at the base of the terrarium to let CO2 and water escape. The hole should be just big enough that water does not bead up and plug the hole. A 3/8 inch hole will accomplish this nicely. Note that a small, snug hole needs to be drilled in the side of the cooler to allow the air line to get inside the cooler. You can not just loop it over the side of the cooler and slam the lid on it. You will not get enough humidity if the lid does not fit tightly. See the following diagram:



A second method to implement this strategy is to put the air pump inside the terrarium. This way the same air is constantly recirculated, constantly increasing its humidity. This can increase the humidity to close to 15% over ambient. This implementation has several disadvantages. First, the key to getting the higher humidity is recirculation of the same air over and over again. This means no hole can be placed at the bottom of the terrarium to allow water and CO2 to escape. You will need to eliminate CO2 at least once a day. The second disadvantage is the fact that the air pump generates some heat and can warm the terrarium by over 10 degrees F. This may or may not be acceptable. One point needs to be noted. The air pump will create some vibration. It is best to suspend the air pump from a rubber band to absorb this vibration. A stiff piece of coat hanger wire can be suspended from one side of the terrarium to the other and the air pump hung from it. Instead of the air tube going through the side of the terrarium, the power cord for the pump goes through the side. Also note that the positioning of the stiff wire to hold the air pump is not critical. It may be better to rotate it 90 degrees from what is shown in the following diagram so that it is easier to remove the drip shield when servicing the terrarium. Also, the power cord and air tube should have some slack in them so that are not being pulled on as the pump vibrates. The ideal scenario is to tie wrap them to the supporting wire. See the following diagram:



Method 3: Using an Ultra Sonic Humidifier

This is the best method. It will free you from the tyranny of your terrarium. It will effortlessly produce enough humidity to support as many mushrooms as you can grow at once. This setup will automatically eliminate CO2 buildup before it occurs. The only draw back is that ultra sonic humidifiers cost around $40. A little more for a super nice one, a little less for a budget version. Just about any ultra sonic humidifier will work.

A steam humidifier is not easy to integrate into this terrarium setup. First, the vapor it emits is too hot and will kill the fungus. The second reason is they typically run full blast. They do not have a control to throttle them way back like the ultra sonic humidifiers do.

Materials needed:

- Ultra Sonic Humidifier Where to find
- 8 feet of 7/16 inch outer diameter, 5/16 inch inner diameter vinyl tube
- 1 dozen 3/8 inch inner diameter grommets
- 4 clear 2 liter coke bottles
- 3/8 inch, fine thread bolt
- tube of silicon glue
- pliers

First, a small hole needs to be placed in the Basic Growing Chamber to let water and CO2 escape. It should be at the very bottom of the cooler. It needs to be big enough that water will not bead up and plug it. 1/2 to 3/4 of an inch is good.

This setup uses the ultra sonic humidifier to produce air that is close to 100% in humidity. The air flow out of the humidifier is limited by the fact that it has to travel through the 7/16 inch vinyl tubing. That is OK, because we want to limit the amount of air we feed into the terrarium. The humidifier will generate very humid air, but the air will also have many suspended water particles in it. Any time one of these water particles touches another water drop, they will merge. We don't want moisture forming on the rice cakes, so limiting the number of suspended water drops we allow into the terrarium is a big step towards this goal.

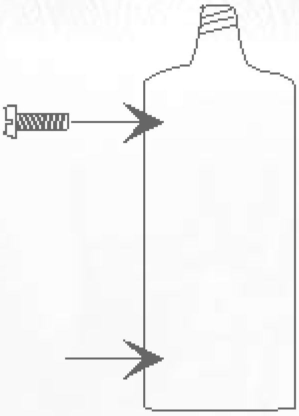
Even so, the air must be dried further. Adaptation-21 The air is passed through several stages where it is allowed to swirl and condense. Each one of these stages is comprised of an empty 2 liter coke bottle or some other suitable container. These stages are connected together using the 7/16 inch vinyl tubing.

Every time a piece of vinyl tubing is used, it needs to be fluted. This means it is not cut off square, but rather at a very sharp angle. This is necessary to help moisture that condenses inside the line to drip out once it reaches the end of the line. Otherwise, it will form a big drop and eventually plug up the line. At that point you have no humidity entering the terrarium.

Drill a 7/16 inch hole in the center of the exhaust lid for the humidifier. Insert a grommet. Apply a bead of silicon glue to the slit through which vapor normally exits. You want to plug this slit up. The only exit for vapor should be through a piece of vinyl tubing that will be placed inside this grommet.

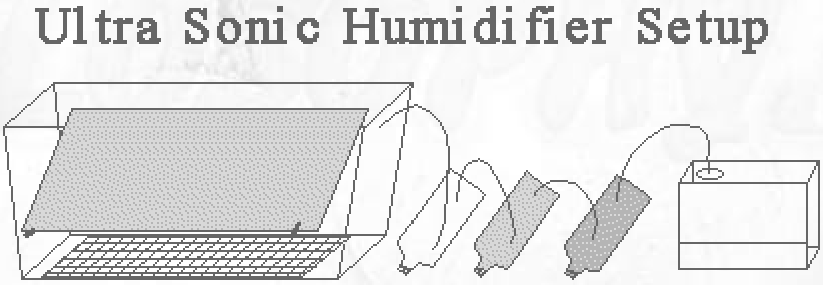
Remove the labels on the coke bottles. Any large plastic container can be used but the 2 liter coke bottles are real nice because they allow you to see inside. Adaptation-24 This is useful to determine if the terrarium is running correctly later. Also, you will be able to see if moisture that has collected in the bottle needs to be emptied out of it.

Heat up the threads on the 3/8 inch bolt using a propane touch or burner on a gas stove. A cigarette lighter will work, but it will take a long time. Hold onto the bolt with the pliers. When the bolt is hot, quickly and neatly poke two holes in each 2 liter coke bottle. Adaptation-15 See the following diagram for details:



The bolt that is used is deliberately a little smaller than the hole that needs to be generated. The hot bolt will melt the hole a little bit bigger than it is when it pokes through the plastic bottle. You may need to insert the bolt a second time into the hole and let it touch the sides to expand the diameter of the hole. Some times little chunks of plastic stick to the side of the hole. Use a sharp knife to clean up the edges and insert a grommet. Check the fit of the vinyl tubing through the grommet. It should be very snug and air tight, but it should not collapse the inner diameter of the tubing very much.

Connect a piece of tubing from the humidifier to the first coke bottle. Flute both ends of each piece of vinyl tubing. Connect the this coke bottle to the next. Do this until you have all four coke bottles connected. The picture shows 3 coke bottles because that is what is normally required, but for now connect in all 4. Now connect the last coke bottle to the terrarium. You will need to poke a hole in the side and insert the tubing. The tubing should be blowing humid air into the part of the terrarium that is above the drip shield. It should be setup as follows:



Checking out the Ultra Sonic Humidifier Setup

Fill the humidifier with water and position the various stages of the coke bottles between the humidifier and terrarium. At no place should the vinyl tubing have a low spot for condensation to form and plug up the line. Condensation will form in the lines but it should run to the end and drip harmlessly out of the line.

Set the humidity level at the minimum setting. This is still more than you should need. Adaptation-19 After you give it time to stabilize, you should see that each stage of the coke bottles has less fog in it than the preceding stage. Usually, 3 bottles is the right amount, but depending on your humidifier and ambient humidity, it could be more or less. You want the last coke bottle to just have the slightest hint of fog in it. Add or delete stages as necessary.

The humidity in the terrarium should stabilize at about 90%. The ideal amount of humidity is as much as you can get without moisture forming on the rice cakes. Keep in mind that most humidity meters you get at department stores are not very accurate.

Back to table of contents

The Growing Cycle

This section is relatively short considering its topic. That is because when you get to this point you are only needed to make sure the fungus has the right conditions to thrive.

Once you place a fully colonized rice cake in the terrarium it just needs several things to grow mushrooms. It needs high humidity, temperatures below 85 degrees F. and a little light. Once the mycelium network has gained access to enough nutrients the cake can initiate mushrooms if conditions are right. The initiation of mushrooms requires some light and temperatures in the mid to upper 70's F. The mushrooms can grow at higher temperatures, and in fact grow faster at higher temperatures. But the fact remains that the temperature range is fairly narrow to start new mushrooms. Normally, it takes about a week for pin heads to form if the rice cake was removed from the culture jar as soon as it was 100% colonized. It can happen after just a couple days if the mycelium network is well established, or it can take several weeks if things aren't just perfect for the cake.

If you keep the terrarium's temperature in the mid to upper 70's F. you will be constantly initiating new mushrooms (pin heads) while providing a good environment for the growing mushrooms to mature. This is the simplest way to grow if you can arrange for this to be the case. Adaptation-16 If you deviate outside of this temperature range, you will still get a few mushrooms, but the fungus will initiate new pin heads only occasionally. You will spend a lot of time waiting for a mushroom to form.

The rice cakes need a small amount of light to initiate pin heads. Mushrooms are not plants and do not need light to grow. However, P. cubensis is a phototropic mushroom. This means it needs light to trigger a hormonal response in order to form mushrooms. If you can see the rice cakes, there is enough light for this to happen. Many mycologists believe the reason light is important in the growing cycle is because it provides a reliable clue to the mycelium that it has reached the boundary of the substrate in which it is growing. In nature, P. cubensis often lives in a pile of cow manure. Once it has grown through the entire substrate and reaches the edge, light hits it and provides the mycelium with the information that if it forms a mushroom there, it can release spores into the air for distribution. It is not productive to form a mushroom inside the substrate because the spores can not be distributed in that case. Any normal spectrum of light that you have available will work. Sun light, fluorescent or incandescent are all fine and will work. A few minutes of light a day is sufficient but an hour or two will guarantee that pin heads form if everything else (temperature, humidity, the mycelium network is well established, etc.) is right. Be careful not to heat your terrarium too much if you use artificial light near the terrarium.

The rice cakes will have a very bright white appearance when they are first placed in the terrarium. Soon, they will be coated with a thin layer of fluffy mycelium. If the cakes refuse to fruit but continue to form more and more fluffy mycelium this is an indication that the humidity is too high and needs to be adjusted downward. For people using a humidifier in their terrarium setup, this is the single biggest cause of failure assuming they get the rice cakes colonized successfully.

When pin heads form, they will look like a short section of a common pin. Hence, the name. The end of these pin heads will soon grow dark brown. This is the cap beginning to form. When the rice cakes are fresh, the small mushrooms will start adding bulk rather than grow longer. They will form balls the size of a marble. Then, they will start to thin out and grow long, adding bulk the whole time.

If the mushrooms have mycelium growing on the caps, it is an indication that your humidity is too low in the terrarium. In this case, you have just enough humidity to allow the cakes to fruit, but you are right on the edge of failure.

You should avoid the temptation to grow the mushrooms as large as possible. Significantly more psilocybin is produced during the early periods of growth. By letting the mushroom grow too large you are simply consuming nutrients and moisture from the rice cake for no purpose. Also, the mushrooms taste increasingly bad as they get larger. Lastly, the mycelium network in the cake can only provide so much in the way of nutrients and water to maturing mushrooms. If you let the mushrooms grow too big, they will hurt the development of other mushrooms on the cake. The mushrooms should be picked just as the veil underneath the cap is starting to tear away from the stalk.

On the average, you should expect to get between 4 and 6 average size mushrooms per 1/2 pint cake. On the average you should expect each cake to produce 1 mushroom a week but this number can vary in either direction greatly.

As the cakes get older, they will produce less and less and it will be more difficult for the mushrooms to grow. Adaptation-17 This is a result of the moisture in the cake being consumed by the earlier mushrooms. You will eventually see mushrooms form and start to grow but never bulk up during the initial phase of development. These mushrooms will seldom get big enough to develop caps. You can harvest these mushrooms but it is an indication that the rice cake is about exhausted.

Back to table of contents

Drying and Preservation of the Mushrooms

Once you have grown and harvested some mushrooms, you need to think about preserving them. They will only keep for a short time in their fresh state. Sometimes a single mushroom needs to be harvested and it isn't enough for a dose. Other times, too many mushrooms will be fully grown for a single dose. Either way, you will be in a situation where you want to preserve them for later. And, even if this didn't happen, you may find your self in a situation where you simply don't have the time or inclination to trip. The good news is that if they are dried correctly, nearly all of the psycho-active compounds can be preserved for many months.

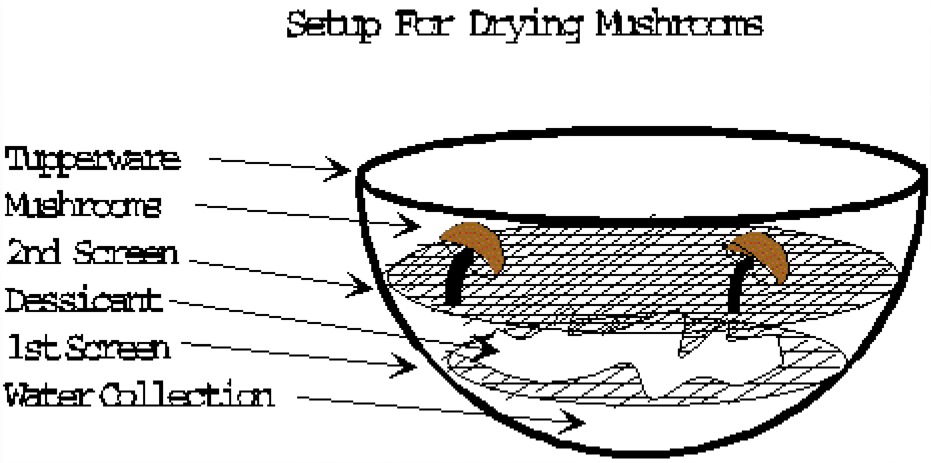
There are several ways to dry them, but we will only cover the best way. What ever you do, don't use heat to dry them. Heat is very harmful to the psycho-active compounds. You will drastically reduce the mushroom's potency if you use heat to dry them.

Materials needed:

- 1/4 inch wire mesh
- old wash cloth or rag
- carton of Damp-Rid or Damp-be-Gone (Anhydrous calcium chloride)
- Medium or Large size Tupperware bowl with sealing lid

Several pounds of calcium chloride can be purchased for a couple of dollars at any large building supply outlet. It will usually be found in the paint department because it is used to dry the air in musty closets before painting and things like that. If possible, get the bulk refill containers. It will be cheaper than the calcium chloride that comes with the units to hold it and the moisture pulled from the air. You won't be using the unit, so don't buy it unless you have to.

The drying chamber needs to have a space at the bottom for water to collect. This allows the calcium chloride to function well for extended periods of time. As it pulls moisture from the air, it drips to the bottom of the chamber. The calcium chloride is held above the water by a circular section of the 1/4 inch wire mesh with a wash cloth spread out on it. See the following diagram for details. The wash cloth keeps the calcium chloride from falling through the wire mesh but any water that forms can drip through it to the bottom of the chamber.



The calcium chloride should be spread out evenly. If you use too large of a Tupperware bowl, you may have to add some structural strength to the screen in order for it to support the calcium chloride. You can simply lay a stick or ruler underneath the mesh and use tie wraps to secure the mesh to it.
Cut another circular section of mesh so that it fits above the calcium chloride and leaves a nice air gap. The mushrooms will be placed on this mesh in order to dry them. Make sure the calcium chloride is not touching the bottom of this screen. There should be an air gap between the top of the desiccant and the bottom of the screen. You do not want your mushrooms to touch the calcium chloride while they are drying because some of it will dissolve into the mushroom if this happens.

That is the entire preparation for preserving your mushrooms with minimal loss of potency. In order to dry your mushrooms, simply harvest them and place them on the wire screen. Close the Tupperware container so it is air tight. The mushrooms will shrink and shrivel over the next couple of days. After about three days, they will be fairly hard and contain very little moisture. If you are not pushed for space inside the drying chamber, you may was well leave them there for five or six days to thoroughly dry them.

After the mushrooms have been in the drying chamber for three days, they can be moved to a zip-lock bag for long term storage. Remember that the dryer the mushrooms are, the longer they will keep. Adaptation-18
The reason this system works so well to dry the mushrooms is the calcium chloride is a good desicant. It has a very strong affinity for moisture and can pull almost all the moisture out of the air. Eventually however, liquid will start to collect in the bottom of the drying chamber. Mushrooms are 92% water by weight. This moisture has to go somewhere when the mushrooms are dried, and it will eventually find its way to the bottom of the container.
When moisture starts to collect in the drying chamber you can simply drain it out and continue to use the old desiccant. The chamber will continue to work as long as there is sufficient calcium chloride in it. You should be careful not to contaminate the sides of the container or the top screen with residue from the desiccant. You do not want your mushrooms to touch the residue. For one thing, it tastes terrible, but in addition to this, the mushrooms will not dry completely. The residue will attract moisture. Whenever you empty the moisture, it is best to wash the Tupperware container completely.

Back to table of contents

Dosage and Various Ways to Ingest

First, we need to make sure some thing is understood. Before you dose, you need to be some one that likes your self and feels pretty secure about your self. You should not have any major troubles in your life. If this does not describe you, don't dose! Go find some other drug to play with.
OK, you've decided that your going to dose. After all, why did you grow these little devils if you weren't going to trip? The most important question to answer is how hard do you want to trip? If a 170 pound person had

never done alcohol before, this is the advise I would give him. Dosage could be anywhere from 1 beer to 12 beers. 1 beer is just enough that you might feel something, but everything will be pretty normal. 4 beers is enough you will have a strong sensation of what alcohol does, but you will be in complete control. At 6 beers, you will start to be drunk. At 12 beers, you are pig drunk and may pass out. I would recommend 4 beers the first time out. This would give you a good feeling for what alcohol is about, but still keep you out of trouble.

These mushrooms will be fairly consistent in potency. They are all grown on the same medium under the same circumstances. If you take 4 average P. cubensis mushrooms, that will put you at the same relative spot on the spectrum as 4 beers. But remember that psilocybin is more powerful than alcohol. What you experience will be more intense than 4 beers. However, on the spectrum of what is possible, you will still be on the low side. What are average size mushrooms? Mushrooms are like snowflakes. No two are the same. I would call a mushroom that has a stalk 3 inches long and a cap 1 inch in diameter average.

Drying the mushrooms as described in this document will have minimal impact on their potency. Many sources claim that dried mushrooms are significantly less potent that fresh ones. If you use the method to dry the mushrooms described in this document, you'll find that claim is not true. It's your choice whether to eat them fresh or in their dry state. Some people have strong feelings one way or the other because of their taste. Most people agree that these mushrooms will never win any culinary awards. Try some each way. Find out if one way or the other is better for you.

Some people find that these mushrooms cause some nausea. **AN165023@anon.penet.fi** suggests the use of digestive aids available over the counter at any pharmacy. This will make consumption of the mushrooms a lot easier on you if you are susceptible to nausea. Also note, that most people should avoid consumption of alcohol while using these mushrooms. When the mushrooms are mixed with alcohol, even people with cast iron stomachs can loose their lunch.

If you find the taste of these mushrooms particularly distasteful, you can always bury them in a burrito or peanut butter sandwich. If you do this, it will slow the onset of the effects some what. Some people just chew them up and wash them down with orange juice.

Some people dislike the taste so much, they are willing to go to extraordinary measures to disguise the taste. Several popular recipes follow. With the exception of the first recipe, these recipes all suffer from a common problem. They use heat. Heat will cause some of the psilocybin to break down and as a result you will need to use more mushrooms for the same effect than if you had ingested them directly. This fact in and of itself is not too big of a deal. After all, you can grow as many mushrooms as you need. A 25% to 50% loss of efficiency is not ideal, but it may be worth it to some people in order to avoid the nasty taste of these mushrooms. The real problem is it is impossible to predict how strong the effect is going to be. It depends on how hot you heat them when you do the preparation and how long they are hot. Use caution!

Mushroom Juice

Put several spoonfuls of frozen juice concentrate into a blender. Dole's Orange-Pineapple-Banana works especially well but regular Orange Juice or Lemon Aid will work. Add a bit of water, but keep the resulting juice on the strong side. Throw in a few ice cubes and your shrooms (fresh or dry) and whiz on high for a minute or so. Let it sit for a few minutes after you turn off the blender, then drink.
A 500 mg vitamin C capsule can be added and will make the juice more tart which is beneficial in masking the mushroom taste.

Mushroom Tea

Take the fresh mushrooms (6-7 per person depending on size of caps) and cut the caps and stems into very small pieces. Place mushroom pieces into medium sized pot 3/4 filled with water. Boil the water along with the mushrooms. Boil for ten minutes. Remove from the heat and let cool for 10 more minutes. Strain mushrooms with a coffee filter, or paper towel. At this point, if you truly desire tea, a mint flavored version works well. Otherwise, Kool-aid is an option. Grape Kool-aid mixed stronger than usual will definitely cover the taste. Serve with ice to chill the Kool-aid to the desired temperature.

Mushroom Soup

Using Ramen Pride or any other dried noodle soup, follow directions on package, except put cut and cleaned mushroom pieces in the broth. Prepare as usual. If the mushroom pieces are small they are relatively unnoticeable.

Mushroom Pizza

Cook your favorite frozen pizza according to directions. Several minutes before the pizza is done cooking, add finely sliced fresh mushroom pieces to the pizza. Optionally, you can add some grated cheese on top of the newly added mushroom pieces. Adding cheese will help encapsulate the mushroom pieces and dramatically help mask the taste. Place pizza back in oven and cook until done.

Obviously, some of the people that grow these mushrooms are going to be looking for a 'mind melting' experience. Bad trips on mushrooms are rare, but they do happen. One of the most common reasons for bad trips on mushrooms is taking a high dose of mushrooms that have grown on cakes that also have contamination growing. Toxins get absorbed by the mushrooms growing on these contaminated cakes and as the dosage gets higher it starts to become an issue. Care should always be taken to avoid contamination but if you plan to dose on the high side, it is absolutely mandatory. Think about it. How fun would it be to have a nasty allergic reaction to some toxin while tripping hard. The email I've received on the subject suggests it is not very pleasant. Throw out any cake that is contaminated and any mushrooms that were grown on that cake even prior to when the contamination was noticed.
One final note. If you ever find that you have dosed too heavily, just remember that 90 minutes after ingestion will be the peak experience. Things will start to settle down after that. The good news is that medically you can't overdose on psilocybin. If you remember these things, and believe them, they can help ease you through a high dose experience.

Back to table of contents

How to Get a Spore Syringe

This section is ordered for some one just starting off in the home cultivating experience. Once you have grown a crop, this section is ordered backwards for your needs. The intent is to get you started easily. In order to grow subsequent generations of fungus you need to generate a spore print and use this to create a spore syringe. This information is at the tail end of this section.

In order to use the process detailed in this document, you need a sterile, viable spore syringe. The spores should be Psilocybe Cubensis spores. Preferably, they should be of the Amazonian strain. The Amazonian strain has wider parameters for fruiting and is more tolerant of mistakes. However, any Psilocybe Cubensis strain will work. There are several ways to get started. The easiest way to get started is to order a spore syringe but alternatively, you could obtain a spore print and use that to prepare a spore syringe.

Once you have grown some mushrooms, it is worth while to learn how to generate your own spore prints so that you can produce spore syringes when ever you need one. Currently, you don't have to do this if you choose not to because the spores are still readily available from mail order suppliers. Many people believe the day is coming when this will not be true. Many of the sources of psilocybe spores have quit selling to the public and others have destroyed their cultures because of mandates given by the DEA. If you have a sterile, viable spore print, you can eliminate your dependence on these suppliers.

Sources for a Spore Syringe

(Check all sources for current address and prices before ordering)

[Note: The following information about Spore Syringes is very out of date. The listed businesses may no longer sell spores, prices may have changed, ownership/management may have changed. Psylocybe Fanaticus is no longer in business. Verify everything before acting on any of the information in this section.]

Currently the most cost effective place for a United States resident to order a spore syringe is from the company that pioneered many of the concepts in this document. They have a very fast turn around time and are very reliable. Their spore syringes are $10.00 (US) and that includes shipping. They are very high quality. They currently supply P. cubensis Matias Romero. This is a substrain of the Amazonian strain.

If you are outside the United States, there is a $10.00 shipping charge. All their packages are shipped in a discrete manner. However, be aware that outside the US, a customs sticker with the description "mushroom spores in blunt-tipped pipette" is stuck on the box.

If you wish to minimize the paper trail, you can send cash to Psylocybe Fanaticus. They are totally reliable and you will get what you order. Psylocybe Fanaticus advertises that they do not keep customer files and by sending cash, you can distance your self from any records of the transaction.

If you learned about Psylocybe Fanaticus here on the Web, please mention it when you order. Currently, Psylocybe Fanaticus doesn't believe much business comes their way because of the net. We would like for that to change.

In Europe, there is a very cost effective spore seller, Smart Botanics. They also sell dried mushrooms if your country will allow them to be imported. They only charge $8.00 for a spore syringe and $3.00 for shipping. You can place an order through the mail or directly from their web page.

Also of interest is the fact that this supplier can provide you with either the standard strain of Psilocybe cubensis spores or 'Gulf Stream' Psilocybe cubensis spores. The 'Gulf Stream' strain is slightly more tolerant of heat and fruits a little easier in warmer temperatures. The standard strain is more appropriate for cooler climates. Simply specify which one you prefer when you place your order.
Check, Diners Card and American Express are accepted.

Smart Botanics
P.O. Box 158, 2800 AD Gouda
The Netherlands.

In Canada there is a company called Hemp Nation. They are reliable and ship promptly. They sell suitable spore syringes (Psilocybe Cubensis Amazonian strain) for $20 (US). There is a $5.00 shipping charge within North America. I used to say the main reason you would want to order from this company is they are in Canada. If you're in Canada, your order will not have to go through customs. There is another reason you might want to order from this supplier. This company is the focus of a Constitutional Challenge to legalize hemp in Canada. The profits from your purchase will assist this.

Christopher Clay, Proprietor

On the net they have a site: WWW.HEMPBC.COM

Sources for Spore Prints

In the event you wish to start with a spore print instead of a spore syringe, this section provides a few places you can obtain suitable spore prints. In general, the first time grower really ought to start with a spore syringe because it eliminates many of the sterility issues. The one benefit to starting with a spore print is you can make close to fifty 10 cc. spore syringes from a single spore print. However, this is really a moot point. Once you have grown a crop of mushrooms, you can generate as many spore prints as you want. One spore syringe is guaranteed to produce a crop if you follow the directions in this guide.

Mostly, this section is included just for completeness. In the event you can not obtain a spore syringe for some reason, you can get a spore print and use that to make a spore syringe.

The following information was pilfered from the mushroom FAQ on Hyper-Real.

Homestead Books P.O. Box 31608 Seattle, WA 98103	P. cubensis spores ($25), kits ($70), and books/videos about growing. (Phone: +1-206-782-4532)
Pacific Exotic Spora P.O. box 11611 Honolulu, HI 96828	Panaeolus cyanescens and Coplandia cyanescens spores. Very expensive, $40-$75.
The Shroom King P.O. Box 17444 Seattle, WA 98107	Str. cubensis print and a book for $25, above above plus compost and agar for $35. (Phone: +1-206-784-9328)
SYZYGY P.O. Box 619 Honaunau, HI 96726	$15 + $1 (S&H) for a Str. cubensis print on a slide.
J.L.F. P.O. Box 184-SC Elizabethtown, IN 47232	Supposedly sells some rare species ready to and lotsa weird stuff. Free catalog. (Phone: +1-812-379-2508)

How to Make a Spore Syringe

Sterility is key. If your spore print is contaminated or you introduce contamination into the spore syringe, you will have difficulty later in the process. Ideally, there should be no fans blowing or drafts of air. You should clean the area where you will be working carefully and make sure that everything is tidy.

Materials needed:

- spore print
- 10 cc. syringe with long needle Where to find
- shot glass
- regular glass
- coffee mug
- cigarette lighter
- X-Acto knife or sharp steak knife
- microwave oven

Several things need to be accomplished. First, we need to sterilize a shot glass to easily mix the spore solution and we need to sterilize a syringe to hold the solution. We also need some sterile water in which to suspend the spores. The following procedure will accomplish all of this.

Fill a coffee mug with water and place a shot glass inside the coffee mug. Make sure the shot glass is completely submerged. Place the coffee mug in the microwave oven and get the water to a full boil for 10 minutes. It does not need to be a violent boil. Adjust the heat level of the microwave oven to keep too much water from being lost if necessary.
Remove the shot glass and empty the excess water out of the shot glass. Place another glass over the shot glass. This will keep air born contaminates from settling in the shot glass while you wait for the shot glass and water in the spore syringe to cool.

Fill the syringe with hot water from the mug. Eject the hot water and repeat several times. This will insure the inside of the syringe and the needle are clean and sterile. This is especially important if you are using a syringe from a previous crop. When the needle is inserted into the substrate, it is possible to get nutrients up inside the needle and for contamination to grow. The last time you fill the syringe with hot water, do not purge it. Let it sit in the syringe until it is cool. This is useful for two reasons. First, the continued heat from the water can still work to eliminate any remaining contaminates. Secondly, once the water is cool it can be used as the sterile water needed to fill the syringe. Make certain that nothing touches the needle of the syringe.

The Psilocybe mushroom spores will be killed if they come in contact with anything too hot. You need to wait until the shot glass and spore syringe are at room temperature. When it is safe to proceed, use the cigarette lighter to flame sterilize the X-Acto knife and the needle of the syringe. Let the blade of the knife cool, but make sure it does not touch anything. When it is cool, carefully open the spore print and scrape a fleck of spores into the shot glass. A fleck 1/4 inch by 1/4 inch is more than sufficient for a 10 cc. spore syringe. Use the needle of the syringe to stir the spores into a few drops of water. Usually, there will be a few drops left over in the shot glass from when you emptied it. Otherwise, you can get the drops from the syringe. Stir the fleck of spores until they are well broken up and 'dissolved' into the water. Purge the water out of the syringe into the shot glass. Pull the water back into the syringe, being sure to suck the spores in also. Do this once or twice more to make sure the spores are well mixed in the spore syringe. Often, it takes several tries to get the spores fully broken apart and well mixed.

If the spores in the print have been dried and are not fresh, it is best to wait six hours to use the spore syringe. The spores need to rehydrate. If your in a hurry, the spores can still rehydrate in the culture jars.

How to Make a Spore Print

Once you have a mature mushroom, you are in a position to make a spore print and use it to continue cultivation of mushrooms. The cap should be harvested when the mushroom cap has become flat or is starting to invert.

Sterility is key. Adaptation-25 Be careful not to do anything that will compromise the sterility of your spore print. The typical procedure is to cut the stalk off of a mature mushroom very close to the cap. A sterilized knife or razor blade is used to do this. The cap is then laid on a sterile piece of tissue paper or card stock and a small glass set over it. The glass is needed for two reasons. First, it keeps the spore print insulated from airborne contaminates. Secondly, it helps keep the humidity high so the mushroom cap can continue to live and drop its spores. One note of caution. Some humidity usually needs to be allowed to escape. You want the environment inside the glass to be slightly less humid than the environment in which the mushroom was grown. If you have problems getting a cap to drop its spores, try using a piece of paper for the print that fits entirely inside the glass and spreading out a wash cloth flat on the table. Let the edge of the glass seal to the wash cloth instead of the paper. This will usually allow enough humidity to escape to cause the cap to drop spores.

If everything goes well, after a day or two the cap will drop its spores. Adaptation-26 There will be a purple-brown dust underneath the cap. These are the spores.

Eye glass lens paper is good source of sterile tissue paper. A box of waxy tissue paper that deli's use to pick up donuts and rolls is another excellent source of sterile tissue paper. Card stock (such as a recipe card) is a bit easier to use later when you want to prepare a spore syringe, but you have to expend the extra effort up front to sterilize it. To use card stock, place in a 425 degree F. oven for 15 minutes. Let it cool with a glass over it before you place the cap on it.

Once you have a spore print on the paper, remove the glass and cap. Fold the spore print in half and seal the edges so air can not get in. A piece of scotch tape on each side will do nicely. The spores will stay viable for 18 months if they are kept in a cool, dry and dark spot. If you place a small amount of desiccant in the bottom of a film container and place a cotton ball on top of the desiccant, you have an ideal container to keep the spore print. The cotton ball will keep the desiccant from touching the spore print. Seal the spore print in the canister and place the canister in your refrigerator until you are ready to use it.

Note that if you want to be self sufficient, it is a good idea to have multiple spore prints and store them separately. You just never know when you are going to be surprised with a massive contamination problem or thermal death. The safest thing to do is have a couple viable spore prints so it is easier to recover from disaster. A spore print is typically viable for about a year if it is stored in a cool, dark location. As a print ages, germination gets slower and this process becomes more prone to contamination.

Combination of Spore Print and Preparation of Inoculant

This excellent idea is from: **AN165023@anon.penet.fi**

If it is your intent to use a mushroom to immediately generate inoculant for a successive crop, you can eliminate some of the above steps and reduce the risk of contamination.

Poke a small nail hole in the cap of a wide mouth jar. Cover the nail hole with a piece of electrical tape. A 1/2 pint canning jar similar to that used for the cultures is fine. Sterilize both the jar and the lid.

Place the harvested cap in the sterilized, wide mouth jar. Seal the top with the lid and wait until a spore print has been generated on the bottom of the glass. Open the jar and remove the mushroom cap. Add 3/4 cup of sterilized water. Seal the top of the jar with the lid and shake the jar. The spores need to be mixed well into the water. This procedure elements the need to transfer spores from a print to some container to make the solution. The spore print is generated inside the container and the only extra step is adding water. It also has the benefit of making a large amount of solution that is easy to use.

Now, any time you need inoculant, you can shake the jar and peel the tape back to expose the nail hole in the lid. Simply insert the needle of the syringe into the inoculant and pull some into the syringe. The syringe needs to be sterile or you risk contaminating the entire jar of solution. The solution will keep longer if you refrigerate it. You still should keep some spore prints on paper because it is possible to contaminate the entire jar of inoculant if you make a mistake.

The Author's First Trip

OK, some of you experienced druggies are going to get a chuckle from this. This is a description of my first trip. I grew up in a real conservative environment. I always wanted to hallucinate but I was real scared of LSD. After all, I'd been told it causes chromosome damage and that a lot of the people that trip on it either jump out of windows or end up in a permanent psychosis. I'd heard that even the lucky ones that make it through the trip ok suffer from uncontrollable flash backs for the rest of their life. Pretty scary stuff.

I never was around people that used psychedelics much. The few times I had the opportunity, I was unable to find out enough about the source and quality to put my ignorant self at ease. It seemed like I was never going to get to have a psychedelic experience.

Well, I was surfing the net one day and decided to test the reach of information contained on it. I was trying one exotic topic after another in Yahoo. I was amazed at the knowledge contained on the net. I decided to push it to the limit. I asked about psilocybin. To my amazement, a few indexes to documents came back. I quickly down loaded them and started studying them. I was astonished to find out that the spores for Psilocybe mushrooms could be mail ordered because the spores did not contain any controlled substances. And best of all, there was no overdose for psilocybin.

It doesn't take a rocket scientist to figure out what I was thinking! The net contained bits and pieces of information. I was able to learn some of the basic concepts for growing shrooms but there was a lot of uncertainty and contradictions in the information I had. I kept increasing the depths of my searches on the topics. It eventually became obvious that my best chance of success lay with Psylocybe Fanaticus' method. I promptly ordered their Tek Notes and a spore syringe.

I followed their directions and had cultures well under way soon enough. But, I was frustrated with their humidification techniques. They did not work for me even though I experimented like crazy. My job involves doing research and development at a high technology computer company. I was determined to solve the problem and make it easy for others with access to the net to succeed. I found a few people on the alt.drugs news group that had vast mushroom growing experience and they helped me with advice that got me over some of my initial problems.

I was going home in a few months on vacation to visit old buddies. I told them I thought I was going to be able to bring some shrooms so we could all trip together. They freaked with joy. I have a basic personality flaw. Anything worth doing, is worth doing to excess. I didn't know how many shrooms I would need so I figured I had better grow a couple pounds. I worked out the problems I was having and simultaneously ramped production. I had a couple pounds of dried mushrooms by the time I headed north on vacation.

We were at a friends cabin on the lake when the time was right. I broke out my stash of shrooms as we prepared to go out on the lake fishing. Of course I offered some advice about what I thought was a reasonable first dose, but then I made the mistake of trying to comfort them with the information that it was impossible to overdose on psilocybe mushrooms. My friends have my same basic personality flaw about doing things to excess as I do, except worse. The closest I can figure, I ate about an eighth of a cup of crushed, dried shrooms and they all ate about twice that. **My first dose was significantly higher than the Dosage section of this document recommends. Just because I got away with it, doesn't make it a smart thing to do!**

Being the scientific type, I grabbed my camcorder just in case we needed to document anything and we headed to the boat to go fishing. The first 25 minutes seemed pretty normal, but then I started to feel myself coming on. I had done enough research to know that the peak experience was a good hour away. I kept fishing. Soon I had to put down my fishing pole and just watch my buddies. I just had way too much stuff going on to be holding my fishing pole.

I had heard that the most basic visual experience was how colors became vibrant while tripping. I kept looking for this, but never noticed it. I was wondering if we dosed high enough or if I had gone to all the trouble to grow these damn things and eat those awful tasting shrooms for nothing. I started to feel a little down. I just stared at the seat where one of my buddies was sitting.

Suddenly the seat was alive. I became mesmerized by how the grain in the wood seats of the boat would not stay still. Every time I looked at the seat, it would ebb and flow. Too cool! The surface of the water was even more intense. The patterns formed by the little ripples and waves were unbelievable. I was frying big time. Even though my buddies dosed way higher than me, they seemed unaffected. They just kept fishing and cracking jokes. I was still 30 minutes from peak.

I was looking across the lake at the far shore. There were lots of clouds blowing across the sky. I was enjoying just watching them. Then it happened. It became obvious to me which clouds were going to break apart into little clouds and which little clouds were going to combine to make bigger clouds. I spent a lot of time trying to figure out if I was just imagining this ability or if I could really do it. I just kept watching the far shore. Eventually my buddies noticed my fascination with the far shore and I became the focus of their jokes. They still didn't seem like they were tripping. I told them about my new found ability. That only encouraged them to make more jokes. I challenged them to predict which clouds were going to break apart and which ones would combine. They admitted that would be impossible. When I told them I thought I could do it, the jokes really started.

Naturally, I had to prove I wasn't making up this ability. I started pointing and telling my buddies which clouds were going to do what. They were real skeptical at first, but finally I convinced them. One of them realized that we ought to get this on the camcorder tape or nobody would believe this had happened. It was a little work to get the camcorder setup because we were so fucked up, but I got about 5 minutes of this on tape. This was real valuable in making me a believer that psychedelics really can expand your mind and give you insight that you never had before.

Later that day, everybody commented on how they thought they were the only one affected by the shrooms until the cloud incident happened. We were all having a good time, but nobody recognized that the others were tripping hard. I was only at 1/2 the dose my buddies were at, so it's not too hard for me to believe they were really looped.

The next day, everybody wanted to trip again. I gave them some advice. I told them that a person's tolerance builds quickly to psilocybin and that they would have to dose significantly higher to get the same effect. Interestingly enough, they all thought they wanted a little less of an experience. The first trip had tired everybody emotionally and intellectually. Strangely enough, that day, straight or tripping, I was unable to repeat my cloud predictions. It seems to have been a one time experience. Yet, I know and have proof I was able to do it that one time. It turns out the real life value of being able to predict cloud behavior is pretty small, but the important point is that psychedelics can give you insight you would not have had otherwise.

When we got back to town, all my buddies wanted me to teach them how to grow shrooms. My buddies are not very scientifically minded people. I have been trying to get them to use computers and get on the net for a long time with no success. I did not think I could just explain the steps and have much probability of them succeeding. I thought about this problem for a little while. I wanted to write a comprehensive guide for the people on the net and I wanted to get my buddies on the net. I could kill two birds with one stone. I told them that if they figured out how to get on the net, I would have a simple guide there for them to follow.

Bulk Substrate Growing

This section is for the mycrophile that has some experience and desires to cultivate a large crop of mushrooms. This section is intended for someone that has already grown several crops using the PF Tek procedure detailed earlier in this document. This section assumes a certain amount of experience and expertise. Please do not attempt this technique without first gaining the experience; you will most likely fail if you do so.
The procedure detailed earlier in this document is the best one known for making it possible for a first time cultivator to succeed. But it is very inefficient and the culture jars take a significant amount of time to manufacture and colonize. If you desire to grow a large quantity of mushrooms, you will find it is not practical for your needs.

The following procedure is an adaptation of the traditional mushroom cultivation techniques. It assumes you have some experience and don't need to be warned about this and that. The following description of the bulk growing procedure should be sufficient for an educated person to follow. There are many fine books on the subject and rather than compete with them, I suggest you get one if you start having difficulties The Mushroom Cultivator However, if you are careful, these directions should get you a truck load of shrooms.
There has been such a demand for instructions to accomplish growing on a bulk substrate, the author has decided to help. But the following process has not been 'idiot proofed' yet. You will need to use common sense and adapt as issues arise. Please note that this process depends on sterile procedures being in place. If you fail, it will most likely be because you introduced contaminates.

Materials needed:

- 1 quart canning jars
- Whole Grain Rye (Organically Grown)
- Fresh Psilocybe Cubensis Mushrooom or 100% colonized culture jar
- Pressure Cooker
- Food Processor
- 1 Quart canning jars
- Coarse Ground Vermiculite
- Large Cake or Roasting Pans
- Mixing bowl

Step 1:
The first step in the process is to generate several spawn jars. Place 2/3 cup of Rye in each canning jar. Add 3/4 cup of water to each jar. Loosely screw on the caps and sterilize the jars in the pressure cooker. 45 minutes at 15 PSI is usually good. Note that a pressure cooker is necessary for several reasons. First, bulk grain is more difficult to sterilize. Secondly, in order to get the grain to absorb as much water as possible, pressure is required.
As the Rye cooks, it will expand and all of the water should soak into the rye. Let the jars cool to room temperature. The rye should be loose and break apart if you rotate the jars. That is the main reason rye is used instead of some other grain. This will be important later.

Step 2

At this point you need mycelium to inoculate the grain. You will need a clean food processor and set of blades for it. If you can sterilize it in the pressure cooker, this is best. If not, throw it in the dish washer with lots of soap. Don't open the pressure cooker or dish washer until you are ready to use it.

If you are using a mushroom, perform the following steps. Sterilize 1/4 cup of water. Let it cool. Put the water and the mushroom into the food processor and turn the mixture into a slurry. Don't mix the slurry more than you need to. You are creating small fragments of mycelium by chopping up the mushroom. The more you chop it up, the more damage you do to the small pieces of mycelium.

Open each spawn jar and place 4 or 5 cc's of the prepared slurry in the jar. Close the lid and rotate the jar so the Rye kernels tumble and mix inside the jar. The idea is to get as many kernels as possible to have mycelium fragments on them. Loosen the lid and place the jars in a warm, dark location.

There are several reasons why tissue from a mushroom is preferred to spores for the inoculation of the spawn jars.

- Mycelium does not need to germinate. It starts growing immediately.
- Normally only 1/3 of the diakratic tissue in a multi-spore inoculation is capable of fruiting. By defination, this tissue came from a fruit body and is capable of fruiting.
- Since every mushroom grown on the bulk substrate is of identical genetic origin, they will be very close in potency.

If you are using a 100% colonized culture jar, perform the following steps. First, the culture jar should have been 100% colonized for at least a week. This lets the mycelium grow into the cake and results in more of it being available for the inoculation. Birth the cake, and place it in the food processor. Turn it into little pieces smaller than a pea. Dump the sterilized rye into the food processor and turn it on just long enough to mix things up well. Place the contents of the food processor back into the jar and cover it loosely.

The cleaner your environment the more likely you will get through this stage without introducing contaminates. This is the most likely place to induce failure.

Step 3

Loosen the lid and place the jars in a warm, dark location. In 3 or 4 days you should see isolated spots with white mycelium growing. Check the spawn jars periodically. When you see large areas of aggressive growth, tumble the Rye to mix things up. Rotate the jar enough to thoroughly mix the kernels. The idea of mixing the Rye is to get kernels with mycelium growing on them scattered throughout the jar. Ideally, no kernel should be too far from a kernel with mycelium growing on it. Repeat this process every 3 or 4 days when the mycelium growth has been aggressive for a while. Once there is mycelium growing within 1/2 inch of every other location no further mixing is needed. At this point just let the mycelium expand outwards until it is every where.

Step 4

Once every kernel has mycelium growing on it, leave the jar sit undisturbed for a week. The idea is to let the mycelium grow as fast as possible.

Step 5

Sterilize more jars filled with rye and water. Let the jars cool.

Step 6

Most food processors have a plastic blade that comes with them for the purpose of mixing things instead of cutting things. Use this if possible. Make sure your food processor and blade are clean. Empty the contents of a colonized spawn jar into the food processor. Turn it on until the Rye kernels are all broken apart. Add some of the freshly cooked Rye to the food processor. Depending upon your confidence and the sterility of your environment you can add anywhere from 4 to 20 times the amount of grain in your spawn jar. The less you add, the less likely you will have problems with contamination. The more you add, the faster you can create substrate. Initially, you should stay on the low side. Turn on the food processor and mix the freshly cooked Rye with the colonized Rye from the spawn jar.

Place this material in a container that can be loosely covered. This material should be treated exactly as the earlier spawn jars were treated except you should see quicker growth of the mycelium patches. The amount of spawn you have can be compounded again and again until you have enough to inoculate massive substrates.

Step 7

Once you have sufficient spawn colonized and available for your substrate, lay it out in a deep cake pan to a depth of 1.5 inches. Attempt to keep the surface even. If you have a very clean environment, you can perform a mass expansion and lay out the uncolonized grain instead of waiting for it to colonize in the jar. This will save several days and a little effort, but in general it is not worth the risk.

Cover the pan with a sheet of plastic wrap. Do not seal it absolutely tight, but make sure that very little air is exchanged. Note that some air does need to be exchanged to keep the CO2 level from getting too high. But air exchange increases the likelihood of contamination. Keep it to a minimum.

This is one of the big benefits to bulk substrate growing. Whatever grain is not used to prepare a substrate can be used as spawn for new jars. When you get to this point in the process, you can easily be preparing a new bulk substrate every couple of days. You just make sure you never use all of the colonized grain as substrate. You hold back some to use as spawn for the next set of jars.

Step 8

Wait a few days until the freshly laid out substrate is showing aggressive growth. Laying out the grain breaks up the mycelium networks, and it takes several days for the mycelium to recover.

Step 9

Casing the substrate is the next step. Various recipes are available but the simplest one consists of course ground vermiculite and water. Course ground vermiculite is a requirement because the fine ground vermiculite packs too tightly and seals the substrate.

Soak the vermiculite in water. Wring it out, but leave it fairly damp. Later versions of this guide will have exact measurements but for the moment, you will need to adapt. If any of you think you have an optimum mixture, please post it in the alt.drugs.psychedlics and rec.drugs.psychedlic newsgroups.

Lay out the casing material to a depth of 3/4 of an inch. Try to keep it smooth because this will result in the mycelium poking through everywhere at the same time. Cover with plastic wrap and wait. Typically, it will be about a week for the mycelium to break through the surface of the casing.

Step 10

Initiate fruiting. Take the plastic off of the pan and place it in your terrarium. Make sure you have the temperature at about 75 F. Have some indirect light available. As pins start to develop, use a hand sprayer to mist the casing and keep it moist. But be careful. Do not saturate it to the point of being wet and having water drops that will not soak into the vermiculite.

Step 11

After the first flush, you can get a smaller second and third flush if you let the substrate rest for a while. There are a lot of factors affecting this. One particularly important factor is home much of the first flush's moisture came from the substrate and how much came from the casing. If you can mist your casing several times a day, that will help the longevity of your substrate.

Back to table of contents

Where to find Difficult Items

Several items used by this guide can be difficult to locate. Currently, this section will be most useful by people in the United States, but input from others in order to expand this section will be appreciated.

Brown Rice Flour

If you can't find brown rice flour at a health food store near you, you can get some help from Arrowhead Mills. Their phone number is 1-800-749-0730. They used to sell brown rice flour as a mail order item. They no longer do this, but you can ask them for the name and location of a store in your area that sells their brown rice flour.

It is one of their major products.

Ultra Sonic Humidifiers

Some ultra sonic humidifiers don't advertise the fact that they use ultra sonics in order to create humidity. For example, the 'Visible Mist' humidifier by Holmes is an ultra-sonic humidifier. If you can't find an ultra sonic humidifier at a department store or pharmacy, try calling Holmes. They make very good ultra sonic humidifiers. Ask for a distributor or retailer near you. Their phone number is 1-800-546-5637. Alternatively, you can break out your credit card and order one directly from them but the price is a little high ($69.00) that way.

If you can not find an ultra sonic humidifier, you can use other humidifiers. Don't get too hung up with this item. The big problem to watch out for is heat. If you get forced to use a humidifier that is not ultra sonic make sure it does not put out a warm mist of air. Any ultra sonic humidifier can be made to work. This statement is not true of other humidifiers.

Vermiculite

Vermiculite is cheap and readily available. Vermiculite is made from ground up mica. It is normally used as an additive to potting soil to make the soil hold moisture and allow roots to easily penetrate through the soil. The easiest place to get it is a well stocked Garden Center at a local department store. If they sell several different kinds of potting soil and fertilizer, they will probably sell vermiculite. If they don't, be a little persistent and get some one that knows what the stuff is and ask where you can get it.

Prices vary dramatically, but a big bag of it with several cubic feet of vermiculite usually runs less than $10.00. Much smaller bags are available and sell for several dollars.

If you can't find vermiculite in any of the well stocked garden centers in your area, you can call Piedmont Pacific. They are a large supplier of vermiculite. Their phone number is 1-770-725-6853. You can ask them for the name of a store in your area that sells vermiculite.

10 cc. Syringes

The most likely place to find large syringes is a feed store. Some localities have ordinances prohibiting the sale or possession of syringes without a prescription. If this is the case, your simply going to have to order a spore syringe and be careful not to damage it. Usually, a 10 or 12 cc. syringe can be purchased at a feed store for under $1.00. If you don't have any luck at the feed store, you can try a local pharmacy. They usually have syringes, its just a question of convincing them to sell you a suitable one.

Providing Feed Back and Getting Questions Answered

Growing mushrooms is not trivial. The proceedure used in this document drastically simplifies the process, but even so, you may find yourself in a situation where you need help. There are a lot of people that know about growing mushrooms in the alt.drugs.psychedelics and rec.drugs.psychedelic newsgroups. If you need help, you can almost always get solid advice there.

If you have a suggestion, you can get it to the author of this document by posting it to these same newsgroups. If you have something you only want the author of this document to read, please encrypt it with PGP and post it to the above newsgroups. I will see it. My PGP key is:

Index of Adaptations

Adaptation-1 Using bigger culture jars
Adaptation-2 Using a pressure cooker to sterilize the substrate
Adaptation-3 Slowing colonization by packing the substrate
Adaptation-4 Lowering contamination risk by inoculating 1 site
Adaptation-5 Speeding colonization by using more inoculant
Adaptation-6 Speeding colonization by using optimum temperature
Adaptation-7 Speeding colonization by providing more oxygen
Adaptation-8 Removing the rice cake before 100% colonization
Adaptation-9 Waiting to remove the rice cake
Adaptation-10 Checking out the terrarium before use
Adaptation-11 Use of a higher quality cooler for terrarium
Adaptation-12 Use of a humidity gauge in the terrarium
Adaptation-13 Use of a tank heater when using fish tank bubblier
Adaptation-14 Use of plastic wool to produce finer bubbles
Adaptation-15 Extra terrariums when using ultra sonic humidifiers
Adaptation-16 Use of ice-pak to help initiation of pin heads
Adaptation-17 Adding moisture to the rice cake by injection
Adaptation-18 Continued drying of shrooms while being stored
Adaptation-19 Circuit modification to ultra sonic humidifier
Adaptation-20 Adding moisture reservoir to cake during substrate preparation
Adaptation-21 Use of a timer to control water droplet Water Droplets and Stimulate Fruiting
Adaptation-22 Use of home made rice flour to speed colonization
Adaptation-23 Lowering of contamination rate by Presterilization
Adaptation-24: Using a 2 1/2 gallon water jug for filtering
Adaptation-25: Producing contaminate free mushrooms for generating spore prints
Adaptation-26: Producing a clean spore print from a questionable cap

Back to table of contents

Adaptation-1: Use of Big Substrate Jars

Normally, 1/2 pint canning jars are used to prepare the rice cake cultures. It is possible to use 1 pint canning jars instead. In fact, in some parts of the country you may have a difficult time finding the 1/2 pint size.

Advantage:

The main benefit to using the larger 1 pint size is that more substrate can be growing mushrooms in your terrarium. The terrariums described in this report typically will hold 6 or 8 cakes. If you want more substrate growing mushrooms, one way to accomplish the goal is to use bigger cakes.

Disadvantages:

There are several disadvantages to using bigger cakes. First, it takes several weeks longer for the fungus to colonize the entire cake. Another disadvantage is that if you suffer from contamination, you will be throwing out more substrate material. Lastly, you need to make sure when you construct your terrarium that you leave a few more inches of space under the drip shield for the cakes to reside. Since they are taller, they will require the drip shield to be placed higher.
You may notice mushrooms trying to grow inside the jar before the substrate is 100% colonized. This is not ideal because you are using up moisture in the cake for something that you won't consume, but it is a fact of

life using the 1 pint jars. It is normal.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-2: Use of a Pressure Cooker to Sterilize

Normally, most people will elect to use a large kitchen pot to sterilize the culture jars. A pressure cooker can be used instead. Instead of letting the substrate jars sit in boiling water for 1 hour, you can place them in a pressure cooker set to 10 or 15 P.S.I for 20 minutes.
One caution. Do not release the pressure until the unit is fully cooled. The substrate in the culture jars will be at 250 F. If pressure is released, moisture will boil out of the substrate.

Advantage:

If you use a pressure cooker, you can sterilize the jars quicker and with more certainty.

Disadvantages:

Pressure cookers cost money. If you already have one, there is no disadvantage. You may as well use it!

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-3: Tight Packing of Substrate to Slow Colonization

You can slow the colonization of a jar dramatically by simply packing the substrate material very tightly in the culture jars.

Advantage:

Normally, people want the substrate to colonize as quickly as possible. In the case where more culture jars are being prepared than can fit in the terrarium, it is good to space out the colonization of the jars so that some of the early rice cakes are consumed and spent before the last jars in the batch are ready to be placed in the terrarium. This technique allows you to space out the colonization of your jars so you can prepare more of them at one time and harvest them later than usual.
If you are doing twice as many jars as will fit in your terrarium, pack half of the jars very tightly.

Disadvantages:

The substrate material will compress a little bit when packed tighter. You may have to mix up a little extra substrate material to fill the tightly packed jars to the proper level.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-4: Injection at Only 1 Site

You can inject only one site instead of the usual four sites in the culture jar.

Advantage:

There are two advantages to doing this. First, you use significantly less inoculate. Generally it is not worth while for this reason. The inoculate is not very expensive if you purchase spore syringes. It is virtually free if you prepare your own spore syringes.

The main reason why this is sometimes worth while has to do with contamination. By far, the most likely spot for contamination to enter the culture jar is at the site of the inoculation. If you have a spore syringe that may not be entirely free of contamination, you can increase your probability of keeping the culture free of contamination by only inoculating one site. Note that commercial spore syringes are typically very sterile. If you do nothing to change this fact, it is best to inoculate at four sites in the culture jar.

In order to illustrate the point, assume that the spore syringe has slightly 'dirty' contents but is still viable. Assume any given injection site has a 50% chance of becoming contaminated. If you inject only one site, the culture has a 50% chance of becoming contaminated. If you inject four sites, the culture has a 0.5 * 0.5 * 0.5 * 0.5 = 6% of **NOT** becoming contaminated. If you do everything right, this technique to increase your probability of producing a contamination free culture should not be necessary. However, many people have problems generating sterile spore prints at the start of their cultivating experience and this will help those people continue to generate cultures until they get enough experience. The first time you use a spore syringe that you prepared yourself, you may want to inoculate half of your jars the normal way, and the other half this way. If your spore syringe is just a 'little' dirty, this will give you second chance to grow more mushrooms and prepare a cleaner spore syringe.

Disadvantages:

It will take significantly longer for the jar to become 100% colonized.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-5: Large amounts of Inoculate

You can speed up the colonization of a jar dramatically by simply injecting the substrate material with more inoculate.

If you inject 1 cc of inoculate at each site, you will get many germination's and the cake will colonize significantly faster. You should place the beveled side of the syringe needle against the glass so that the inoculate is coming out of the syringe and heading towards the glass. It should form a thin puddle of liquid between the glass and the substrate. 1 cc of inoculate should produce a puddle several inches in diameter.

Advantage:

Normally, people want the substrate to colonize as quickly as possible. This will help accomplish that goal. Also, the sooner and more fully the cake gets colonized, the less chance there is that contamination will get a foot hold and destroy the cake.

Disadvantages:

This adaptation requires extra inoculate. If you are producing your own spore syringes it is not a factor. A single spore print can produce many (close to 50) spore syringes. If you are purchasing your spore syringes, you may wish to wait the few extra days to avoid the extra cost of using more inoculate.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-6: 80 Degree Colonization Temperature

The culture jars can be colonized at a temperature higher than room temperature. 80 Degrees F. is ideal. Slightly higher is OK.

There are several easy ways to accomplish this. If you have a floor heater with a pilot light and it is summer time (so the heat is not going to come on), you might be able to put the cakes in a shoe box and set them on the unit. The top of your water heater might be a good candidate. You can fill a cake pan half way with water and put a submersible fish tank heater in the water set to 80 degrees. Then simply put the jars in the cake pan. However you choose to do this, make sure the temperature does not get above 90 degrees. Check out the heat source before you subject your cakes to it.

Advantage:

Colonizing the substrate at 80 degrees F. is the ideal temperature for several reasons. First, the mycelium will grow faster and the substrate will be colonized in the shortest amount of time. Secondly, when the cakes are removed from the jars, initiation of fruiting is enhanced by shocking the cakes with a temperature drop, lower CO2 levels, and light.

If you plan to have your terrarium at normal room temperature, then colonizing at 80 degrees will help you initiate a massive flush of mushrooms when you place your cakes in the terrarium.

Disadvantages:

None.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-7: More Oxygen for Colonization

The culture jars can be given more oxygen during colonization. This is done by inverting the jars so that the lid is down.

Advantage:

As the CO2 builds up, growth of the fungus slows down. Indeed, the mycelium benefits from increased CO2 during its vegetative growth stage, but eventually it gets too high for optimum growth. If you invert the jars, the CO2 can drain out and is replaced by fresh air. This will speed the colonization of the substrate.

Disadvantages:

There are several disadvantages to this. First, the rice cakes normally shrink a little bit while in the jars and when you invert the jars they will slide down a little bit. This will create a vacuum and pull some air into the jar. This air could have contaminates that get a foot hold in the uncolonized portions of the cake.

The second reason you will want to avoid doing this is the initiating of the fruiting process is triggered by three things. A drop in temperature, a drop in the CO2 level and light. You may confuse the fungus and inhibit a massive flush when you take the cake out of the jar. You will still get a crop, but it may take longer to consume the cake.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-8: Taking the Rice Cake Out of the Jar Before it is 100% Colonized

The partially colonized substrate can be removed from the jar if the uncolonized portions of it are cauterized. Remove the cake from the jar and heat a nail head red hot using a propane torch or burner on a gas stove. Brand the entire uncolonized area.

Advantage:

Nothing will grow on the uncolonized, cauterized portions of the rice cakes. If you need to remove a cake early from the jar this will keep contamination from having a place to get a foot hold. There are very few good reasons to exercise this adaptation. The reason the authors have included it is sometimes growing cycles overlap and you want to start a new culture in every jar you have. If you birth the rice cake early, you have an extra jar to prepare cultures in. One other reason for doing this is travel. If your leaving on a trip (one where you will be out of town) and your cake will be overly colonized by the time you get back, you can use this adaptation to birth the cake early and move it to the terrarium.

Disadvantages:

This is dangerous. It is asking for trouble. First, you are assuming that you can inhibit growth of contaminates on the uncolonized portion of the cake. The bigger the area that is uncolonized, the more risky this assumption is.
Secondly, the process assumes that when the cake is removed from the jar it has sufficient networks in place to provide the nutrition needed for the fruiting process. If you take the cake out too early, this may not be the case.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-9: Waiting to Remove Rice Cake From the Jar

The colonized substrate does not need to be removed from the culture jar immediately after it is 100% colonized. You can wait until primordia form on the substrate.

Advantage:

There are a number of reasons why you might want to delay the 'birthday' of the rice cake. You may not have room in the terrarium or be planning a trip where you won't be around to maintain the terrarium. Also, waiting gives the mycelium more time to fully develop its network throughout the substrate and can result in larger flushes.

Disadvantages:

The continued development of the mycelium network will take place at a slower rate in the jar than it would with lots of oxygen available.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-10: Checking Out Terrarium Prior to Removing Rice Cake

The colonized substrate does not need to be removed from the culture jar immediately after it is 100% colonized. You can wait until primordia form on the substrate.

Advantage:

There are a number of reasons why you might want to delay the 'birthday' of the rice cake. You may not have room in the terrarium or be planning a trip where you won't be around to maintain the terrarium. Also, waiting gives the mycelium more time to fully develop its network throughout the substrate and can result in larger flushes.

Disadvantages:

The continued development of the mycelium network will take place at a slower rate in the jar than it would with lots of oxygen available.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-11: Use of a Coleman Cooler instead of a Styrofoam Cooler

A fancy, nicer, plastic cooler can be used instead of a Styrofoam cooler.

Advantage:

The nicer, plastic coolers typically have more space in them so they can hold more rice cakes. Also, it is nice to have a cooler with a hinged top that simply flips up and allows access easily. Lastly, the plastic coolers are more durable than Styrofoam coolers. If you plan to use the terrarium a lot, go ahead and use a plastic cooler from the start.

Disadvantages:

Cost is one disadvantage. Another disadvantage is the plastic coolers are more difficult to modify for use as a growing chamber than the Styrofoam coolers.

Back to construction of basic growing chamber
Back to table of contents

Adaptation-12: Adding a Humidity Gauge to the Terrarium

A humidity gauge can be added to the terrarium. Especially for Styrofoam coolers, it is easy to cut out a window in the side of the cooler and insert a combination humidity/temperature gauge. The gauge should be put below the drip shield so that it is showing the actual conditions where the mushrooms are growing. In reality, the conditions will not vary much inside the terrarium, but there is no reason to add inaccuracy. The gauge can be glued in place with silicon glue. Make sure the vents in the gauge are only open to the inside of the terrarium and not the outside world. The combination gauge can be got very inexpensively at any department store.

Check all the gauges on the shelf. Most likely, some will deviate greatly from the rest. You want to pick one that seems to be accurate! Bare in mind that usually there are several different brands of gauges available. Check and see what various gauges from different brands are reading. Use some common sense to eliminate the obviously inaccurate gauges. Even so, you are making the assumption that at the high end of the humidity spectrum the chosen gauge will be accurate. Remember that absolute accuracy is not so important as knowing the relative conditions inside you terrarium over time. Even if you gauge is off a little bit, it will tend to be off in the same direction all the time. The easiest way to use a gauge during the growing process is to know what it used to read during previous growing cycles and keeping close to that reading. If a problem does develop, it will provide a clue which direction you need to move.

Advantage:

A humidity gauge is very helpful during the growing cycle, but it takes up valuable real-estate inside the terrarium. This gets it out of the way inside the terrarium and makes it easy to see the state of the terrarium with out messing around inside the terrarium.

Disadvantages:

None.

Back to construction of basic growing
Back to table of contents

Adaptation-13: Use of Fish Tank Heater to Raise Humidity

If you are using the fish tank bubblier system to create humidity in your terrarium, you can use a submersible fish tank heater to help raise the humidity. You can place the fish tank heater in the water and use it to raise the water's temperature 10 or 15 degrees F. over ambient. This will make it easier for the air bubbling through the water to absorb moisture, thus raising the humidity. The higher you set the temperature of the heater, the more humidity you can get. You should be careful not to allow the inside temperature of the terrarium to get above 80 degrees F. In order to effectively use this adaptation, your terrarium will need to be in a cool location.

Advantage:

You will be able to generate an extra 5% of humidity over ambient by using this adaptation.

Disadvantages:

You will increase the temperature inside your terrarium some by doing this. You can minimize the temperature increase by using a container to hold the water that is well insulated. You want the water warm, but you don't want heat leaking any more than necessary into the terrarium.

Back to Method 2, Using a Fish Tank Bubblier
Back to table of contents

Adaptation-14: Use of Angel Hair to Raise Humidity

If you are using the fish tank bubblier system to create humidity in your terrarium, you can place angel hair or anything else that will slow the bubbles rise in the water container. Simply pack it into the container. This will increase humidity by several percent. Ideally, you want to slow the bubbles but also split them into smaller bubbles. Some plastic versions of steel wool for use washing dishes work well. Steel wool would work well except that it will rust and get nasty.

Advantage:

You will be able to generate an extra 1% or 2% of humidity over ambient by using this adaptation. The smaller the bubbles are and the more time they spend in the water, the greater the benefit.

Disadvantages:

None.

Back to Method 2, Using a Fish Tank Bubblier
Back to table of contents

Adaptation-15: Supporting Extra Terrariums with the Ultra Sonic Humidifier

First, build an extra Growing Chamber. Then on one of the 2 liter coke bottles, poke an extra hole. Insert a grommet and make this bottle the last stage for drying the air. Even the most basic ultra sonic humidifier can feed more than one terrarium with sufficient quantities of humid air to keep everything in the ideal range for the fungus.

Advantage:

You get twice the growing area for your mushrooms. Your crops can be twice as big. Alternatively, you can use one terrarium for older cakes. Older cakes are significantly more likely to become contaminated and pose a threat to the other cakes in the terrarium. Moving older cakes to the second terrarium drastically reduces your chances of a crop failure.

Disadvantages:

You need to build an extra Growing Chamber, and it takes up a little space.

Back to construction of Ultra Sonic support system
Back to table of contents

Adaptation-16: Use of an Ice-Pak to Initiate Fruiting

You can keep the terrarium's temperature between 80 and 95 degrees F. If you have a terrarium setup that uses an ultra sonic humidifier, you can place a reusable, frozen Ice-Pak in the Terrarium. This will cool everything down and let the rice cakes slowly shift through the fruiting temperature range. Note that everything else must be right. The rice cake must have a fully developed mycelium network and there must be light. The Ice-Pak should be placed between 1/4 and 1/2 inch from the rice cakes. A flat Ice-Pak will work, but if you have the option, get one that is designed to slip into the center of a six-pak. It will have circular indents molded into each side and it will conform to the shape of the rice cakes better. If everything was ready, you should see pin heads develop 3 or 4 days after you perform this adaptation. If you don't see any develop after 3 or 4 days, you can repeat this operation again. The networks may not have been developed full enough and the few days since the last attempt may have been enough time to change this fact.

Advantage:

You can still initiate prolific flushes with the terrarium above the normal temperature range. The optimum temperature for growing mushrooms is higher than what is necessary to initiate new mushrooms and is between 80 and 90 degrees F. This adaptation can let the cultivator grow at the maximum rate, and still produce new mushrooms on the cakes.

Disadvantages:

The Ice-Pak will lower the humidity in the terrarium. Mostly, this is an issue when you have mushrooms on cakes that are part way through the growing cycle and not ready to harvest. They will usually survive the bad growing conditions for the six hours it takes the Ice-Pak to initiate fruiting, but they will suffer for it. You need to have an ultra sonic humidifier setup on your terrarium. Nothing else will be able to keep the humidity high enough. You can turn the humidity control up a little, but you will have to continue to adjust it down as the Ice-Pak loses its cool. If too much moisture forms on the cakes, it will prevent the initiation of pin heads and that was the whole purpose of this operation.

Back to the Growing Cycle
Back to table of contents

Adaptation-17: Adding Moisture to the Rice Cake

After a cake has produced several mushrooms you can add moisture to it. Flame sterilize a 3/16 inch drill bit. Let it cool. Use it to drill a hole at the center of the cake. You can do this by hand. You do not need a drill. Do not go all the way through the cake, but drill a deep reservoir into the cake. Cut a plastic straw to 4 inches in length. Insert the straw 1/2 inch into the hole. The straw should fit tightly in the cake. Straws from McDonalds are larger than most and work well. They seal well and hold more water. Fill the straw with water daily. A 10 cc. syringe works well to fill the straws with water. You should wait to drill the hole until the cake has produced some mushrooms because the inside of the rice cake is not colonized as quickly as the outside. Also, there is sufficient moisture in the cake at the start so there is no need to add water immediately.

Advantage:

The rice cake will produce many more mushrooms than it would have without adding moisture. Using this adaptation allows the nutrients in the rice cake to be almost totally consumed before the cake is exhausted.

Disadvantages:

Care should be taken when drilling the hole because there is no way to monitor for contamination inside the hole. Also, you will need to add water on a daily basis.

Back to the Growing Cycle
Back to table of contents

Adaptation-18: Continued Drying of Mushrooms During Storage

You can place a small glass with a small amount of desiccant in the long term storage bag to continue to extract moisture from the mushrooms. A shot glass with 3/4 of an ounce of desiccant is sufficient to keep the humidity very low in the long term storage bag. A larger glass that is more stable might be a better choice in order to avoid an accident of spilling the desiccant inside the bag.

Advantage:

The mushrooms will continue to dry and their preservation is enhanced.

Disadvantages:

You will need to be careful not to knock the glass over and spill desiccant in the storage bag. This is only suitable if you can leave the bag in a stationary location.

Back to Drying and Preservation of Mushrooms
Back to table of contents

Adaptation-19: Reducing Output Of Ultra Sonic Humidifier

The output of the ultra sonic humidifier can be reduced by changing the circuitry. Almost all ultra sonic humidifiers use a 5 K-ohm or 10 K-ohm potentiometer to control the output. By adding a 5 K-ohm or 10 K-ohm resister in series with the potentiometer, the original 'low' setting becomes the new 'high' setting. The humidity output can be turned down even lower than originally possible. Simply cut the wire going to the potentiometer and solder a similar sized resister (available at Radio Shack) in series. You may need to set the humidity control above the minimum setting once you make this modification.
Note that this adaptation is mutually exclusive with Adaptation-21. If you try to combine them, it won't work.

Advantage:

This drastically reduces the suspended water particles emitted by the humidifier. However, the big advantage is that the humidifier uses significantly less water. It is possible to fill up the humidifier and leave on a trip for 10 days without having to add water.

Disadvantages:

Complexity is the major disadvantage. The above instructions are deliberately technical. If reading them doesn't give you enough information, don't attempt to do this. Find someone to help you. It is very easy and straight forward for someone that is handy with a soldering iron to accomplish.

Back to Method 3 of Terrarium Construction
Back to table of contents

Adaptation-20: Providing a Moisture Reservoir in the Substrate

A reservoir for moisture can be built into the cake while packing the jars with substrate material. Start with an empty jar and tamp 1/4 inch of substrate material in the bottom. Next, position a magic marker or some other object with a cylindrical shape and a diameter of about 3/4 inch in the center of the jar. Fill the jar as normal. Next, remove the object and fill the bore with damp vermiculite. Lastly, pack 1/4 inch of substrate material over the entire jar, sealing the damp vermiculite inside the cake.

The damp vermiculite can be mixed separately from the substrate material. Use about 1 cup of vermiculite and 1/3 cup of water. This should produce enough damp vermiculite for a dozen 1/2 pint culture jars.

After the cake has fruited, occasionally inject water into this reservoir. The easiest place to inject is the position of the cake that used to be at the center of the bottom of the jar. Just insert a syringe filled with sterile water and inject water until it is full.

In case you are wondering, the substrate material can't be injected with water directly. The rice flour and vermiculite form a very tight seal and it is next to impossible to inject water. Even if you do manage to inject water, it doesn't spread through the cake. Having this reservoir filled with damp vermiculite gives the mycelium network access to a lot of moisture.

The easiest way we have found to implement this adaptation is to cut the bottom off of a 10 cc syringe and press the bottom of the syringe into the wet vermiculite several times. This will load the syringe with wet vermiculite. Then place the syringe in the culture jar and pack the substrate around it. Use the syringe's plunger to hold the wet vermiculite stationary while you remove the syringe. Tamp an additional 1/4 inch of substrate material over the entire surface of the jar.

Advantage:

This adaptation will dramatically extend the longevity of the cake. The cake's yield are normally limited by the amount of moisture in the cake. This procedure allows you to replace moisture as it is consumed by mushroom growth. In general, you will double the total output of the cake compared to not implementing this adaptation.

Disadvantages:

It is a little bit of extra work to prepare the jars this way. Also, there is a need to be careful to use sterile water when injecting moisture during the growing phase. There is no way to check for contamination introduced inside the cake by injecting water.

Back to preparation and colonization
Back to table of contents

Adaptation-21: Use of a Timer to Control Suspended Water Droplets and Stimulate Fruiting

The ultra sonic humidifier can be placed on a timer to control the amount of suspended water droplets that are released into the terrarium. Because the humidifier is turned on and off the humidity in the growing chamber will rise and fall. There is starting to be some evidence that this helps stimulate fruiting.

This document used to recommend using a timer that gives control on a minute by minute basis. These timers are becoming increasingly difficult to locate and more expensive. To accomodate this, there has been a strategy shift on this adaptation. Find a timer that lets you limit the 'On' cycle to 15 minutes. Intermatic makes two version that sell for under $15. They are model numbers SB811C and TB811C. They are available in the electrical section of Home Building Centers. You may also find them in the hardware section of a department store.

Since the shortest amount of time the timer can switch on is 15 minutes, it is important to make sure the cakes do not get water droplets forming on them in this much time. In general, the condensation filter chambers should be set up identically to the normal humidified chamber setup. You just may not need as many filter stages since the humidifier will not be running steady.

The other parameter you need to set is how tight to seal the chamber. You need to make sure the chamber's humidity does not drop too far during the 'Off' cycle of the timer. Typically, the 'Off' cycle is at least an 1.25 hours. (On the Intermatic timers, this coresponds to every third switch being up.) Ideally, you want the humidity to fall to 85% by the end of the cycle. (If your chamber seals tightly, you may be able to go every fourth or fifth switch).

Advantage:

There are several advantages to using a timer.

- Less drying stages are needed for the humidifier. The output can be piped more directly into the terrarium.
- The humidity in the chamber will be moving up and down which seems to stimulate fruiting.
- Water consumption by the humidifier is automatically reduced making unattended operation more possible.

Disadvantages:

Cost and availability are the major disadvantages.

Back to Building Terrarium with ultra-sonic humidifier
Back to table of contents

Adaptation-22: Use of a Home Made Brown Rice Flour

This idea is from: **AN165023@anon.penet.fi**
Rather than use brown rice flour available at a health food store, you can grind your own from long grain brown rice. Simply put the dried rice into a coffee grinder or a blender and let it chew the rice into a chunky flour. You will need to increase the water from 1/4 cup per 1/2 pint jar by 1 and 1/2 tablespoons. The chunky home ground flour absorbs a little more water than the normal flour.

Advantage:

Cost is one benefit, but that is not the reason this adaptation is useful. Using home ground flour will speed the colonization of the substrate. It has been reported that a 1/2 pint jar can be 100% colonized in 11 days if fresh spores are used and the jar is kept at 85 degrees F. during colonization. Note that this is the current record, and most jars will take a bit longer, but overall, the colonization time period is reduced.
Also, the home made brown rice flour seems to yield much more consistently and produce slightly more mushrooms per cake than store bought flour.

Disadvantages:

Extra effort.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-23: Lowering the Contamination Rate by Presterilization

The raw ingredients of the substrate can be sterilized separately to eliminate nearly all of the contaminates. Spread the vermiculite and rice flour evenly into separate cake pans and bake in a preheated oven at 300 degrees F. for 20 minutes. While these are baking, boil a large bowl of water in for 10 or 15 minutes. Use these materials to mix the substrate. It is still necessary to sterilize the jars filled with substrate.

Advantage:

Nearly all of the possible contaminates in the raw materials will be eliminated. The sterilization of the substrate after you mix and prepare the substrate will only need to address any new contamination that you added during that process. The sterilization of the mixed substrate will be much more guaranteed. You should experience a lower contamination rate. This adaptation is particularly useful if you are not using a pressure cooker to sterilize the culture jars. Boiling the culture jars only gets them up to a temperature of 212 degrees F. This adaptation provides an opportunity to eliminate contaminates that require a higher temperature to kill them.

Disadvantages:

Extra time and effort.

Back to preparation and colonization of substrate
Back to table of contents

Adaptation-24: Using a 2 1/2 gallon water jug for filtering

This idea is from 'Dangerous Dan'. A large, 2 1/2 gallon water jug from store bought water can be used instead of 2 liter coke bottles. These large jugs can be used for all stages of the filter, but if only using one, it should be the first one after the humidifier.

Advantage:

Using these water jugs provide a few advantages.

- Because of their size, they don't need to be emptied as often.
- They have a simple to operate valve that can be used to ease draining.
- Their shape makes it easier to stack neatly along a shelf.
- Because of their large volume, less filtering stages are needed.

Disadvantages:

The worst disadvantage is the fact that these containers are typically not transparent and if used for all the stages it is difficult to see how much fog is in the system.

Back to construction of Ultra Sonic support system
Back to table of contents

Adaptation-25: Insuring the Sterility of Caps Used for Spores

If you are going to use a cake to generate spores, you can insure that the caps stay free of contaminates. When you birth the cake from the culture jar, set it on a clean wash cloth in the terrarium. Place a large glass jar over it and seal it to the wash cloth. A large peanut butter jar is usually perfect. You need to have enough room inside the jar for the mushroom to grow to maturity. Humidity will be able to leach through the wash cloth and surround the cake, but air currents will not be present and the cap should be relatively free of contaminates. This setup assumes the floor of the terrarium has a wire mesh to support the cakes.

Advantage:

A much cleaner cap will be available for making prints. This will lower the chances that contamination is introduced into the process.

Disadvantages:

Extra effort. Extra space in the terrarium.

Back to Making a Spore Print
Back to table of contents

Adaptation-26: Producing a clean spore print from a questionable cap

Setup everything the way you would normally to generate a spore print. Keep an eye on where in the process the cap is. After a cap has been dropping its spores for three or four hours, you can change the plate on which the spores are being deposited. Simply discard the initial plate. The new plate will be contain a much cleaner spore print than would have been possible with only one plate.

Advantage:

A much cleaner print will be generated. If contaminates get on the gills of the mushrooms, as the cap starts to drop spores, the first spores contain most of the contaminates. By discarding the initial spores, you will end up with a cleaner spore print.

Disadvantages:

You need to catch it at the right time.

About

Latest news: Robert ' Billy' McPherson, creator of the PF TEK, has passed away. Here is a recreation of his fanaticus website about mushroom cultivation, which existed from 1995 to 2003.

The mind of Robert 'Billy' Mcpherson, once better known as Psylocybe Fanaticus, has succumbed to hepatitus C. He will not be with us in 2012. He is in coma since 11-11-11 and in his final hours before leaving his body. His techniques will survive forever.

I guess that still most psychonauts who cultivate Psilocybe cubensis for entheogenic and other purposes use his creation, the PF TEK, to do so

remember...

Over half a century has passed since Albert Hofmann identified psilocybin as the psychedelic (="mind manifesting") material in several species of Mexican mushrooms. One of those is Psilocybe cubensis.
Since then many hundreds similar psychedelics have been made. But psilocybine still stands out as nature's friendliest and best liked psychedelic. Today, over one hundred psilocybine producing mushrooms are known. From all of those, Psilocybe cubensis still is the largest, fastest, easiest cultivatable and third most potent one. Especially the PF Classic cubensis, known by some as penis mushroom.

Beginning in the nineteen sixties, myriad of methods have been published to grow Psilocybe cubensis. But only one technique can do without petri dishes, -pressure canner or other laboratory equipment. That is the Psylocybe Fanaticus Technique or PF TEK, created by Robert McPherson in 1991, which currently is the worlds most popular method to grow 'magic' mushrooms (downloaded, printed, distributed and practiced many millions of times).

The PF TEK is to the entheogenic experience what the hot water extraction is to the caffeine experience. People will be using it many centuries from now.

Levitate well Billy... you are now known by a small circle of friends but your practices are and will be followed by many for as long as mushrooms and mankind will coexist. The spores of your knowledge will be spread to the stars and beyond.

It was and is a pleasure to have grown with you!

Yachaj

The PF TEK magic mushroom revolution began in September 1991, with its introduction in High Times magazine. It is now the most popular magic mushroom growing technique of the world, and this is the undiluted original.

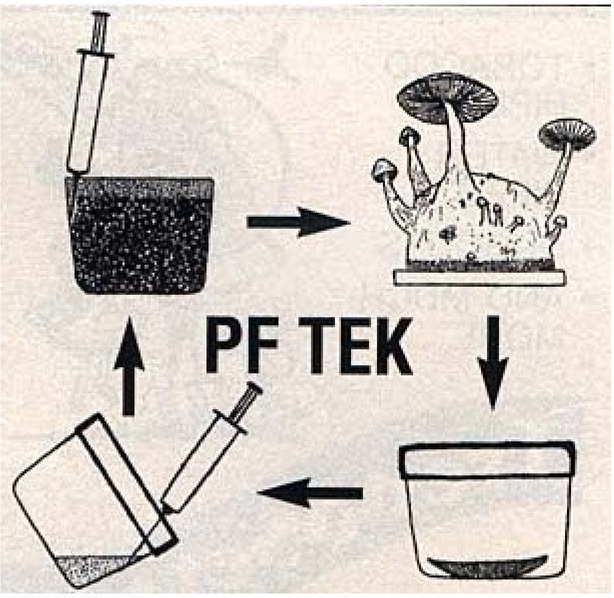
ESSENTIAL PF TEK DOCUMENT

INTRODUCTION

magic mushrooms, ala PF TEK

The PF TEK is basically a brown rice method with an improved formula by using vermiculite as a base and adding pulverized brown rice. The secret is in the vermiculite. When mycelium is cultured in just grain, the mycelium turns into a mass with little air space. But when grown with vermiculite, the mycelial threads stretch across space. The important thing about the PF TEK, is that it copies nature. Instead of the usual cloning of mushroom tissue and growing mushrooms from that, a mass spore inoculation is employed directly to the fruiting substrate. That way, the genotype remains complete. Senescence (mutating and ceased fruiting) is no longer a problem. The spores insure a never ending succession of fungus, with all the power of the spores reproductive ability intact.

Overview of PF Techniques



1. Brown rice powder, vermiculite and distilled water are mixed and loaded into a 1/2 pint jar, which is steam sterilized. The jar is then inoculated by the spore syringe.
2. After the substrate cake in the jar colonizes and begins to show signs of fruiting, the cake is released from the jar and placed into the dual chambered terrarium to fruit.
3. A mature mushroom is decapitated and spore printed in a jar.
4. Spore syringes are prepared with the spore print jar to begin another life cycle.

Basic materials list for cultivation

PF jar preparation and culturing (Stage one) (Domestic products - supermarket - department - drugstore - hardware store)

1. Measuring cups and spoons
2. Large pot for steaming
3. Shoulder less half-pint jars with lids (Kerr or Ball)
4. Organic brown rice flour (organic food stores)
5. Horticultural vermiculite (medium or fine grade - not powdery)
6. Distilled or filtered drinking water
7. Heavy duty tin foil
8. Heavy duty (professional grade) masking tape
9. Ice pick (for punching needle holes in the culture jar lid)

Mushroom growing (Stage two) Pet shop - Hardware store

1. 10 gallon aquarium
2. Cut piece of transparent plastic (Plexiglas) - (terrarium chamber partition)
3. Strips of wood with connectors and screws (terrarium lid)
4. Plastic film and thumb tacks (terrarium lid)
5. Small wall type thermometer
6. "All purpose" water spray bottle with an adjustable nozzle (hardware and grocery stores). Procure one that gives a good strong spray for instant humidification. Avoid recycled kitchen product sprayers. This is a critical piece of equipment. Only a good quality sprayer (a couple of dollars at a hardware store) can immediately supercharge the dual chambered terrarium with high humidity.
7. Wire screen - plastic containers - plastic bags - (drying mushrooms)

8. DESICCANT (drying mushrooms) (scientific - chemical - lab supply)

Spore printing and spore syringe making (Stage three)

1. Micro curved cuticle (finger nail) scissors (cosmetics - drug store)
2. Denatured alcohol (fuel - hardware stores)
3. Tequila shot glass and eye dropper (sterilizing and flaming)
4. Glass stirring rod (Scientific supply)
5. Plastic syringes (10cc or bigger) and 18 gauge 1 1/2 inch needles. Large sized syringes are good (20cc - 65cc) as well as extra long needles if available. (Retail medical - health supply - pharmacies - drug stores - scientific and lab

Table of Contents

CHAPTER 1 - PF SUBSTRATE FORMULATION AND JAR PREPARATION

PF Substrate Formulation

Jars and glasses to be used with this technique are 1/2 pint capacity (8 ounces) - (250 milliliters). They must have tapered sides and no shoulders, otherwise the fungus cakes won't easily come out of the jars.

Appropriate jars; (source - super markets and hardware stores)

1. KERR wide mouth half pint canning jar - preferable
2. BALL wide mouth half pint (similar to the KERR wide mouth half pint) - preferable
3. BALL regular mouth half pint canning jar
4. BALL half pint jelly jar
5. 1/2 pint (250 ml) capacity drinking glasses (tapered sides)

NOTE: Even though the regular mouth BALL half pint and the regular mouth KERR half pint look similar, the KERR is not tapered.

1/4 cup of brown rice powder (Health food stores and co-ops)
1/2 cup of horticultural vermiculite (medium grade) (garden centers and hardware)
1/4 cup of water

or - by volume - one part brown rice, one part water, two parts vermiculite.

The water amount is the crucial element that variates the results. The different brands of vermiculite varies in water holding capacity, creating differing moisture levels. So one can always vary the water amount (less or more than 1/4 cup), take notes and compare results. The highest water content can really make a great fruiting and give several flushes when the balance between the substrate elements is good.

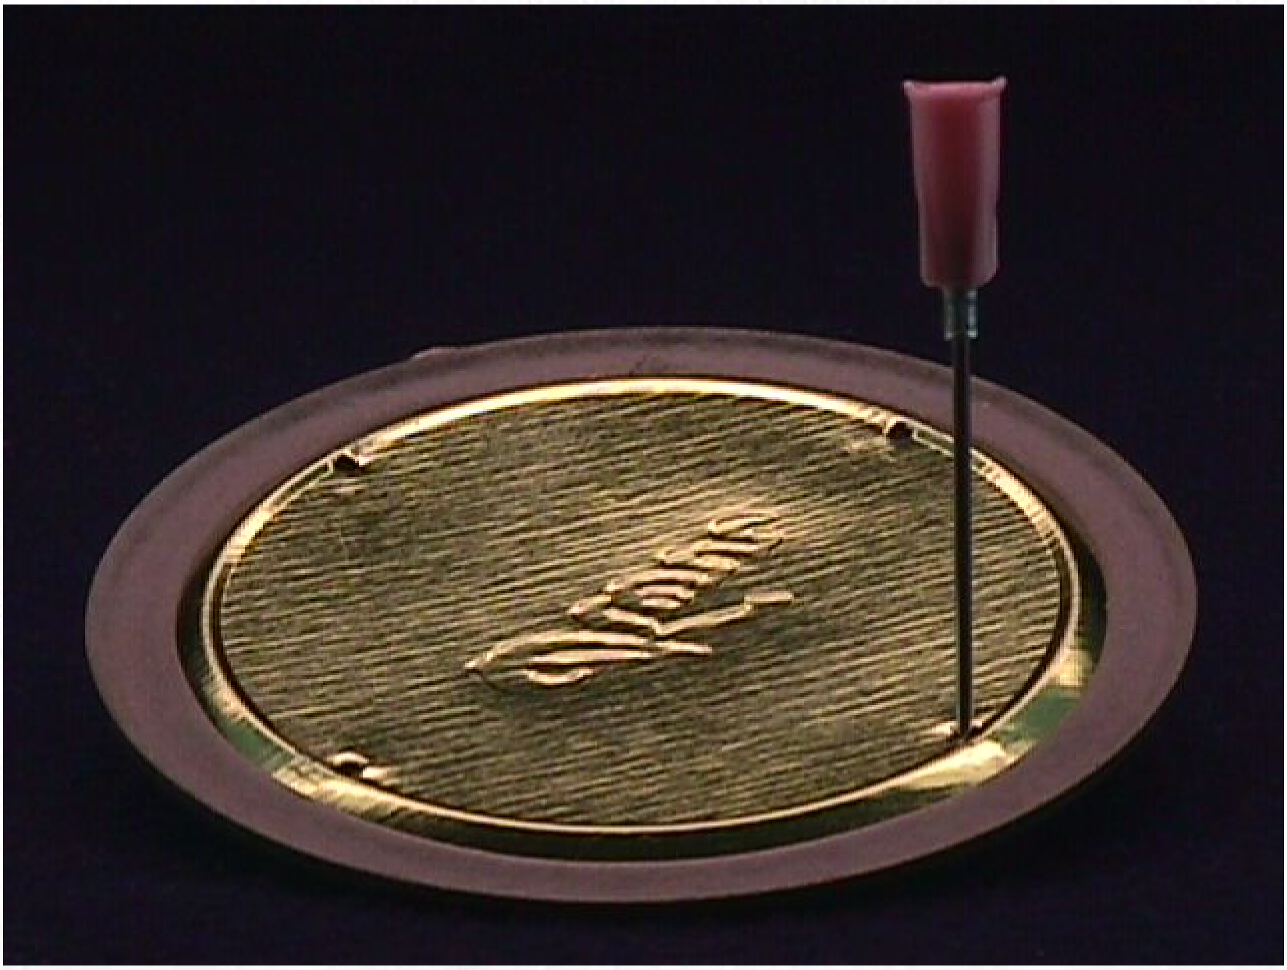
Not all vermiculite is the same. The coarseness varies quite considerably among different brands. The coarser type will hold less water than the finer type which will alter the water holding capacity. If the formulation (water content) results in a really wet or sloppy substrate, use less water. Keep notes on formulas for replicating the substrate formula that fruits the best.

The above formula utilizes "HORTICULTURAL" vermiculite - a medium grade. To ascertain the size of the vermiculite particles, observe them under a photo magnifier next to a millimeter ruler. The finer type of vermiculite has particles averaging around 1 millimeter across (some larger and some smaller). The coarser type has particles averaging around 4 or 5 millimeters across and up to 8 millimeters. Stores usually carry one type, the "horticultural grade".

To make homemade brown rice powder, place some regular brown rice in a small canister type coffee bean grinder and grind it to fine powder. Freshly ground brown rice is recommended over prepackaged type. The freshness sometimes makes a big difference.

A note on water: - Water quality is indeed important. I have found out that "natural" water is the water to use. It makes for better cultivation of this mushroom on this simple substrate. Distilled water is good for making spore solutions and syringes and storing spore solution. But for growing, they seem to like the "natural" water such as: swamp, lake, stream, pond, river, ground or any water that is rich in organics. I have heard that "mineral" type drinking water is good and makes a difference. I suppose that water seeping from an organic compost pile would be about the best.

If the measuring cup specs aren't true, the formulas will be off, setting up certain failure or diminished growth. Check the cup measurers this way: 1 cup is 237 milliliters which is 1/2 pint or 8 liquid ounces (English measurement). There are 2 cups in a pint, 2 pints in a quart and 4 cups in a quart.



Prepare the canning lid by placing it with the rubber sealing edge upwards on a supporting surface and with a sharpened 3 penny nail (held with vise grip pliers) (or ice pick), punch 4 holes inside the periphery of the rubber sealing edge.

When using two piece canning jar lids, the inner lid (with the rubber edges up) rests on the top of the jar and when the lid band is screwed off, the lid remains resting on the jar top. To make the lid and band act as one lid, place pieces of masking tape on the lid attaching the band to the lid. Then, the lid can be adjusted for air ventilation and looseness like an ordinary one piece jar lid (after spore inoculation).

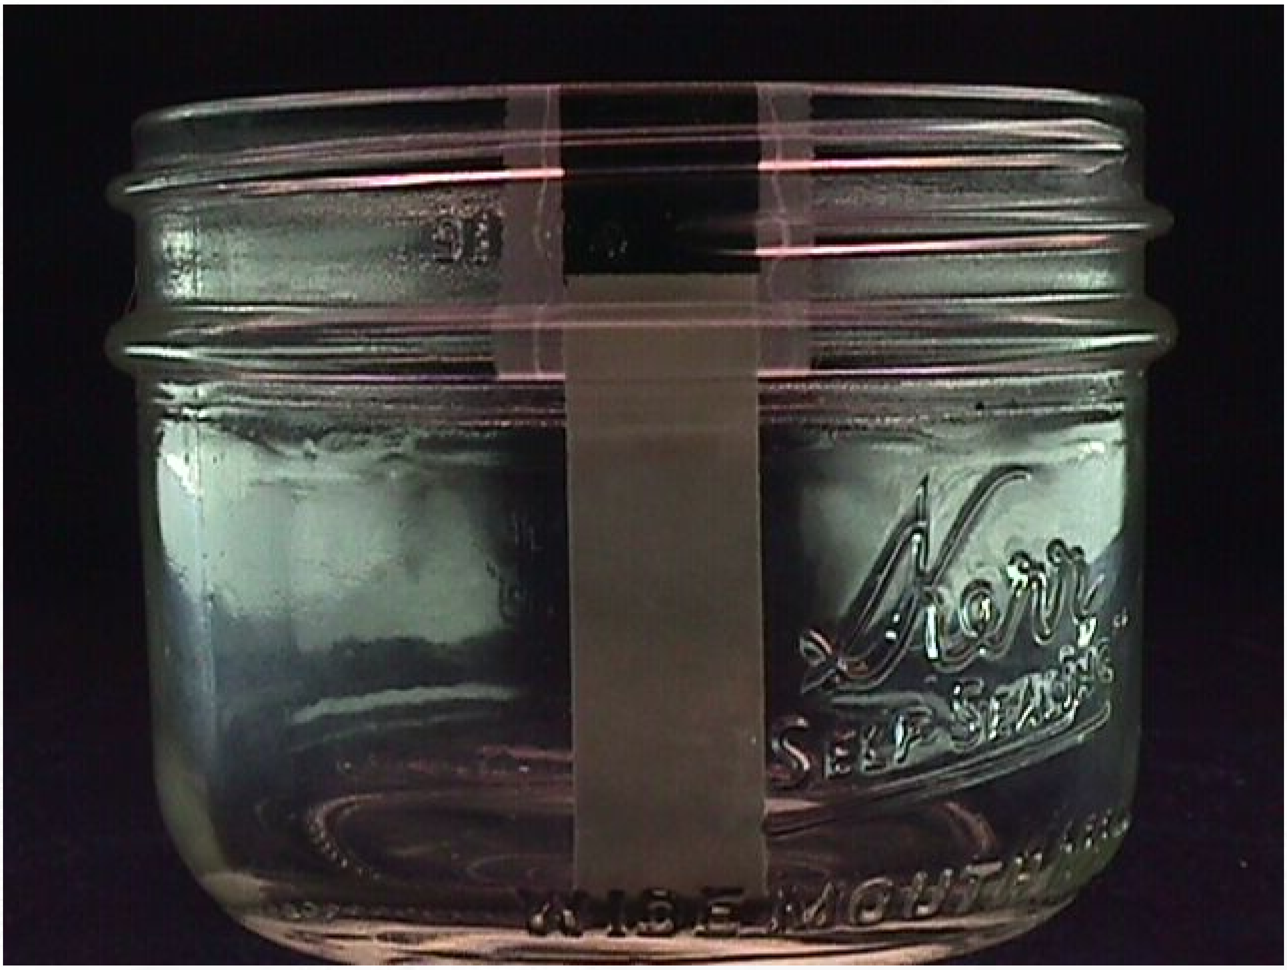
PF Substrate Jar Preparation

Steam sterilizing PF substrate jars with regular cookware is possible because there is no grain to cook up and the substrate is airy. Other regular jars (other than canning type) or small drinking glasses (with tin foil covering) can be substituted for these canning jars. To insure similar results, make sure the jars or glasses are tapered sided with no shoulder of any kind, and that they have a 1/2 pint (8 ounce - 250 ml) capacity. It is important to note, that jars somewhat larger than 1/2 pint can be unreliable for the PF TEK and fail easily, unless the grower has experience with the PF TEK and compensates the formula. The low form KERR 1/2 pint canning jar is the most versatile (fits into tight spaces et).

A 3 piece vegetable steamer (pot, basket insert & lid) is used for the steam sterilizing stage. Also, the stainless steel vegetable steamers that fold out and stand on the bottom of the pot are good. Anything is good as long as it keeps the jar bottoms off the pot bottom where the high temperature will crack the glass.

Step 1. Place 1/4 cup of bron rice powder into a mixing bowl. Add the water directly onto the brown rice powder and mix it up and give it a few minutes to soak in. Add the vermiculite on top of the brown rice slurry. Thoroughly mix the ingredients. An electric mixer works great for this and makes it quick and easy. If there is no electric mixer, a couple of table knives does the trick also. The mixture should feel damp and cohesive (sticks together well). More water (or less) can be used if experimenting to improve the fruiting. Mix Each jars substrate individually for loading to insure accurate formula rendering and the best possible fruiting.

Step 2. Fill the jar very loosely. Leave a 1/2 to 3/4 inch space at the top. Level the substrate. With a tissue or a fingertip, wipe the insides of the jar clear of substrate residue down to the top of the substrate (very important - prevents contamination at the top). Fill the top of the jar with plain dry vermiculite and level it off at the top. This upper layer will protect the wet substrate from air borne contaminants. It acts as a contaminant barrier. This is a Psylocybe Fanaticus original discovery. What this dry vermiculite layer does is protect the wet substrate from airborne contaminants and also absorbs and regulates moisture transpiration and condensation.



In the photo, the black tape is the depth for the dry vermiculite. The masking tape shows where the pf substrate goes. The top layer of dry vermiculite must be between 1/2" to 2/3" deep to provide protection from contaminants entering from above.

Tamping down tek

Getting the substrate level correct is very important. A slight tamping down is required. To get an accurate leveling of the substrate, loosely load the 1/2 pint jar and level the top of the mixture with the top of the jar. Screw a cap on the top to hold the mixture in. With one hand, hold the jar and lightly slam the bottom of the jar on the other palm a couple of times to lower the mixture level to around 1/2"-2/3" from the top rim. Further level and adjust the substrate with a fork down to the proper height. Clean the inside of the jar down to the substrate level with your finger tip or a paper towel and fill the jar back to the top with dry vermiculite.

Step 3. Place the lid on the jar with the rubberized edge up (jagged edges of the needle holes down). Screw the lid band on. Place pieces of "professional" grade masking tape (holds on during steaming) over the needle holes. This is to protect the needle holes from contaminant entry. When steaming or pressure canning is performed, the jars must be protected from water dripping down from the underside of the pot lid caused by heavy condensation and drip off during boiling. This water can get into the jars by entering under the jar lids that aren't tight and soaking the substrate - throwing off the formula and setting up failure. To prevent this, wrap some tin foil around the cap to ward off the water. The tin foil can be removed after steaming (with the tape guarding the needle holes - or the tin foil can be left on until it is inoculation time.)

Step 4. Heat the pot of water to a boil first then put the jars into the pot with the lid bands loose so that the steam can penetrate the jars quickly. The jars can sit in water but make sure boiling water can't slosh into the jars. Turn the heat down and GENTLY steam the jars at the lowest possible boil for an hour in a TIGHTLY covered pot (gas stoves are the easiest to control) (begin the timing when the water begins boiling again). A good tight fitting pot lid is essential for successful steaming.

Be careful to not overheat the jars, this dries the substrate. Drying is evidenced by o.k. spore germination and halted growth (the fungus will spread but stop at a certain point depending on how dry the substrate has become). Generally, any halted growth (with no contamination) is a sign of dried substrate. This is an important concept that will enable diagnosis and correction of problems experienced with drying. The remedy is to increase the water content of the substrate formula in use. After the jars have cooled, tighten the lids and store them in a cool draft free place until you are ready to inoculate them. As long as the lid is very tight, PF substrate jars can be kept for long periods before they are to be used. The only danger to this is water moisture loss.

Pressure Canner Use

PF jars and water bottles can be quickly sterilized with a pressure canner. For proper and safe use of the pressure canner, always refer to the manual that comes with it. If the canner is used and has no manual, try to get one from the manufacturer before using it. Pressure canners can be dangerous if used incorrectly.

Sterilization times

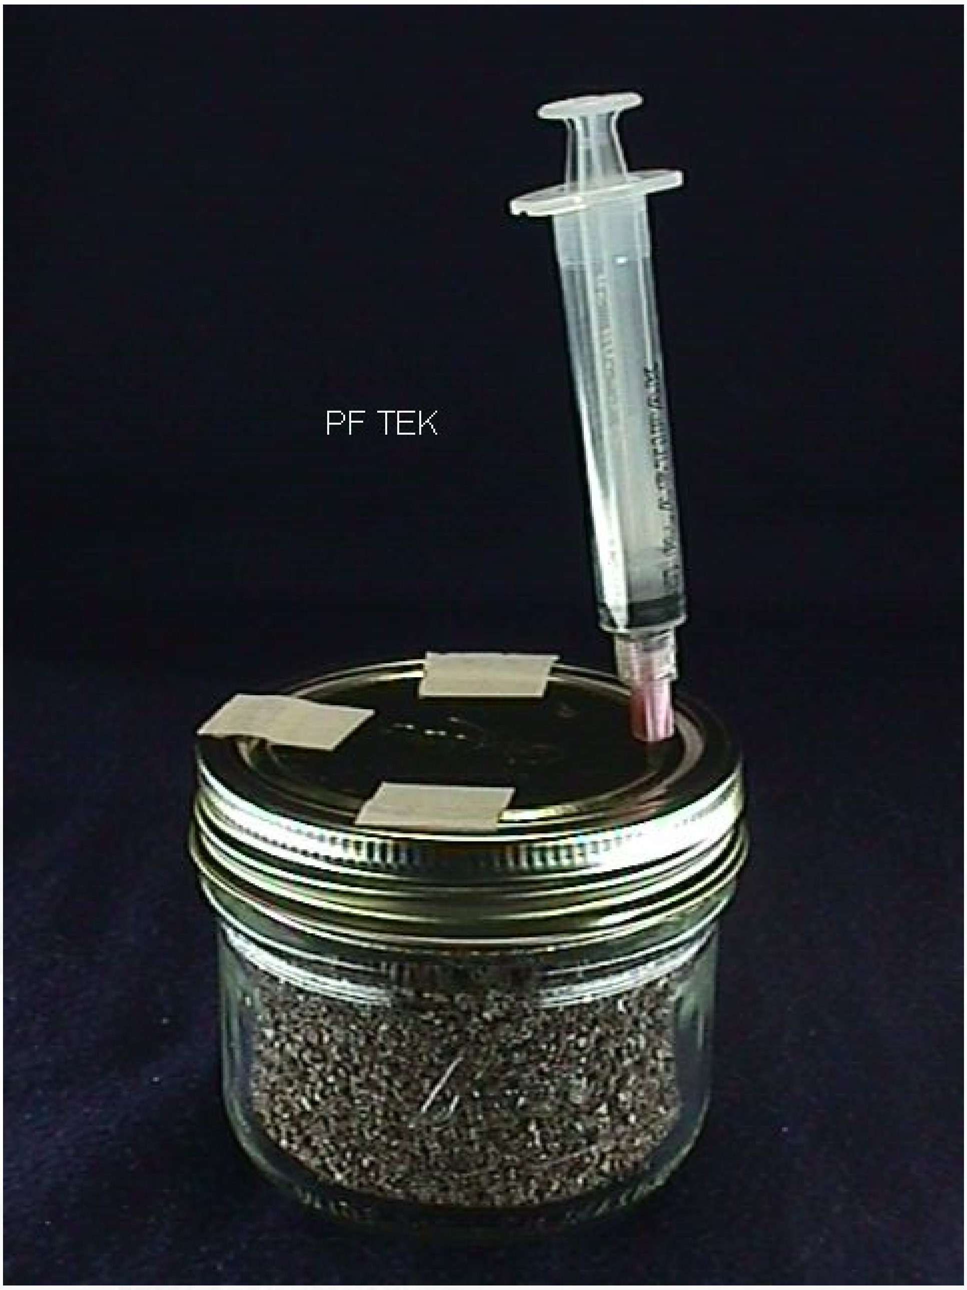
1. 1/2 pint PF substrate jars - 12 p.s.i. for 30 minutes
2. Water bottles - 12 p.s.i. for one hour
3. Syringes and needles - 12 p.s.i. for 10 minutes

Control jar technique

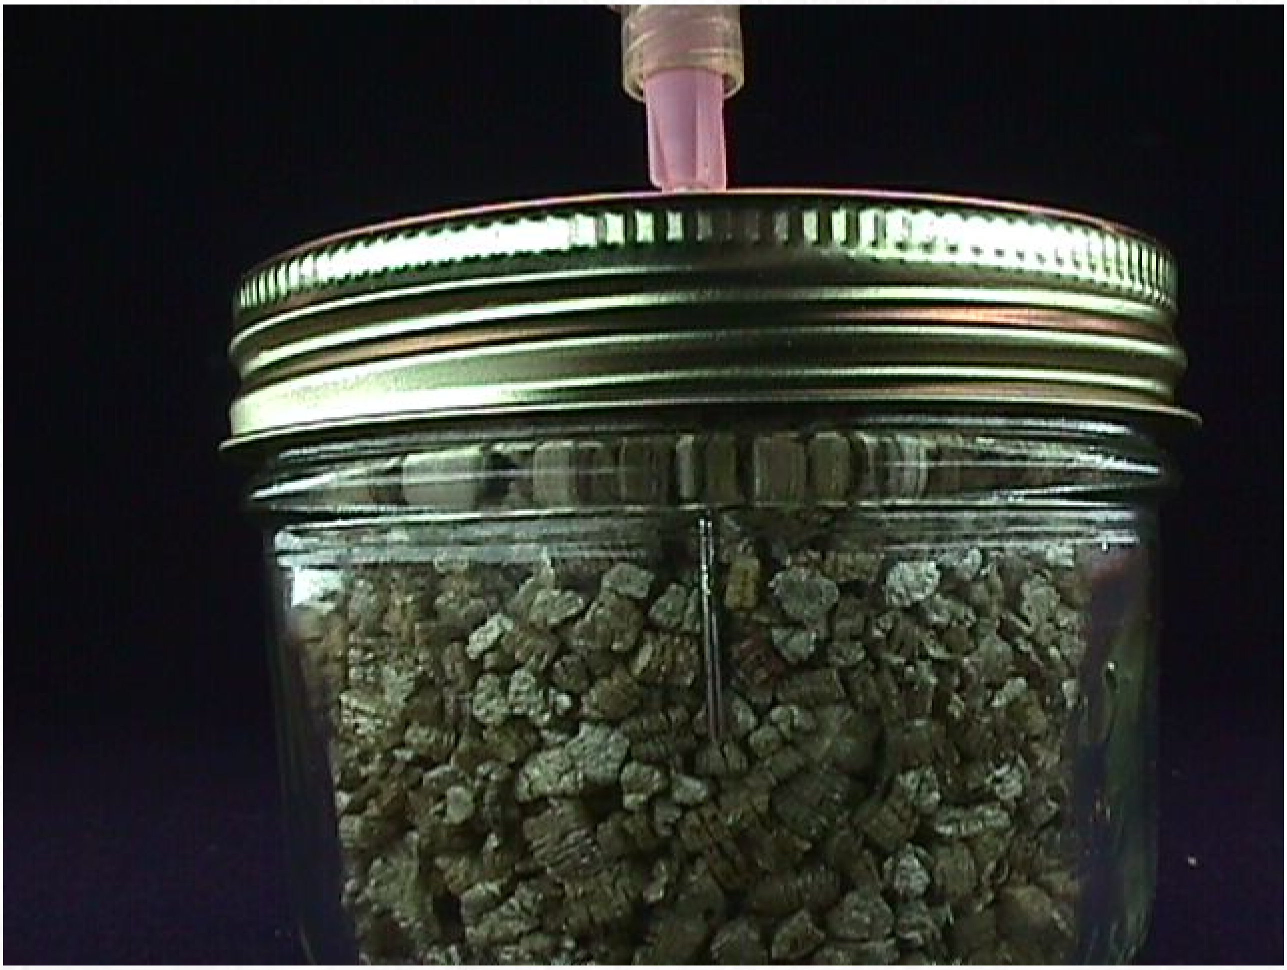
After the jars are steam sterilized, let them cool, tighten the lids and let them sit uninoculated for several days. Watch for any colored growths or changes in the appearance of the substrate. The tell tale rancid odor of bacteria can be easily detected by loosening the jar lid and checking for the odor. If there is contamination at this stage, the sterilization technique needs to be checked. Most likely it will be a to short sterilization time. If there is a problem at this stage, lengthen the sterilization time. If the jars remain clean and unchanged, they are ready for spore syringe inoculation. If contamination occurs after inoculation, the syringe was contaminated or the dry vermiculite layer was breached during inoculation.

Table of Contents

CHAPTER 2 - INOCULATION OF THE PF SUBSTRATE JARS



Any jar to be inoculated must be cool to the touch before proceeding. Make sure the jar lid is tight. Shake the syringe well and remove the tape from the syringe needle guard. This shaking of the syringe is important as to redistribute the spores in the water. Take off the tape covering the needle holes. Remove the needle guard and insert the needle through the lid hole. Tilt the syringe body back towards the center of the lid with the needle tip touching the glass. This distributes the spore water down the side of the jar, giving a good inoculation down the side of the substrate cake. Inoculate a few drops down each needle hole. As the syringe plunger is pressed, observe the needle tip against the inside of the glass. As soon as water appears around the needle tip, release the syringe plunger pressure. In between each hole inoculation, shake the syringe a little to keep the spores distributed. Use 1 cc per jar. This will allow the syringe to inoculate 10 jars. More spore solution per jar can be used (speeds colonization - I use 3 cc per jar), but fewer jars can be inoculated. If the syringe needle plugs up as it is inserted into the substrate, draw the needle back a little and it will unplug.



In this photo, the needle tip can be seen resting against the inside surface of the jar. Then, when the solution is injected, it will run down the side of glass, giving an even inoculation. It is also important to add, that the vermiculite in this jar photo is very course. This makes the needle more visible for the demo. This type of vermiculite is best avoided.

Alcohol Flaming Technique

If the syringe needle is touched, flame the needle to sterilize it. An alcohol flame is a clean flame whereas a butane cigarette lighter leaves behind an undesirable soot residue. To produce a short burning alcohol flame, place a tequila shot glass upside down. Using an eyedropper, put a few drops of denatured alcohol fuel (hardware store) on the hollow bottom of the glass and touch it with a match or lighter. The blue flame will cleanly and safely sterilize small stainless steel tools. Heat the needle in the flame for a few seconds to resterilize it. There might be a few "pops" of boiling water spurt out of the needle, but the spores within the syringe are safe. If there is some left over spore solution, replace the needle guard and store the syringe for later use. Resterilize the needle immediately before re-use. Store the syringe in a dark, cool place.

Also, just wiping the needle with rubbing alcohol soaked cotton will sterilize the needle. Let the needle dry for several seconds to evaporate the rubbing alcohol (alcohol kills spores), or pass the needle through the flame for a couple of seconds to complete the evaporation of the rubbing alcohol.

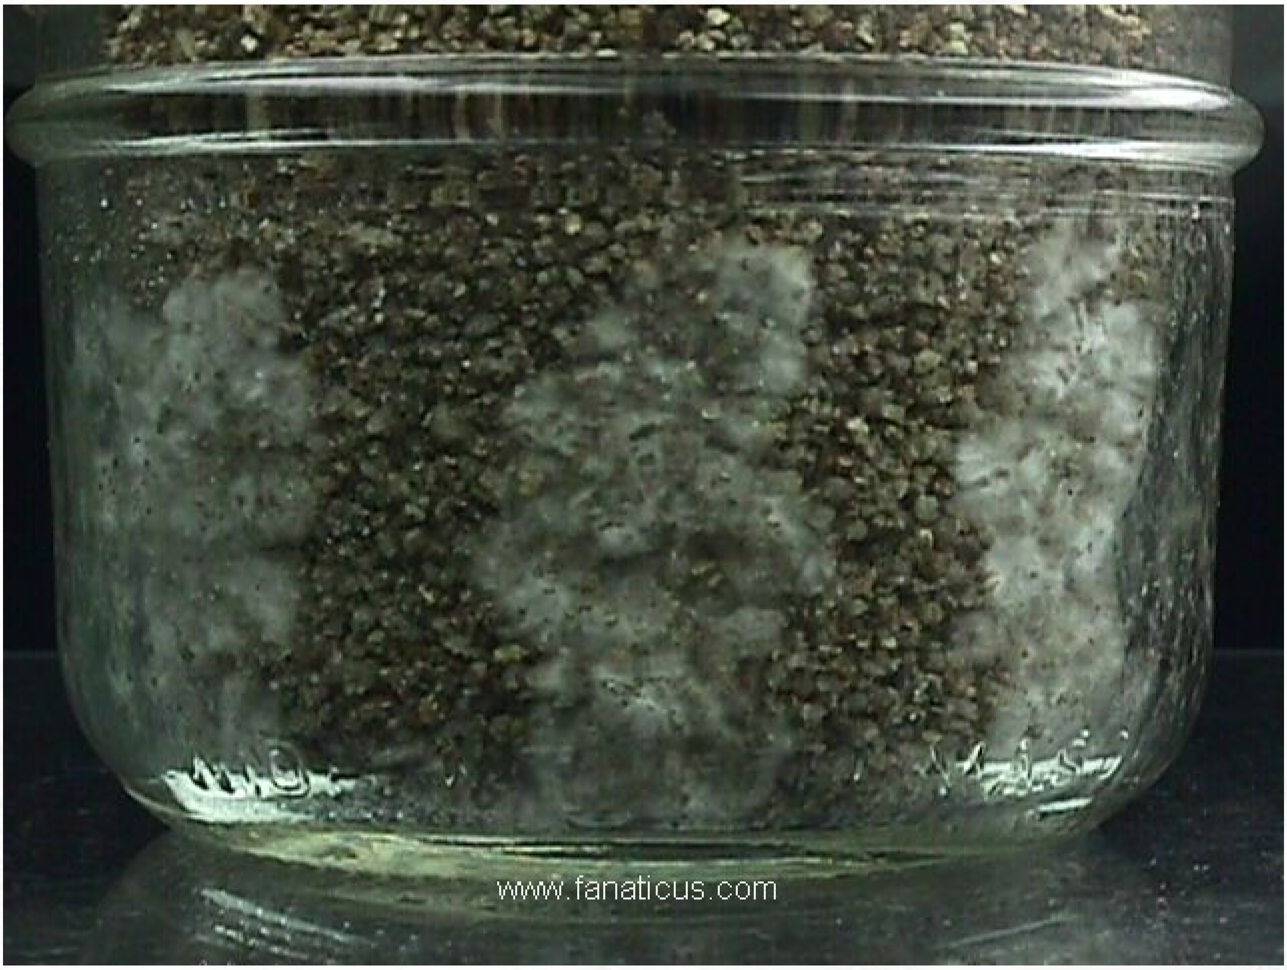
Inoculation of PF Jars Without the Lids

This technique can also be used if canning jars are not available (1/2 pint wide mouth canning jars are perfect and should be used at all cost). If regular drinking glasses are to be used - use regular tapered sided drinking glasses (8 ounce - 250ml)

Jars can be inoculated without using a lid with holes punched. Before trying this technique, inoculate with the punched lid first. That will show how it works without any problems (almost fail proof).

The only precaution to observe is to disturb the dry top vermiculite layer as little as possible, especially when removing the needle after the inoculation. The underlying substrate must not be exposed to the air. Carefully move any disturbed vermiculite back into place (with your finger tip). Replace the tin foil cover after inoculation.

Incubation of Inoculated Jars



After inoculation of the jars, tighten the lid bands and retape the needle holes. A tight lid preserves the water content of the substrate (very very important) and the growing and spreading mycelium will do fine with a tight lid all the way to the appearance of the primordia (using the air in the jar only). Place the jars in a safe place out of direct sunlight. Indirect light is all that is required. If the temperature is kept around 70 degrees, germination will begin within 3 to 5 days. Germinating spores appear as small white fuzzy spots, quickly growing and spreading with cottony white growth and strandy "rhizomorphs". Any room temperature is O.K. If it gets cold indoors, over head light shinning down on the tops of the jars is a perfect heating technique for this culturing stage. A clamping type light with a reflector works well for this. If this is done, keep the temperature around 70 degrees (don't overheat the jars - monitor the temperature with a thermometer). A warm overall house temperature is fine. But in the overall view, cool temperatures are never a problem. The rule is to not overheat.

The Canning Jar Lid (loose or tight)

There are two choices with the lids during incubation - tight or loose. With a very high moisture content (good for fruiting), a tight lid can cause water to collect in the bottom of the jar. This is to be avoided. Water condensing in droplets on the inside of the jar during incubation is normal and is to be expected. If puddling on the bottom of the jar occurs, the lid should be kept on loose during incubation. Tape the canning jar lid to the band to make the lid act as a one piece lid for raising and lowering.

An excellent way of depuddling the jar is to use a long syringe needle and syringe. Without disturbing the top vermiculite layer, insert the long needle down to the bottom of the jar. Tilt the jar so that the water puddles down to the needle point and suction out the water. This works really great, but one needs an extra long needle to do it. Doing this can facilitate superb fruitings with the high water content without the puddling problems and possible deterioration of the substrate because of the water (drowning). With a high water content, there might be more than one depuddling procedure needed.

Also, there is another and even simpler way to depuddle the jar. One just simply inverts the jar and lets the water run down the side and is absorbed by the dry upper vermiculite layer. Most people do this and report excellent results.

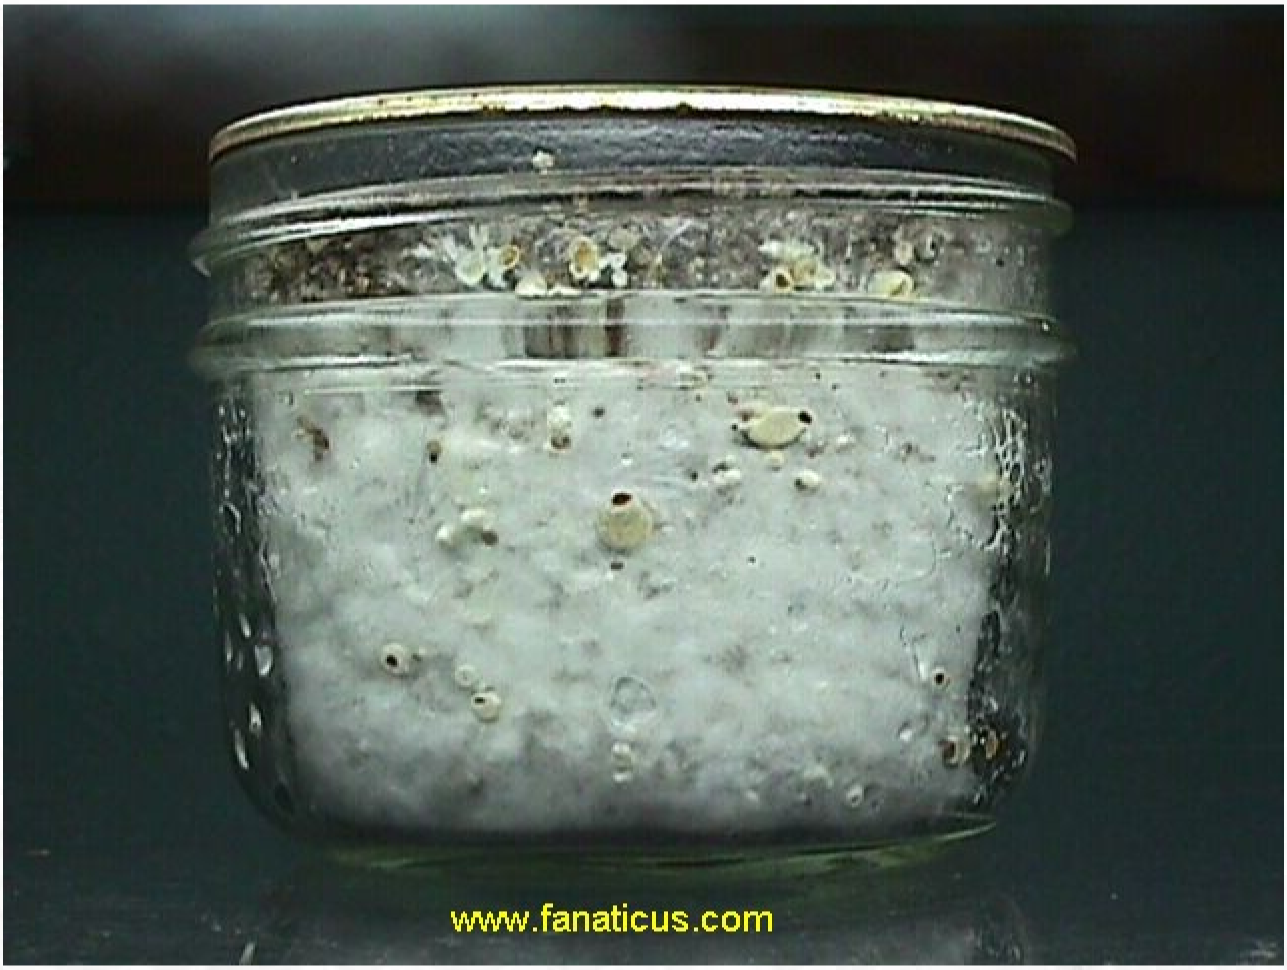
If the substrate is on the dry side, a tight lid will preserve the moisture content. It is all a matter of the balance between the water needs of the mycelium, the size of the jar, the available air space in the jar and the type of vermiculite used. Only by simple experimenting and comparison can the right balance be found for a given set of conditions. Take notes and go with what fruits the best. But after many years of seeing all of this and all over the internet - web - the basic PF substrate formula as given rules.

After the substrate turns white with the mycelium (2 to 4 weeks after inoculation), the jars are left to sit in indirect light. The mycelium will continue to infiltrate the substrate until it gets enough food to trigger the fruiting cycle. In less than a week to a few weeks after surface colonization of the cake (cake appears all white), tiny white "pin" like structures begin to appear. This is called pinning. This is the beginning of the fruiting cycle. Soon after that, within the week, small round fungus growths appear that soon begin to turn yellow.

Lastly, "primordia" start to grow. These are tiny worm like structures with tiny reddish heads. These are the first mushrooms.

Table of Contents

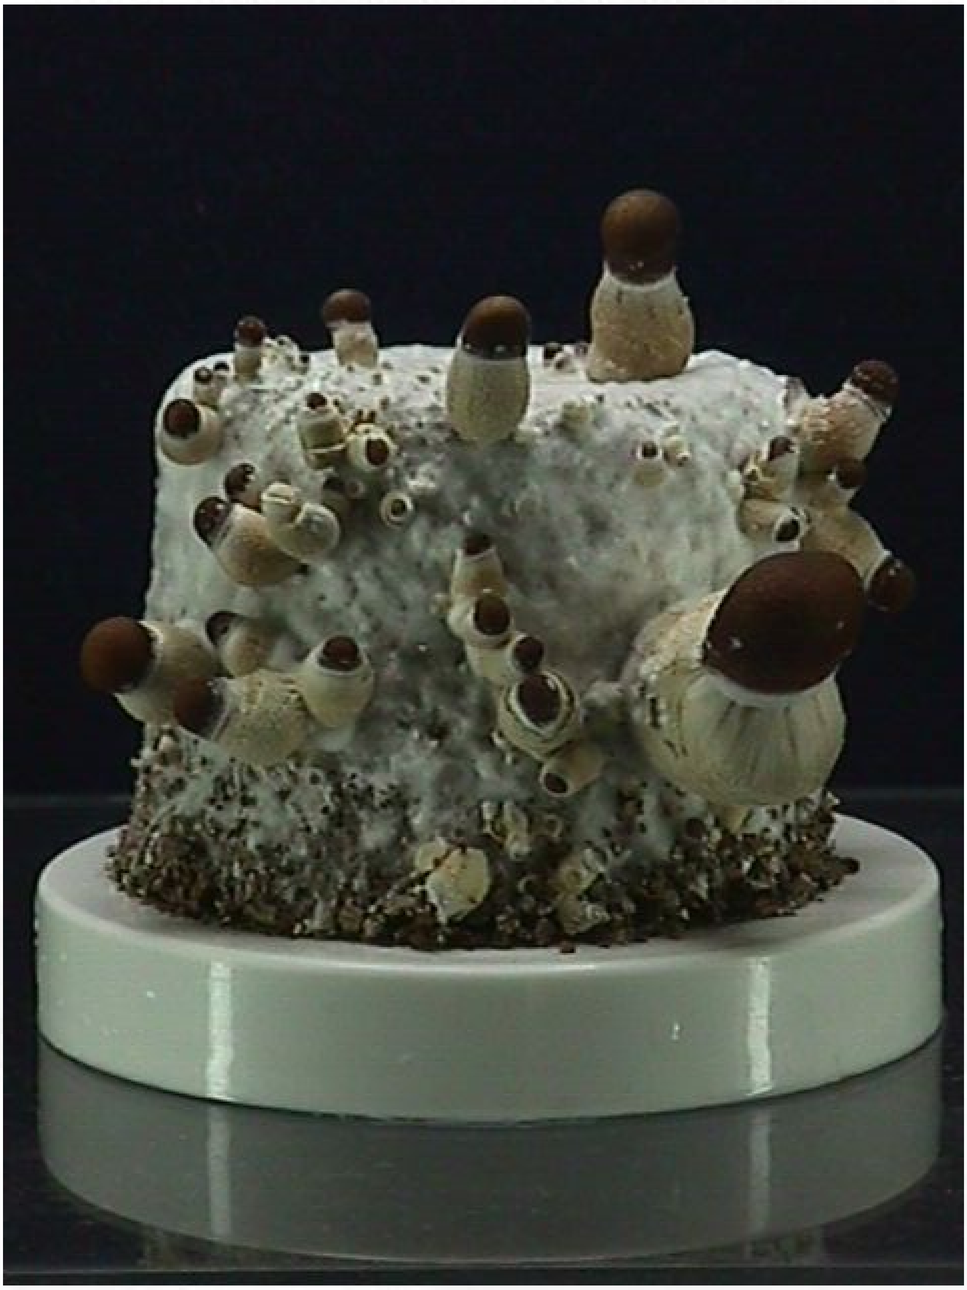
CHAPTER 3 - THE BIRTHDAY CAKE



This photo is of a 1/2 pint PF substrate jar about 23 days after inoculation (done with 3 cc of spore water and incubated at 70 degrees Fahrenheit). The primordia have appeared and it is now time to birth the cake. Wait until you see this, and the fruiting will be maximized. The fruiting is fairly relative to the primordia that appear.
The best time to remove the fungus cake from the jar is when the primordia (tiny worm like structures with reddish heads) appear on the cake while still in the jar. Be careful not to damage them in handling. The rule is to handle with care.

Remove the lid. With a clean fork, scrape away the majority of the dry top vermiculite layer. There will probably be seen some wispy mycelium here and there in the top layer. That is a good sign showing the healthy agressive nature of the mycelium. Place an old jar lid over the jar mouth and turn the jar upside down. Lightly slam the jar down on a table cushioned with a magazine. The fungus cake will slide out onto the old jar cap (BIRTHDAY). What I usually do is hold the jar without the lid on (top down) in my hand and carefully wack the bottom of the jar with a rubber mallet - the cake births nicely. When handling the fungus cake, be careful as not to squeeze and bruise it. Bruising results in a bluish mark. This fungus is resilient and can tolerate a certain amount of handling, but handle it as least as possible. The aroma is distinctly mushroomy, very pleasant.

As soon as the fungus cake comes out of the jar, place the cake with the vermiculite covered end down onto a preprepared soaked vermiculite (or perlite) filled saucer, old jar cap, petrie dish ect. It really makes no difference what end of the cake is down. Also, for some of the cakes, follow the PF casing technique (later in this chapter) as a way to make the fruiting max. Leave some cakes uncased for comparison. Daub the cake with a piece of loose tissue paper to soak up any water droplets that may have deposited on the cake as it comes out of the jar (actually, this doesn't have to be done, because the freed cake drinks it up within several hours). Immediately after the birthday, place the cakes into the dual chambered terrarium for the fruiting cycle.



This is the cake a few days after the birthday. This is a healthy fruiting start. Some of these primordia will abort, but most will go on to full development.

Some of the first mushrooms to form are "aborts" (convoluted caps, gnarly stems and stunted growth), and ironically they are primo in magic alkaloids. They are even more powerful in magic than the stately beauties that will soon dominate the cake. The tiny "baby mushroom" aborts are likewise good. After witnessing the growth of the fungus, recognition of these aborts is easy. As long as the aborts are healthy and pure, they are primo. Also, another form of mutants will manifest, blobs of fungus with little or no cap, also good for harvesting. And along with these mutants, appear the perfect specimens, the sporocarps.

It has been reported that Psilocybe Cubensis is a "weak" mushroom. PF and others have seen this to be not necessarily so. It all depends on how it is grown, on what medium and how it is harvested and preserved.

The secret to potent mushrooms is in their age when picked. It has been scientifically proven that the small immature specimens are significantly more potent than the larger mature specimens. Over half of the small primordia that first form will abort (cease growing, convolute and deform - depending on the strain). Pick these before their heads turn black. A pointed knife blade works well for removing these high potency primordia. These are among the most potent. The abortive mushrooms are also high potency. Harvest them when they are young and before their heads turn black. When the fruit bodies are normal, harvest them before the veil under the cap breaks. The mushrooms will be smaller and their heads will be roundish. It is important to note that the mushroom cakes pictured in this book are all mostly well matured. While these mature specimens are beautiful and perfect, they are not as potent as the diminutive specimens. The mature specimens are good for spore collecting and showcasing (photography) but are weak in psychedelic potency.

Grow them on brown rice, harvest them when they are young and cool dry them with desiccant. When this is done, they are an entheogen of the highest order.

Time Scale of the Mushrooms

1. Spore inoculation to spore germination - within a week, at 70 degrees Fahrenheit.
2. Spore germination to complete colonization of the cake - about 2 to 4 weeks or more.
3. Complete colonization to fruiting cycle start - within 2 weeks or more.
4. The fruiting cycle lasts about 2 weeks. After the initial flush, the mycelium cake begins to turn blue and no more mushrooms form. If the cake is thoroughly cleaned of aborts and stray fungus blobs after the initial fruiting and given the PF double ended cake casing tek, fruiting can be doubled or even tripled.

All in all, the process takes from 4 - 6 weeks from spore inoculation to fruiting.

Contaminant Source Identification

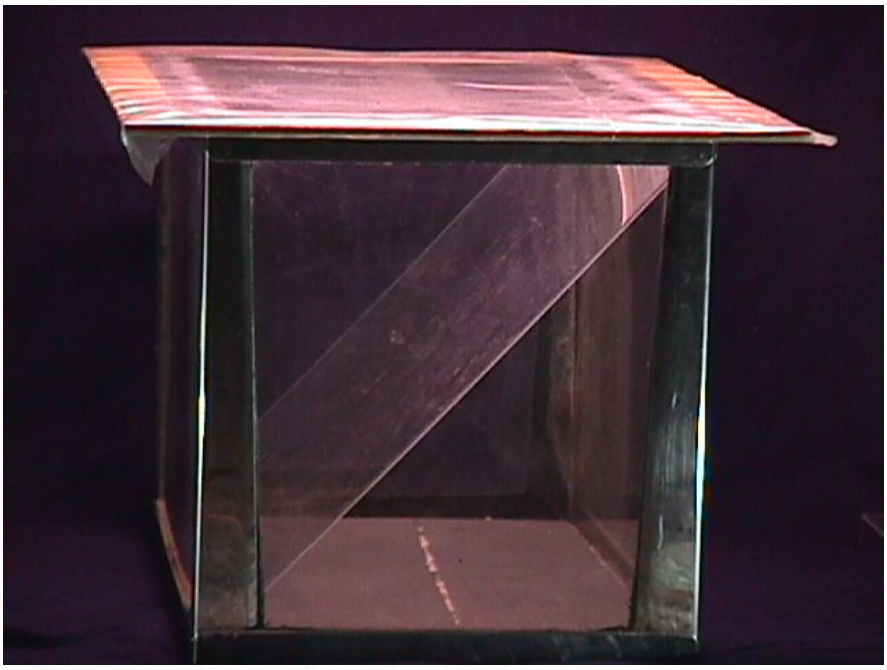
Contaminant invaders appear in various colors from pastels to black. If they appear, the culture is doomed. Bacteria contamination is detectable through the top dry vermiculite layer as a sour foul odor within two days after inoculation (and no spore germination). If the jar is bacteria contaminated, be careful in cleaning it. Keep a safe distance from the contaminated substrate. Don't inhale the bacteria and wash your hands after touching it. Bacteria can be dangerous.

Non-Germination of Spores

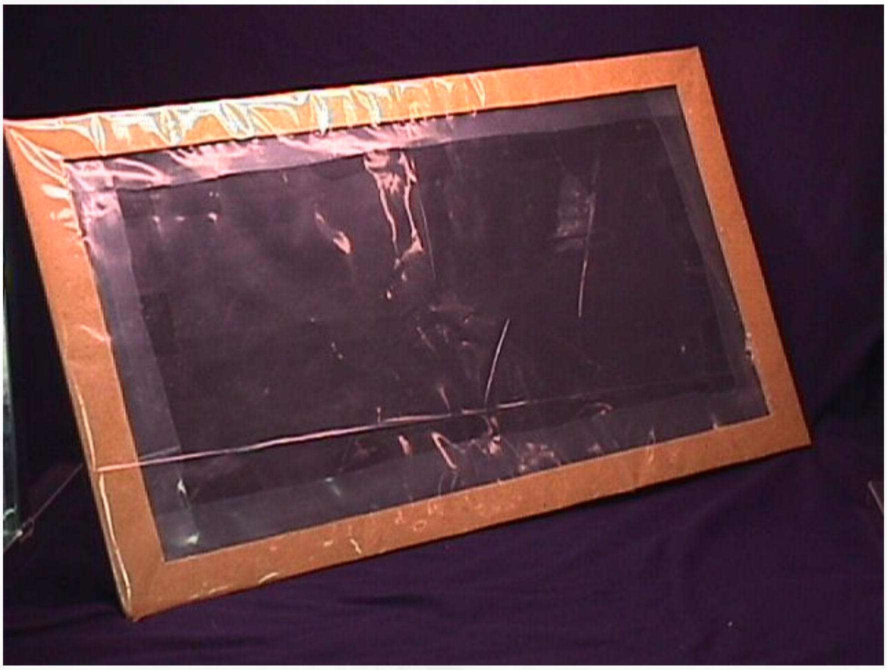
1. The spore solution was not inoculated deep enough down into the jar. Instead of running down the side of the jar and inoculating the substrate cake, the solution was absorbed by the non-nutritive top vermiculite layer. To avoid this from happening, make sure that the spore solution flows down along the sides of the substrate cake by inserting the syringe needle so that the tip is below the non-nutritive upper vermiculite layer.
2. The substrate jars were not allowed to cool down after sterilization, killing the spores. Inoculate only when the jar feels cool to the touch.
3. There is evidence now that syringe boxes can be exposed to killing heat during transit (a very rare occurrence). The possibilities are such as over heated airplane cargo holds during intense heat waves or a superheated mail truck parked all day in the sun. Another possibility is that on arriving at the mail box, the syringe package was allowed to sit inside a broiling sun heated mail box, killing the spores.
4. Spore syringes can survive freezing, but extreme low temperatures are probably destructive to the spores.

Table of Contents

CHAPTER 4 - THE DUAL CHAMBERED TERRARIUM



Standard 10 gallon aquarium



The airtight aquarium lid (top)

24" X 14 1/2" outside dimensions
21 1/4" x 12" inside dimensions (dimensions variable).
The frame can be made of flat (unwarped) 1/4" thick board or 4 wood strips connected by screws.

The wooden lid frames' inner rectangular cutout must be LARGER than the top of the aquarium. Clear polyethylene plastic film is tacked to the underside (or upper side) of the frame so that the frame holds it tightly onto the aquarium top. The frame essentially hangs by the plastic film. A simpler alternative is to cover the aquarium top with saran wrap or something similar. The most important point to be stressed is that the aquarium must be sealable with no air leaks, for humidity retention.

The Spray Shield/Chamber Partition

(for a standard 10 gallon aquarium)
Use 1/8" thick clear acrylic (Plexiglas) window insulation available at most hardware stores. Have it cut around 15" x 18" (dimensions may vary - check the aquarium first). A loose fit is good as long as the cakes are protected from the direct spray.

Dual Chambered Terrarium Techniques

The mushrooms get water from 2 sources; the substrate they grow on and the air that surrounds them. The surrounding air must be highly humidified. The fungus needs to bathe in a shroud of floating water molecules. 100% humidity is where there is the maximum number of water molecules floating amongst the air atoms. The dual chambered terrarium easily achieves these conditions.

It all starts with the spray from the hand sprayer. The first rule is to never directly spray the fungus. This initial spray is comprised of water droplets that are giant ponds of water in relation to the fine mycelial networks of the fungal threads. In culture, the droplet of water will drown the micro world of the fungal structures and thereby inhibit or contaminate growth. But the airborne molecularized water floats into the fine structures and gives the fungus humidity as needed. Molecularized water is another way of describing water that has evaporated into the air.

The spray that comes out of the spray bottle must be molecularized for the fungus. The spray shield and the primary chamber accomplish this. The primary chamber receives the initial spraying where as the shroom cakes are behind it. As the spray strikes the shield, it is broken down into a finer mist which flows around the sides of the spray shield into the secondary chamber where the fungus is bathed in the fine humidity safely away from water droplets. In a matter of time, this humidity will condense out onto surfaces inside the terrarium and drip down. The spray shield is slanted and therefore acts as a drip shield and roof, so the more condensation the better. Also, the spray shield adds more surfaces to the insides of the terrarium which increases the amount of moisture that can evaporate.

Spraying Procedure

First, before placing the cakes into the terrarium, spray all the inside surfaces of the terrarium, including the spray shield and lid. Insert the fungus cakes and put the spray shield and lid in place. Then, slightly lift up the lid and insert the nozzle of the water spray bottle in between the lid and the top of the aquarium and vigorously spray downwards into the middle of the shield. After about 5 seconds of spraying, immediately withdraw the sprayer nozzle and let down the lid to seal the swirling mist inside the terrarium. Make sure that all the inside surfaces of the terrarium are foggy or dripping with water. This in itself helps generate humidity.

It has been seen that mushrooms will grow very well in a properly set up dual chambered terrarium, with only one good spraying a day - and even less than that. This is one of the amazing features of the PF TEK. With the cake cased, I have seen great shrooms grown like this with little attention given to the terrarium. PF style cakes actually seem to need less humidity than any other way of growing shrooms as long as the double ended cake casing technique is employed. PF cakes, when birthed, don't need 100% humidity to fruit well. It is very true, that cased grain and such need the very high humidity, but PF cakes don't. And that is because the cakes themselves humidify the space around them because of the vermiculite content. Vermiculite holds a lot of water and will both absorb and release moisture.

Each time the terrarium is sprayed, the fungus should be ventilated. To ventilate, take off the lid, and while holding the spray shield vertically, fan the chamber with a piece of cardboard, and then spray as above. Also, the water that collects in the bottom of the terrarium must be siphoned out (prevents bacteria buildup). This can be easily done using a rubber bulb battery filler (auto parts store) or a rubber bulb type enema bottle.
Expose the terrarium to normal room light (indirect sunlight). A small low wattage fluorescent plant light positioned above the terrarium will make the phototropic mushrooms grow upwards. Leave it on all the time if desired.

Heating

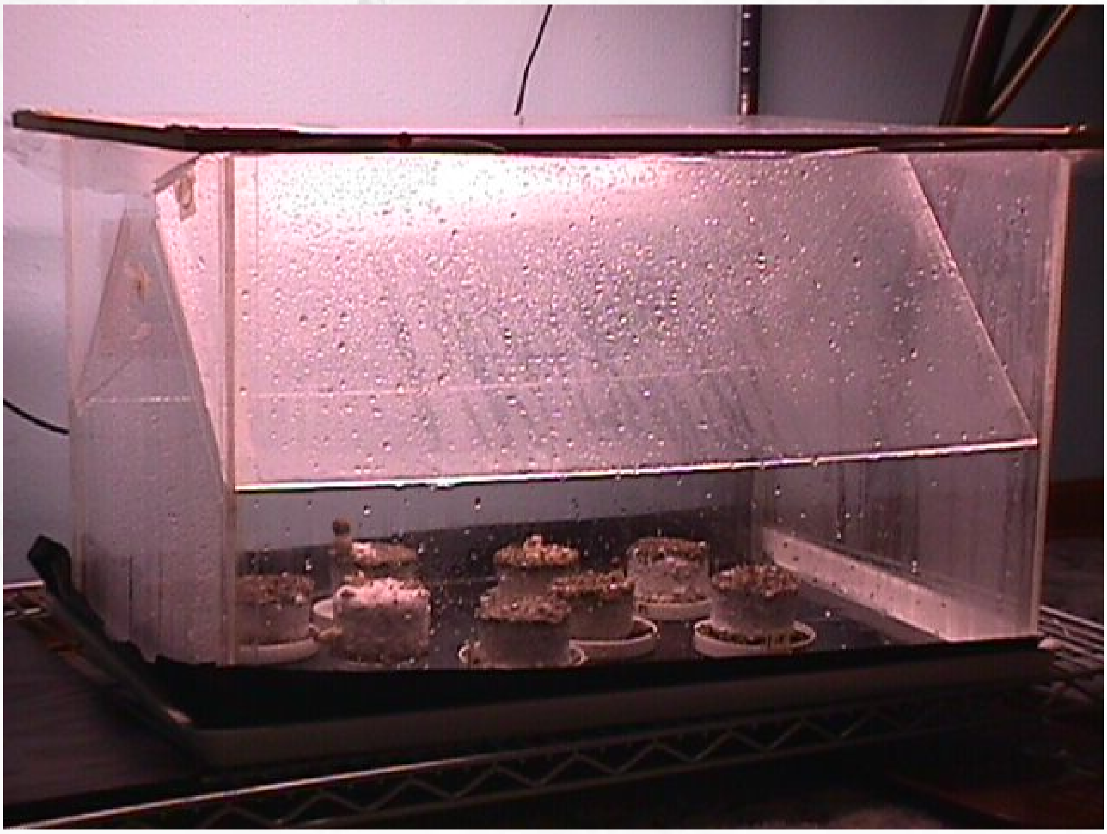
The main rule is to not heat the dual chambered terrarium. Any direct heating works against the humidification andadds a drying influence. Do not use heating cables, heat pads or blankets. Don't shine light directly down into the terrarium. Keep any plant grow light (low wattage only) a safe distance from the terrarium. These fungi grow well at 60 degrees Fahrenheit. PF has even seen them growing perfectly at temperatures cooler than 60 degrees. They grow slowly when they are cool. When warm or at heated room temperature, they grow very fast. Strive for a growing temperature between 65 and the upper 80's. A too hot terrarium will result in lots of spreading mycelium, but no fruiting. It has been reported by other authors, that these cubensis mushrooms will have a higher potency when grown at cool temperatures. They grow much slower, but they seem to be denser in their flesh then when grown warm.

Symptoms of Low Humidity

When the humidity is a bit low, but not low enough to stop fruiting, the mushrooms can have fuzzy white mycelium growing on the tops of the caps. When this occurs, the cap looks like it has a crown of white hair. This is not contamination. This white fuzzy mycelium is perfectly good and does not detract from the mushrooms quality.

Deformed, convoluted, and withering mushrooms and primordia are signs of low humidity. For the best growth, the humidity has to be high.

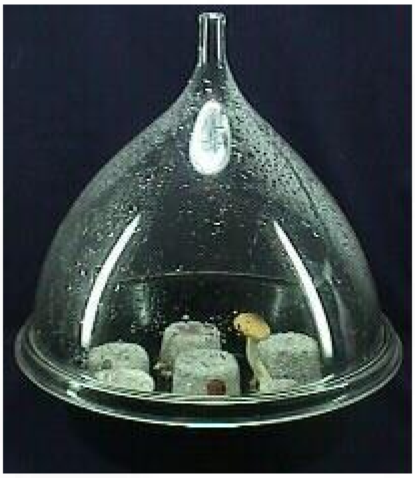
There are many ways to make a dual chambered terrarium. You can use straight toped (square) clear translucent storage containers, the kind you get at hardware stores or walmart. The top of the container must be straight or square to accomodate the lid as described above. This one I made out of plexiglass, a project that I probably wouldn't bother doing now. I presently have something like this made from a translucent tall storage box I got from walmart. You can get some really nice sized boxes with lots of room.



plexiglass mushroom machine

Table of Contents

CHAPTER 5 - THE RICH MANS' TERRARIUM



This is the terrarium that was used in the perlite and terrarium tests. I found it at a new and used resteraunt supply store in Seattle for $25. This is a covered food display tray.

It works great with perlite (and without) and holds 9 half pint cakes. The one above has 7 cakes. The cakes are post initial flush and the fruitings are secondary fruitings. The fruitbodies that appear late are always superb in form.

If you can't find one of these in your local town, you can order one for around $75 (hence - the "richmans'"). Call the manufacturer (Cal-Mil) in California at 1 800 321 9069. They will tell you where you can order it (from one of their distributers near your town).

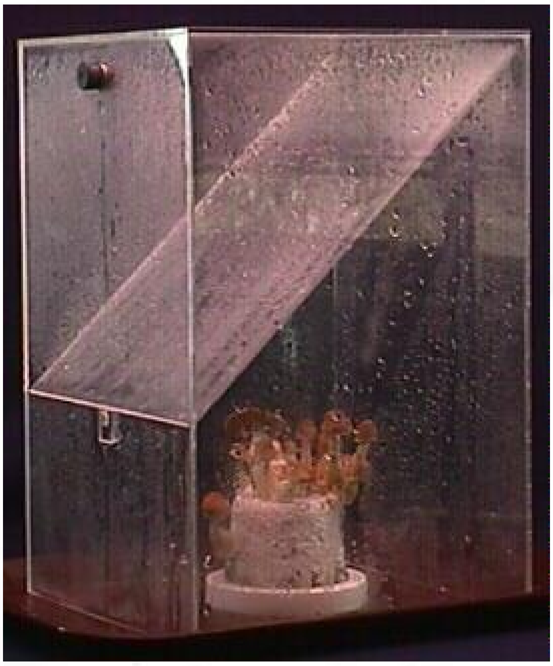
Unfortunately, sometimes a distributer will require a minimum of an order for two. But fortunately, the terrarium they will send you for the above price is bigger than the one pictured. It has room for several more cakes, making for a goodly capacity. All the shrooms pictured at this site were grown in one of these.

The catalog numbers are:
314-15 -- the "connoisseur cover"
316-15 -- "Deep Tray" bottom half
The unit is 15 inches in diameter and about that tall.

To use this terrarium, first spray the insides. Place the cakes in. Hold the cover above the tray and spray a fine mist into the air about 2 feet above the cakes in the tray and immediately lower the cover down onto the tray - trapping mist. Air and mist once a day. But what is so cool about this, is that neglect goes a long way! (set it up and leave it).

Yeah, I know it costs, but it works so nicely, and it makes a nice coffee table display. If your landlord comes by to inspect, he will see it, look down and say, "hey, nice shrooms, what kind are they"? Then you say, "I got it from a science catalog company and it is a new miniature fungi growing kit and the shrooms are not edible - just wild". (or something absurd like that). Then your landlord will look approvingly around, notice the neatness and tiddyness of your domecile, and leave, little knowing that he just observed the food of the gods.

The Ultra Richmans' Terrarium



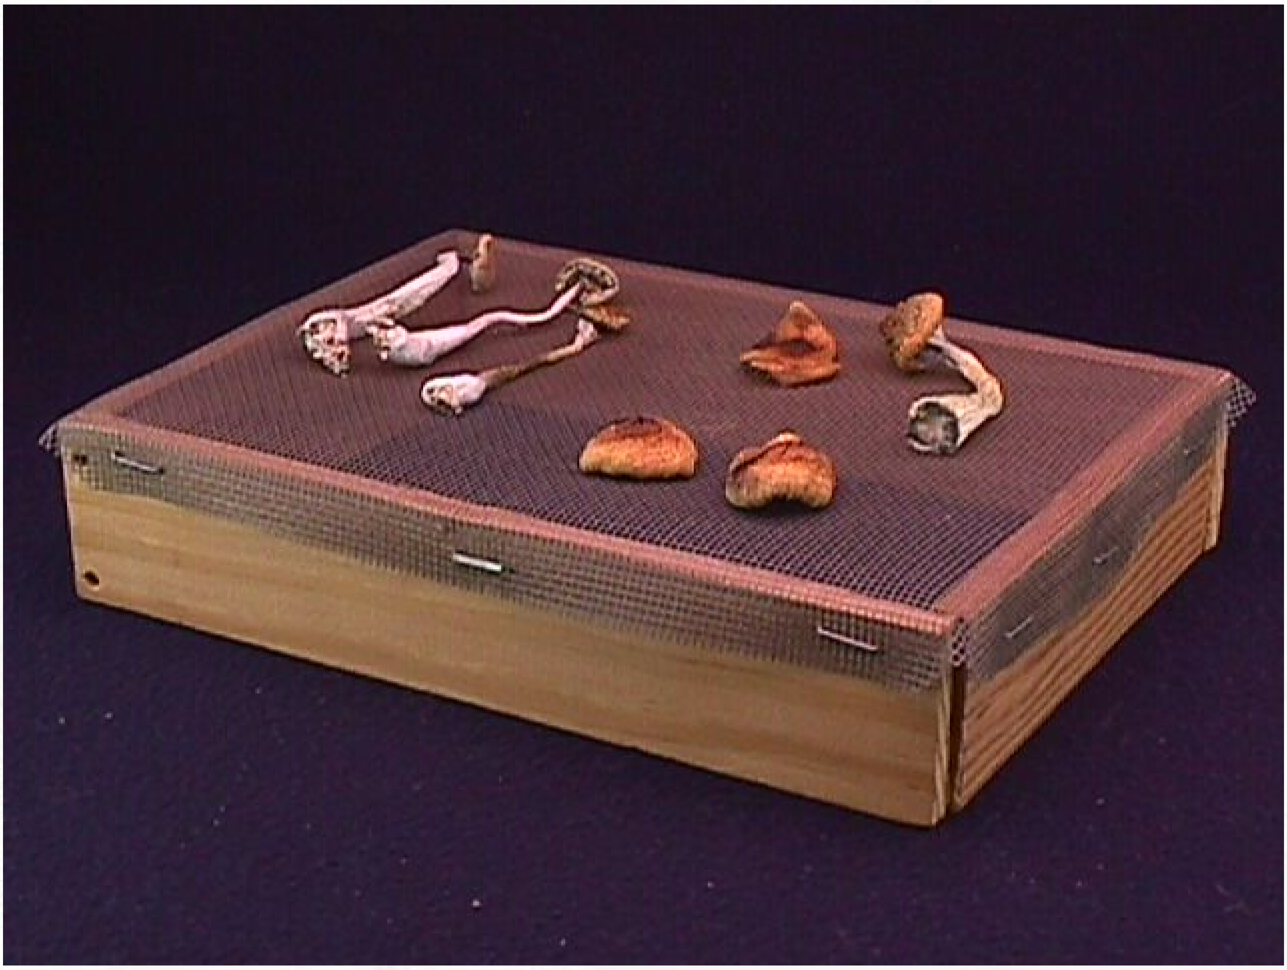
This terrarium was made by a plastics fabrication expert. It isn't cheap (like a poor mans Whalmart plastic storage box) but if you can find the right person - the cost is a bit more than the richmans dome above. It is made out of acrylic clear plastic. It is one piece, with a removable spray shield. At the top, is a spray hole with a rubber stopper. It is designed to hold one fruiting cake to maturity, but it can hold 4 cakes tightly. The cake inside is a first flush PF spore race cake - typical of a first flush obtained with the pf tek.

The terrarium is open bottomed so it fits over the cakes that sit on a tray. This is the most fool proof terrarium one can have. And it can be made bigger - as big as a ten gallon aquarium or larger. The plastics expert can make one just by looking at the photo and you giving him the dimensions that you want or by giving him the tray that you have to fit the terrarium to it. Very tricky - but it isn't hard to find someone (a professional) who can do it if you live in any kind of large town.

Table of Contents

CHAPTER 6 - COOL DESICCATION (drying) OF MUSHROOMS

The immature specimens are the best in quality, digestibility and potency. They are characterized as being very light in color with white stems and light colored caps. The cap will spread out after the veil breaks. Just before or right after the veil breaks is a good time to harvest. The gills on the underside of the cap will be light in color. The mushrooms will be conical shaped and sporulation hasn't really begun yet. These are the mushrooms that are the best for harvesting.



1. The easiest way to dry the fungi is to place them on a wire screen with air available to all sides. Never dry them in an oven or use hot air dryers. The heat leaches the chemical constituents and reduces their quality.
2. Using a frost free (dehumidifying) refrigerator works but it is time consuming and then everyone doesn't have a frost free fridge.
3. Using desiccant to cool dry mushrooms is overall, the best drying technique.

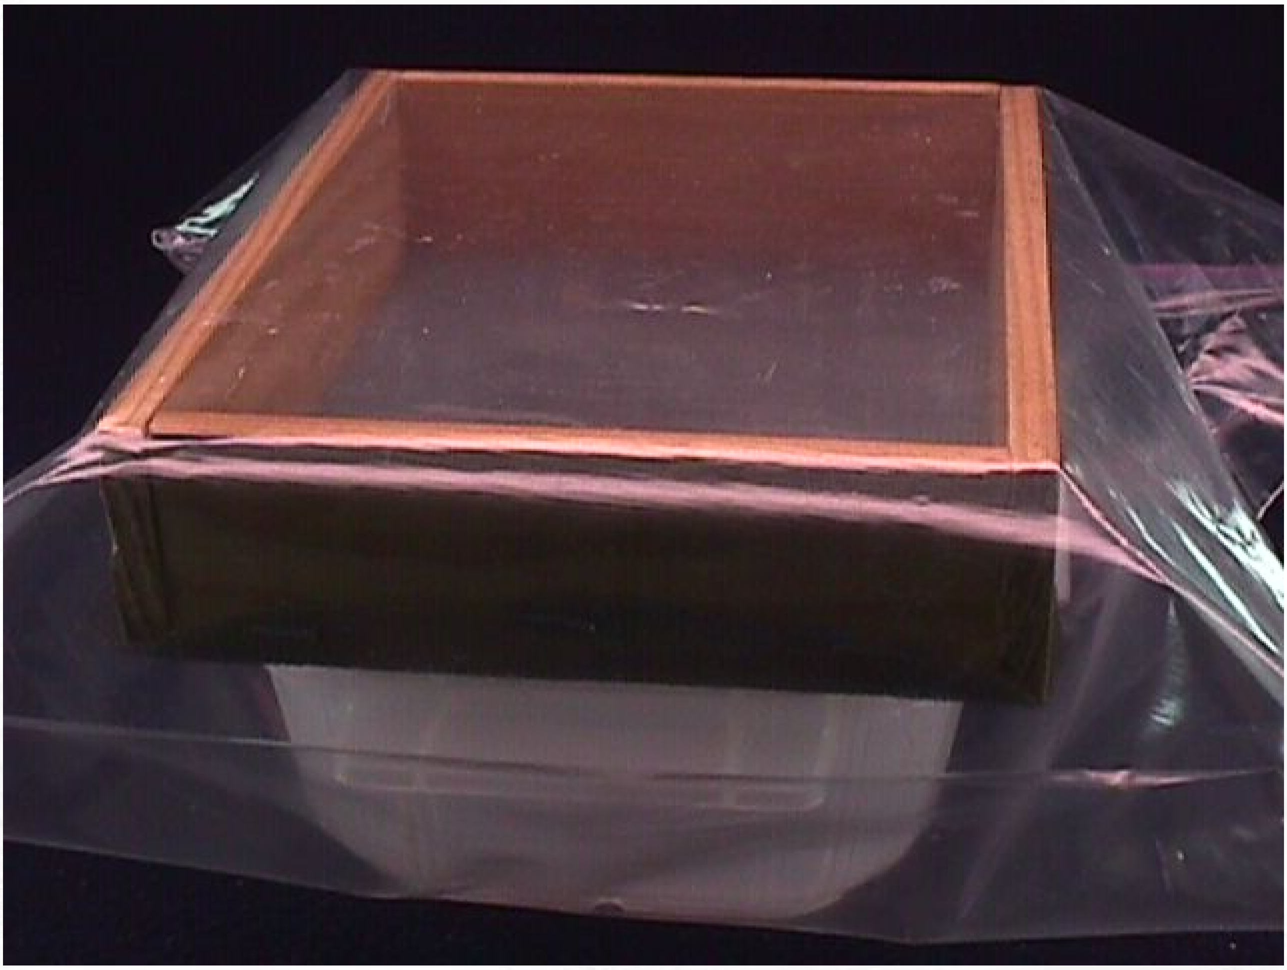
MATERIALS NEEDED - Desiccant - Wire screen - Plastic tub or container - Plastic bag with tie off.

DESICCANT SOURCES

1. "DRIERITE" desiccant. (chemical and science supply retailers). It is the universal lab desiccant.
2. Silica Gel granules - desiccant. (Chemical and science supply).

Note: These products might have toxicity warnings - (don't breathe the dust and try not to touch it directly - it dries skin.). Follow those rules, but know that desiccant in an airtight box and under a screen will do nothing to the fungi except dry them. It is completely safe for this use.

What desiccant does, is absorb moisture out of the air. As the fungus transpires moisture, the moisture is immediately absorbed back into the desiccant, drying the fungi. Desiccant can be reused and lasts indefinitely. After use, the desiccant is heated, dried and stored for future use. To be sure the desiccant is dry and ready to work, heat the desiccant in an oven as instructed by the manufacturer before its' first use. This preheating should be done before the desiccant is used because when it is purchased - it is usually somewhat damp which will thwart its function for drying air. Store it in an air tight container so that it stays dry and ready for use.

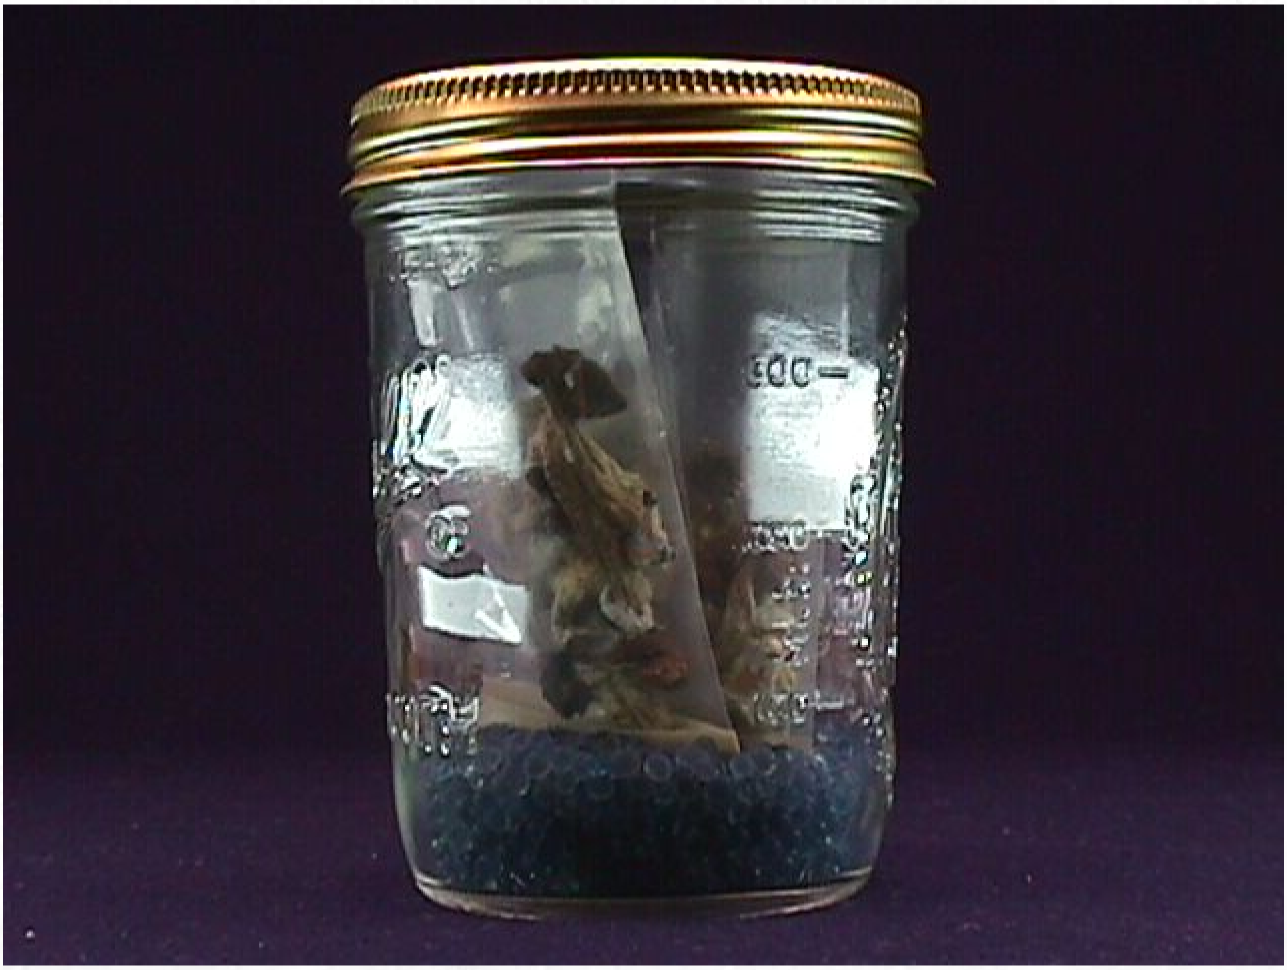


In drying a medium sized mushroom such as Psilocybe Cubensis, use a 1 to 2 inch layer of desiccant on the bottom of the container, under the mushrooms. Place the mushrooms on a wire screen and lay them on the desiccant that is in the container. Put the container with the shrooms and desiccant into a plastic bag. A garbage bag type wire tie is sufficient to close the bag. If a clear plastic bag can be found, use that to observe the drying process. After 24 hours, a little shriveling of the shrooms can be seen. About 4 or 5 days later, the shrooms will be dried rock hard. To check the drying - the stem should snap cleanly when bent.

For the best alkaloid preservation technique, the desiccant box can be put into the refrigerator and the mushrooms dried at near freezing temperatures.

Actually, about the easiest and most effective way to dry the mushrooms is to pre dry the mushrooms in the air on a wire screen. This works very well if the the room humidity is not high. After a couple of days, the shriveling fungus can be quickly and completely dried in the desiccant box. So a combination of air drying and then desiccant drying is one of the best ways there is to dry the mushrooms.

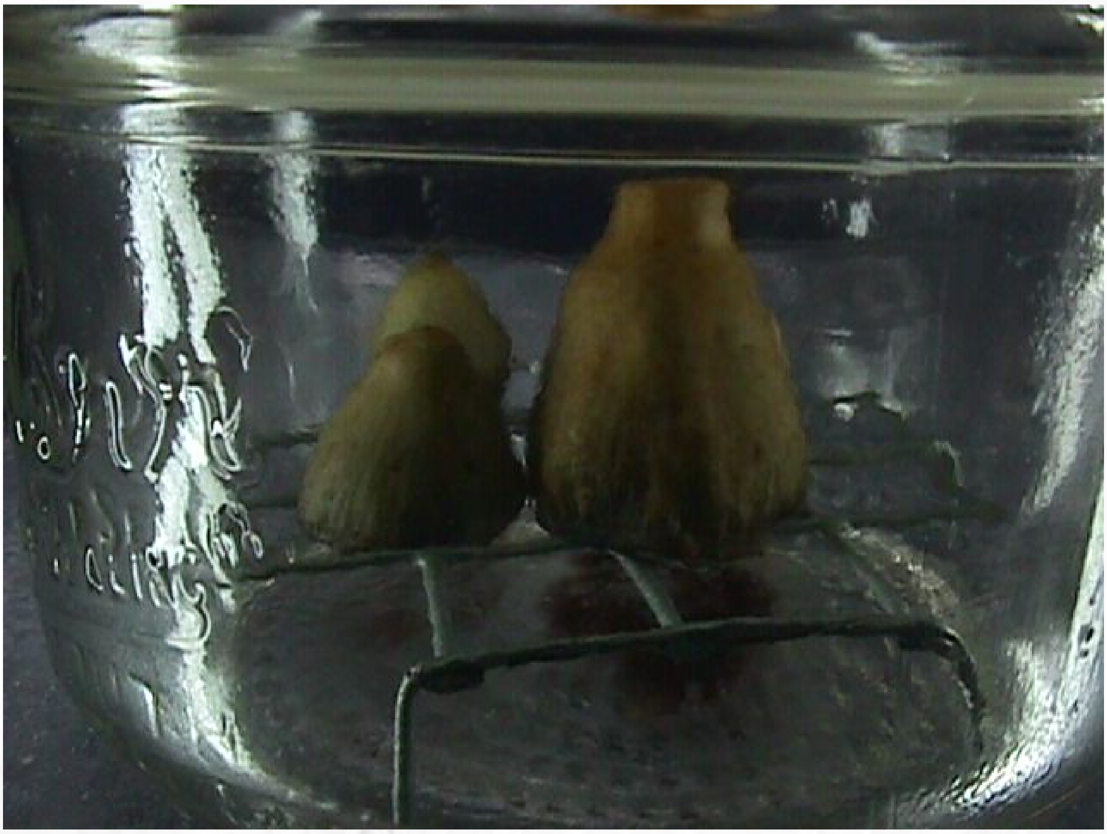
Mushrooms dried in this way lose hardly any chemical constituents and their truly desiccated state preserves them in their prime for months.



Store them by sealing them in plastic bags or keep them in canning jars with the rubber edged canning lid on tight (as in the photo - dried shrooms in little bags stored on top of desiccant). The freezer is a good place for preservation, but make sure the fungi are tightly sealed in their containers to protect them against the moisture in the freezer.

Table of Contents

CHAPTER 7 - SPORE PRINTING AND SPORE SYRINGE PREPARATION



Shroom caps printing while sitting on a wire holder.

The mature specimens are good for spore production, but are not as good for consumption (weaker potency). They are characterized as becoming darker, with dark bluish colors appearing on the caps and stems. The cap upturns and reveals gills darkening a deep brown color. The mushroom will look like an umbrella that has turned up edges. On the stem can be seen the purple deposits of the dropping spores. Mature adult mushrooms release spores by the millions. In the area around the mushrooms can be seen a deepening color of purple. As the spores fall and collect they will color deep purple. This is the signal that the mushroom has matured and is now in its sporulation cycle. This is the time to take their spores.

Spore Printing Equipment

KERR 1/2 PINT WIDE MOUTH (LOW FORM) CANNING JAR. (ANY SUITABLE JAR IS OK)
FINGER NAIL CUTICLE SCISSORS - (cosmetics - drug stores)
ALCOHOL, TEQUILA SHOT GLASS AND EYE DROPPER.

1. Pre sterilize the jar and regular metal lid (rubber edge up) in a small toaster oven at around 300 degrees Fahrenheit for around a half hour. Keep the lid loose during the sterilization cycle. When the jar has cooled down, tighten the lid until it is time to use the jar for a spore print. The rubberized edge will be a bit melted, but that won't be any problem in this technique.
   Note: What follows is a sterile technique. The first rule that must be always followed is to wash hands prior to sterile work. Hands are a prime source for bacteria and micro spore contaminants. Sterilize all the work surfaces with rubbing alcohol. Minimize drafts. Try for a still air environment. Don't breathe on the work. Run a small home appliance style HEPA air cleaner (99.97% rated efficiency - available at drug and department stores) for a few hours in a closed room to clean the air before doing sterile work.

2. Flame sterilize the scissors with an alcohol flame and snip off the mushroom cap. Cut the top of the stem as far up into the cap as possible so that the gills of the mushroom will sit flat on the surface of the

jar bottom. With quick and sure movements, place the cap into the jar and place the lid on loosely. Pierce the top of the cap with a straight pin to pick it up and handle it.

3. Leave the jar with a loose cap for a couple of days in a draft free area away from direct sunlight. After the print is taken, quickly and with as little air disturbance as possible, remove the jar cap and extract the mushroom cap from the jar. With a loose jar cap, let the jar sit in a draft free place to dehumidify for a few days before sealing it up (with tape) because there will be some residual moisture left behind on the spores and glass. Store the spore print jar at room temperatures in a dark place away from sunlight. Don't store it in a refrigerator.

Psilocybe Cubensis spores begin to degrade a few months after they are taken. After approximately 1 1/2 years, spore germination will be greatly reduced or won't occur at all. Germination is massive and quick when the spores are fresh.

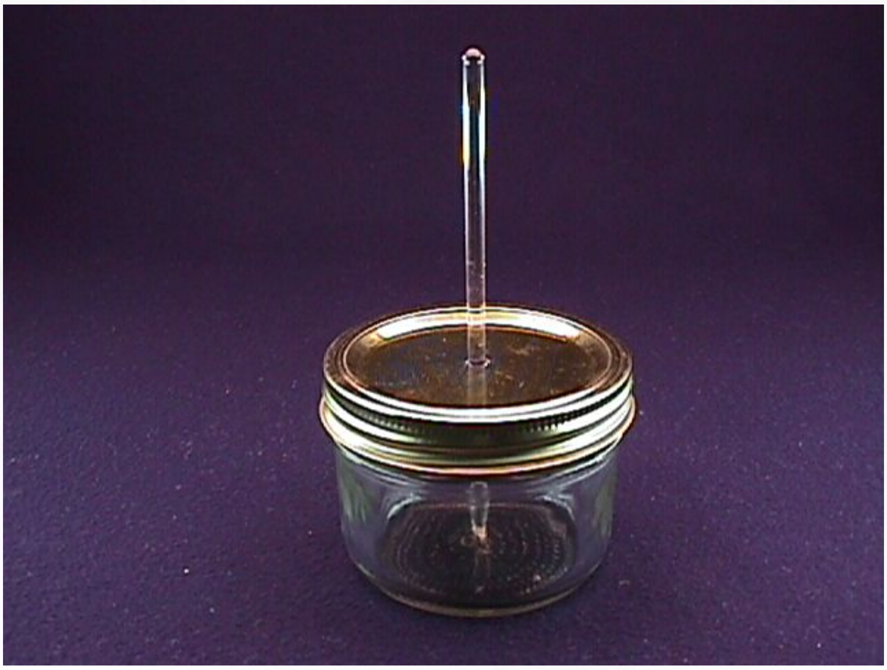
Making a Spore Syringe

Materials list:

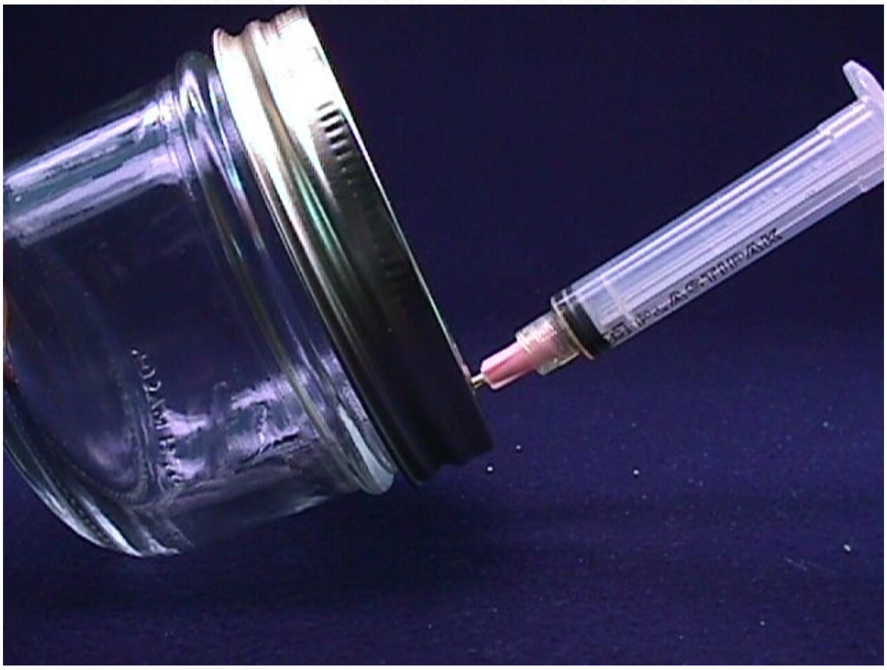
1. Spore print in jar.
2. Sterile syringe with water for injecting water into the spore print jar.
3. Empty sterile syringe for loading spore solution out of the jar.
4. A small Pyrex glass stirring rod (science - lab supply).
5. Alcohol, tequila shot glass and eye dropper.
6. Lid with two holes. Prepare this lid by drilling a hole in the center of the lid to fit the Pyrex glass stirring rod. Punch the second hole near the edge of the lid (rubberized edge up) to fit a syringe needle.

Syringe preparation

Boil a pot of water. Draw boiling water into a syringe and squirt it out several times. Refill the syringe with boiling water, replace the needle quard and wrap the syringe in tin foil. Prepare several syringes like this. Drop the syringes into the boiling water and boil them for one hour. Let them cool before using. Sterilze empty syringes also.
The main point of this technique would be to expose the interior of the jar to as little room air as possible. Always protect the holes in the lid by placing tin foil or sterile surgical tape over the holes before and after this procedure.



A glass lab stirring rod is used to scrape spores off the bottom of the jar and into the water (they stick to the bottom when printed).



The syringe is inserted through the needle hole and suctions out spore solution.

1. Inject sterile water into the spore print jar through the needle hole.
2. Flame sterilize the glass stirring rod and let it cool a minute. Insert it through the center lid hole and with the rod end, scrape spores into the water.
3. Insert the sterile syringe needle through the small hole at the edge of the lid. Tilt the jar until the water comes up to the needle tip and draw the spore water into the sterile syringe.

Store the syringe at cool temperatures in the dark. A properly prepared spore syringe will be good for several months and even up to a year or more.

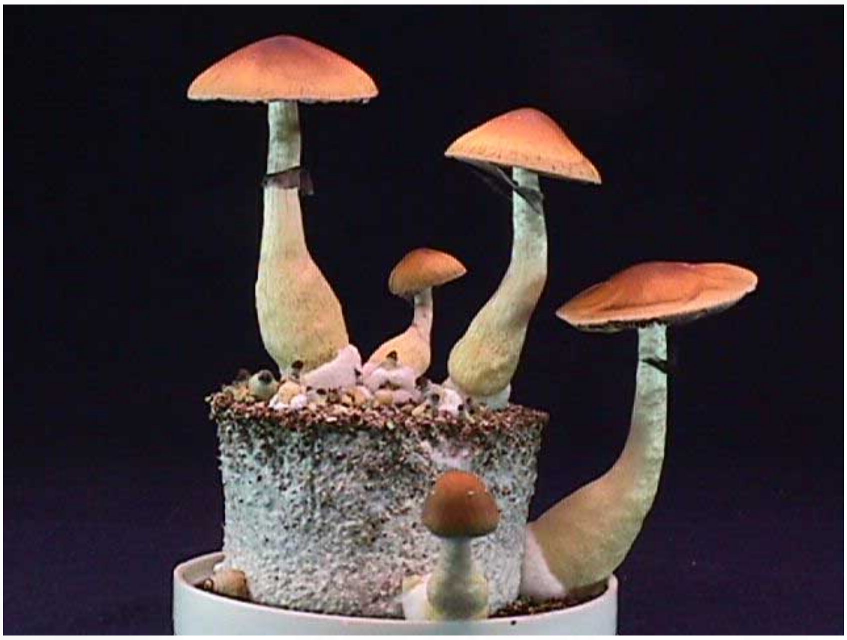
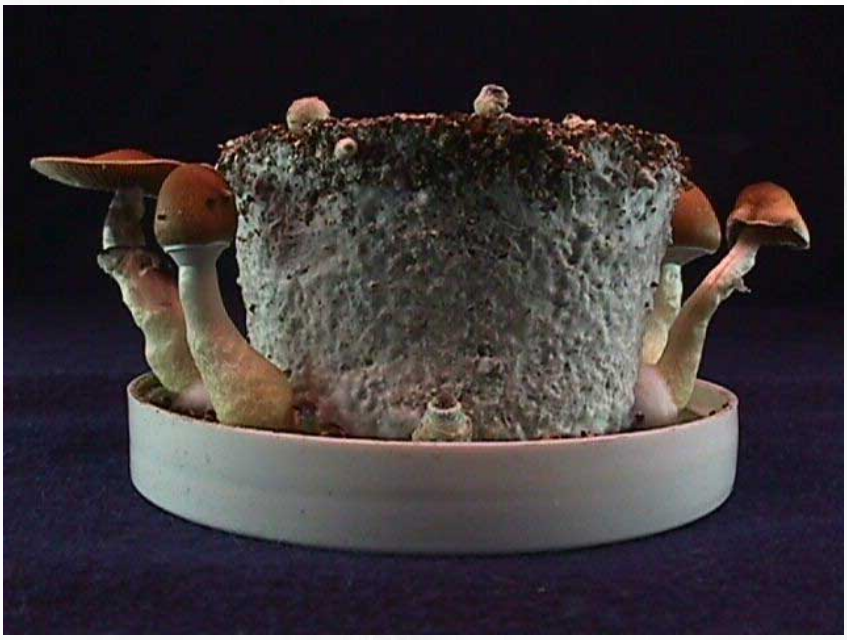
CHAPTER 8 - CAKE CASING TEK

The Double Ended Cake Casing Tek





The photo on the top is a second flush off of a PF spore race cake. The cake under the first photo is a third flush.

First: In Vitro Primordiation
There are many ways to extend the life of a cake and get more shrooms. The essential pf tek is to always allow primordia to appear on the cake in vitro. But not only that, wait for more. So when you spot the first primordia, wait around 3 to 4 more days before birthing. This stimulates more of them, and then your first flush will be fat. This invitro primordiation works well with most all of the spore races (strains) available. A few of the strains don't primordiate well invitro so they need to be birthed after about a month invitro, and then given the casing treatment.

Second: THE CASING TEK
Another really good way to max fruitings, it to not wait for the invitro primordiation. As soon as the cake turns completely white, it can be birthed and then cased. Immediately after the cake is first birthed is the time for a

casing. fill a jar cap with vermiculite, soak it and drain it. Place the cake on top of the wet vermiculite.

Next, pour dry vermiculite onto the top of the cake until it starts to spill off. Flaten the top of the vermiculite with your finger to about 1/8 to 1/4 nch depth. With an eye dropper or old syringe, slowly drip water onto the top dry vermiculite layer until it is soaked completley.

Spraying and maintenance

Once the top layer is totally soaked, place the cake into the terrarium and leave it alone. Follow the Terrarium tek.

Casing and Recasing

The cake whitening phenomenon

One of the most interesting effects of this tek, is the revitalization of the cake. After the initial fruiting, if it is really fat, the cake will be a bit blued. One of the signs of old age in PF cakes is the bluing that will occur. Most likely, the cause of this overall bluing of the cake is moisture loss and thirst of the cake. When the PF double ended cake casing tek is employed, the cake will gradually turn white again. After about a week under the casing tek, the cake will be completely white again and on its way to a good second flush.

This casing tek seems to work better if you completely clean the cake after the first casing flush and recase with fresh vermiculite. After the flush occurs, the top and bottom vermiculite layers should be scraped off and replaced. A good way to do it is like peeling an apple. Hold the cake in your hand without squeezing, and with a knife, scrap the old vermiculite off the cake. Try to clean down to the surface of the cake. The scraping doesn't hurt the cake at all because these older cakes become "tougher". The mycelium tends to be "tighter" and less fluffy and the cake becomes contamination resistant. This "toughening up" and recasing of the mycelial cake is also reported in the old OSS and OERIC (McKenna brothers) mushroom cultivation book published in 1976.

After the cake is carefully cleaned (rather a painstaking procedure but not difficult), the cake is placed on a freshly soaked and drained bottom layer of vermiculite (on a plate or in a jar cap). Then, fresh dry vermiculite is poured over the top of the cake and smoothed down to a layer of 1/8 to 1/4 of an inch and the basic casing wetting procedure is employed. The spray bottle offers a good way to drip water onto the casing. By slowly squeezing the spray lever, the water will drip out in single drops. You can also use an eye dropper. Slowly wet the top layer. If you apply to much water and it over soaks the vermiculite, the cake can be tilted and excess water drained from the top vermiculite layer.
After every flush - reclean the cake and apply fresh vermiculite. What this does is prevent contaminants from building up. The cakes stay uncontaminated and fruitable for a good two to three months. You can get several flushes out of a properly cared for cake. This casing tek keeps the cake white and uncontaminated for its life duration.

PF TEK add on techniques

CHAPTER 9 - THE INNER RESERVOIR TEK

by JK

original source: http://www.fanaticus.com/resevoir.htm

Mazatec fruiting - PF style - 1/2 pint with the inner reservoir tek. The shrooms are all growing from the lower vermiculite layer (upper contaminant barrier when invitro).

Mazatec fruiting - the cake is still bright white with this first flush. Without the innver reservoir, the cake would be blueish (natural drying process - caused by water transpiration from the fungi).

Mazatec cakes fruiting in a plastic storage tub ("Sterilite" - "Rubber Maid" - Walmart - Kmart - Home Depot - ect). Vermiculite was used on the bottom - moistened for humidity. PF uses seperate caps for the bottom layers, but this a bit bigger. Vermiculite might be better than perlite - period. One can conceivable become "perlite free" as so many now are "peat moss free".

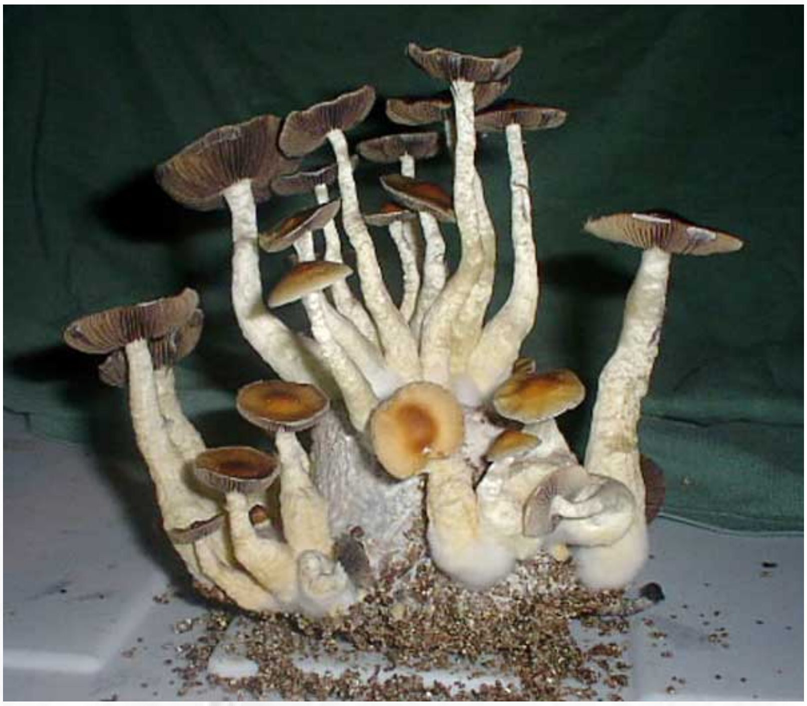
The Inner reservoir tek

The cakes are regular 1/2 pint low form canning jar size. The shrooms are the Mazatec and the Treasure Coast (see below) spore races from PF.

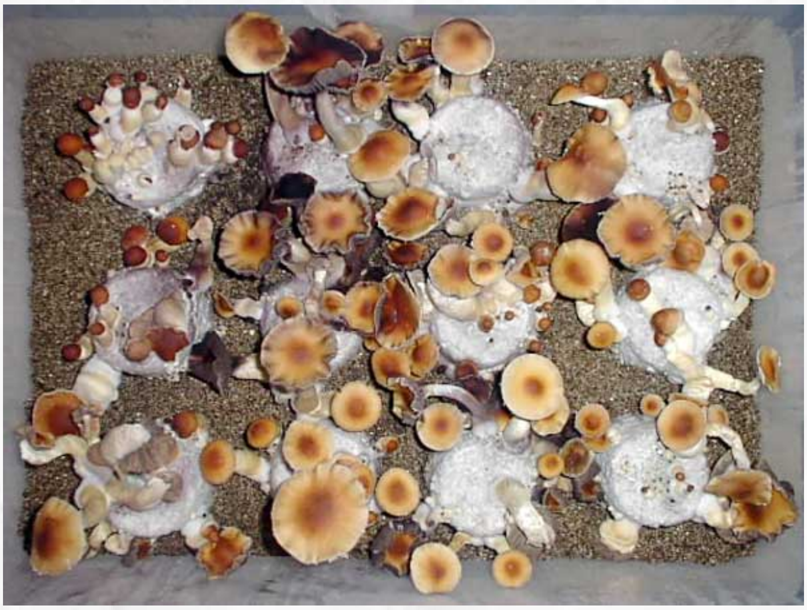
To do this is extremely easy. Everything is done standard PF TEK and when the substrate is loaded into the jar, use the end of a pen (a "sharpie" ink pen is perfect) and insert it into the middle of the substrate and make a hole all the way to the bottom. Any rod no more than 1/2 inch around is good for making the hole. A proper sized wooden dowel can be bought at any hardware store for cheap. If the substrate collapses around the hole or if the hole doesn't keep its shape, that means the substrate is to dry. Properly wet substrate works easy and the hole does not collapse.

Fill the jar with dry verm, proceed as usual and inoculate as usual. When the cake is birthed, inject 10cc of sterile water into the inner reservoir through the top (previously the bottom of the cake invitro).

This is more proof, that casing PF style cakes is not what makes a great PF style fruiting, but the water that is made available to the mycelium. Many beginner cultivators that experience great success with casing cakes, usually credit the casing mixture. But here is a fruiting that equals any cased cake, without a casing. It is the water that does it in conjunction with the potent fruiting potential of PF substrate.



PF classic with inner reservoir tek



PF classic inner reservoir tek cakes on soaked vermiculite bed.

Treasure Coast shrooms - PF style with inner reservoir tek. The cakes are sitting on moist regular potting soil (peat moss - perlite and vermiculite mixtures).

This is PF's first attempt with the inner resevoir using the Hawaiian spore race shroom.

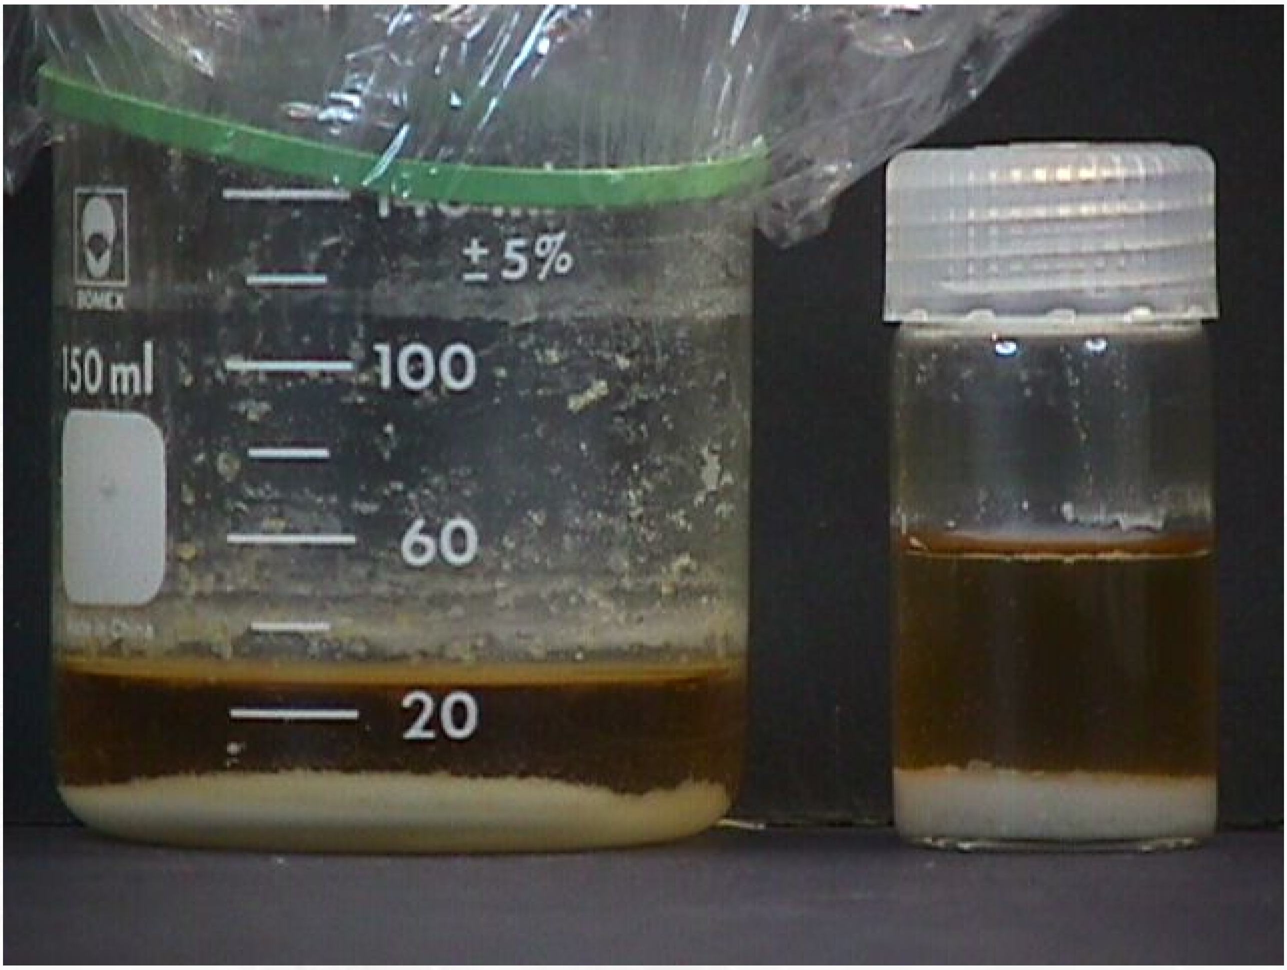
CHAPTER 10 - CRYSTALS OF THE GODS

original source: http://www.fanaticus.com/mycoalki.htm

The following alcohol extraction tek is what I consider to be almost the greatest discovery in the history of the religious use of the ancient entheogens. In all the records and reports around the world of the use of natural plant entheogens, there is a universal truth. And that truth is that the plant entheogens demand a serious price to pay for them to show their wonders, and that price is a very bad stomach reaction. Usually, vomiting is a part of the experience. And that is because one has to take a lot of the plant material to get the entheogenic power therein. But this tek has changed all of that. Now, the easy to grow little mushroom - psilocybe cubensis is now the king of the entheogens. This mushroom is acknowledged as one of the "weak" entheogens". But not any more. It is now the most powerful of them all, put together. So when one adds this tek to the PF TEK, the pinnacle of entheogenic life and experience is effortlessly in the hands of all.

PF Magic Mushroom Liqueur Tek - Crystals of the Gods



Crystalline extract precipitated in 190 proof alcohol "EVERCLEAR"
Left beaker - extract from 16 grams dried shrooms
Right tube - extract from 9 grams fungi

MAGIC LIQUEUR - the ultimate trip - update

Many years ago PF experimented with alcohol extraction of dried magic shroom material. To make the story short, PF found the crystals. But, PF didn't mention that when PF wrote the PF mushroom extraction tek and published it in the PF TEK book (1996) and posted it at this web site.

PF has monitored the WEB for all of these years and has seen no posts concerning this amazingly easy way to extract and seriously concentrate the shrooms magic. PF has always said that this extraction tek solves the "problems" of impotent or mediocre magic shrooms.

Then, finally, this post appeared on the WEB at an interactive myco hobbyist web site:

Excerpts from forums

SEARCHER

By Searcher (Novice) on Saturday, November 16, 2002 - 06:29 pm: Edit
My most exciting piece of beginner's luck came when I got rid of some cakes that seemed stalled in their development (and/or had really uneven surface colonization) by splitting up and drying the mycelium for use in place of mushroom dust to create the liqueur described in the following link:
http://www.fanaticus.com/liqueu~1.htm
By letting the resulting liqueur continue to dry out, I wound up with amber colored crystals that could be crushed and placed in gel caps. A few hundred milligrams of this extract sent a curious friend of mine into orbit, and now he's been bugging the shit out of me to butcher ALL of my cakes to concentrate on this extract and forget about trying to grow shrooms. He claims the trips he got were much "cleaner" (whatever that means) and that the stuff certainly tastes better than the shrooms themselves.

By Searcher (Novice) on Monday, November 18, 2002 - 05:05 am: Edit
As I recall, there were about 6 or 7 jars that seemed to have good mycelial development, but colonization was very uneven, or so slow, that I abandoned them to put better jars in my grow chamber. Rather than just tossing out the slow jars, I decided to break them up and try Prof. PF's extraction technique. By the way, the alcohol seemed to absorb a lot of water from the air - it no longer smelled of alcohol, and the drying process slowed down a lot just before the amber tar and then the crystals appeared. I used no heat, but kept a large fan blowing on the liquid over a large, shallow cookie sheet.

By Searcher (Novice) on Tuesday, November 26, 2002 - 12:53 pm: Edit
Behold, cystals - little white snowflakes - just using 99% isopropyl---
----

By Searcher (Novice) on Sunday, December 08, 2002 - 02:55 pm: Edit
Here are the results from my first methanol soak:
Yielded 3.85 grams of crystals from 8 ounces of mycelium. But wait, there's more! Remember we're doing three, consecutive soaks. Looks like we'll be getting even more residues out of soaks 2 & 3:
Miscellaneous notes on the methanol: You'll note that this residue us lighter in color than residue gleaned from the water soaks. Also, this residue comes out dryer - no intermediate "tar" stage.

When the Professor instigated dialogue about SEARCHERS enthusiastic posts above, others joined in and found SEARCHER to be on the money. And here they are.

By Techno-hippie (Technohippie) on Sunday, December 22, 2002 - 04:58 pm: Edit
I tested my 20g dried shroom, 24cc Solution. AWESOME is all i got to say I had one of the BEST trips ever. We started with 1cc each and started feeling the effects almost immediately. Within 10min we where having the

full level 1 experience. We decided to take another CC, Took us to level 2.... Within 10 min. By this time it was hard to keep track of time. But we did 1 more CC and that was all we needed.
NO unpleasent side effects... No upset stomach, or dizziness... nothing negative. It was VERY euphoric, very clear. We were tripping hard, yet we could think very clearly. Couldn't always speak clearly but the thoughts were profound and clear. The visuals where awesome.... everything was so alive and beautiful. The moon was full... so that made for a magical evening.
The greatest thing about the extract was the control we had over the dosage. Each dosage was equal with magic content. Unlike when you eat the shrooms themselves where the magical content will be different from shroom to shroom. So, dosage isn't quite as accurate. I've split a bag of shrooms with a friend before and got off way more than he did... on the same shrooms. With the extract we both knew we were getting the same amount.
I've had tea, chocolate shrooms, cooked with magic.. even psychedelic coffee, and this is by far the best method of consumption. I will be testing how long the extract lasts in potency.
I had this in the freezer for a week... and it was still very potent.
Anyway guys... there is my experience with the liquid. Freakin awesome!
Thank you PROF and Searcher for bringing that tech. out to us. I've never heard of liquid shrooms until now! WOW!
I'll post my other experiments with this in time.
Peace & Light to all!!
Techno-Hippie

By J. Clay Mcwilliams (Jclaymcw) on Monday, December 23, 2002 - 09:50 pm: Edit
I've done the extract, and yeah the trip is different. I felt happier on the extract. No bad side effects. It didn't come on that quick though it was just a little faster than a regular trip and the peak was hard to determine. my friends who have side effects like stomach discomfort, headaches and bellybutton discomfort said that they had none of the usual side effects. It was everclear evaporated down to 3 grms per 8 cc.

By Techno-hippie (Technohippie) on Monday, December 23, 2002 - 11:41 pm: Edit
Looks like we got a winner here. Last night I tested the extract on some VERY willing friends of mine and they had the same experiences. One of them gets BAD stomach cramps and usually the shits when he eats shrooms or drinks tea... but with the extract he had nothing to report but pure bliss! They both had an amazing trip VERY similar to the one that I had and reported earlier. I think that for the serious tripper this extract could be the preferred method... I know it is becoming mine Take care all... Have a wonderful holiday, remember: the tree looks awesome with a pair of magic goggles!! Peace Techno-hippie
----

By Searcher (Novice) on Sunday, December 22, 2002 - 07:46 am: Edit
Almost any liquid will extract something from the shrooms themselves or the mycelium. Even water will work, producing a brown syrup that can be dried into a sticky tar. Only the acetone was a bust in extracting the magic - but it does extract some other crud that might make it a good pre-wash for more serious extraction's. Recapping the results of the tests using other spirits, 99% isopropyl, 151 proof ethyl alcohol, and 99.9% methanol - methanol was the hands down winner for getting the crystals. Once the pretty white crystals have dried, they can be re-dissolved in grain alcohol for a potent elixir. The crystals tend to absorb water from the air unless they are kept in a heavily desiccated chamber.

By Roo (Tehuti) Posted on Saturday, May 22, 2004 - 11:30 pm:
has anyone tried soaking shrooms in alcohol to get the goodies out of them? PF used to have a great Tek on his site regarding this. I have done it, and it works wonderfully. Its a very clean trip.

By roger rabbit (Skyypilot) Posted on Sunday, May 23, 2004 - 07:53 am:
Agreed, the liquor is the way to go. I like to stop the process just before crystals form, as it's easier to measure for dosing. When I notice the solids begin to separate from the everclear, add just a bit more everclear and heat the mixture to dissolve the solids back in. This seems to give the most potent, measurable dose, and it's

dependable. 1cc of the liquid seems to match 2g of dried product. The best thing is NO stomach upset.

By Solly the Printman (Soliver) Posted on Tuesday, June 08, 2004 - 10:18 pm:
Good stuff -
I followed a combination of PF's extraction and the guidelines I gleaned from Rog Rabbit -
Took one OZ shrooms (I used last year's batch of PR's - still VERY potent, but in need of consumption - I wouldn't be heartbroken if they were toasted, etc, due to my incompetence)
Ground up shrooms in the 'ol coffee grinder, Put them in a quart jar Added one PINT of everclear (Rog says 2 oz to a fifth is good, but I wanted to start with a smaller batch...)
I put it all together, shook, put on the counter, and shook it whenever I walked by. I meant to strain it all the next day, but it ended up sitting in there for about three weeks - I'd say I shook it an average of twice a day...
While it was sitting in there, about 1/4 of the everclear evaporated out of the jar - strange... musta been an air leak or something?
Anywho, yesterday I strained it through a metal strainer, then through a coffee filter, then through 2 coffee filters and ended up with about 250 ml of liquid.
Just for continuity's sake, I added a few ml's of everclear to make it an even 280...
so now 10 mls of fluid = 1 gram dry ...
tried 10mls in some grape juice yesterday, clean trip, no tummy problems (yeah!!) and a good time had by all (me, myself, and I).
If you haven't tried this, you should!!
(second post)
NO stomach upset, no weird ramp-up - it removes all the negatives of shrooms and leaves you with a wicked hit that blows your top off...
The first 15 ml was put into a small glass of cranberry juice and consumed. I went upstairs and got in the shower, as is my custom, and before I even had my hair washed it was coming on. By the time I was out, dry, and dressed, I was tripping my nads off - less than 15 minutes.
My wife and I agree that this stuff is almost too good - shrooms have a downside (for me) that keeps me in check - but the liquor takes that all away.
I don't think I'll ever chew a shroom or choke back a handful of stinky powder again - I'm soaking all my shrooms in liquor from here on out.
If you haven't tried this, I'd strongly suggest it.
I really understand why PF said that this is the most important drug discovery since the PF tek - he's right!
Sol

By Hippie3 (Admin) Posted on Wednesday, June 09, 2004 - 12:30 pm:

> *quote:*
> Would one have to use any more alcohol to extract if, say, one were using some 80 proof vodka rather than some 200 proof? Is absolutely all the magic extracted?
> no and yes. and it doesn't take more than a few minutes either. i've made my friends magic shots by soaking chopped freshies in whiskey 5 minutes or so then straining off the liquor into shot glasses, works every time.

How long does an extraction like this remain potent, and what is the best way to store it to retain potency ?
as for storage, adding some Vit C to the solution will help slow the breakdown. then the extract should be stored in cold dark airless conditions, like in an opaque bottle in the freezer. fill it nearly full to eliminate the air and then seal, should be good several weeks at least, depending on initial potency.

By The Lone Printman (Soliver) Posted on Friday, July 02, 2004 - 01:53 pm:
I dosed my own "elixir" last night yet again, and I can say that it's kick-ass... Of course, it's always good to start with potent fruits, but what your friend plans on doing sounds AOK to me - Pretty much the exact same thing I did except I let mine soak longer (I don't think it matters).
I took a double dose last night - woof! Good stuff, comes on within 10-15 minutes and peaks about an hour later. After a while, I swear I could see right through the table I was sitting at - seemed to cross the space-time

continuum (sp?) with my eyeballs...
I usually take my standard dose, then bump it 2 hrs later, but decided to hit it all at once last night - the effects were devastating - I was a puddle - it was awesome.
(ps -mine's been in the freezer for 2 months now with no loss of potency)

By ShedTheMonkey (Shedthemonkey) Posted on Sunday, October 03, 2004 - 04:33 pm:
My monkey's brother ground up 48 grams of dry mushies and put them in a quart jar, covered the mushies with 153 proof grain alcohol (best he can find in these parts) and put it in a double boiler situation. After a half hour of letting the alcohol boil (without letting the water boil), the whole mess was filtered with 5 micron filter paper in a Buchner filter system using a vacuum cleaner for the vacuum source. The liquid was put aside, and the dry filtrate was put back in the jar, covered with alcohol again and boiled for another half hour. Repeated filtration. Mixed the two extract liquids together.
The wife and I did a bioassay. She said her trip felt about equivalent to a 30 gram freshie trip. I felt about somewhere between 40 to 45 grams fresh. It was weird that from dry mushies that definitely have a distinct feel from fresh, the extract felt more like fresh and THERE WAS ABSOLUTELY NO TUMMY UPSET!! This was about the strongest dose I can take and not end up talking to the goddess at the peak.

SHEDS CRYSTALS from 153 proof

Warning on Alcohol Shroom Extraction

By Thoth (Dr_hyde) Posted on Wednesday, September 15, 2004 - 01:29 am:
I finished off the last few mils of my last extraction. There was a bit of sediment in the bottom of the bottle. I did not think nothing of it, and drank it expecting a 4 gram type trip.
I got more of a 20 or 30 gram trip. The sediment must have been almost pure magic. I have done 20 grams dried before and it was many times more intense than that. It was totally freaking insane. Actually quite interesting, but not something I hope to do again in a few years or so.
This was about 200g of dry material to everclear, the BIG bottle. Its been in the freezer for 4 months, gave most of it away, guess I got the best part.
Stranger yet no bad stomach at all. I had to force myself to purge.
It just wore me out, very tired.

The Crystals of the Gods

March 5, 2003

Psilocybe Mushroom Extractions

Dear Dr. Shulgin:
A friend of mine performed a Soxhlet extraction of 12 grams of powdered Psilocybe cubensis, using 95% ethanol. When the 60 mL of extract cooled to room temperature, many small transparent, colorless crystals had formed on the bottom of the container and did not redissolve on agitation. Do you know what these crystals are? -- Journeyman

Dear Journeyman:
There is a fascinating report in the literature that gives a quantitative measurement of the efficiency of extraction of both psilocybin and psilocin from the mushroom Psilocybe bohemica. The citation to the article is Kysilka, R. and Wurst, M., Planta Med. Vol. 56 pp. 327-328 (1990). These Czechoslovakian scientists studied the efficiency of both methanol and ethanol as solvents, each containing varying amounts of water. The results were, to me, both unexpected and most provocative.
The isolation of psilocybin seemed to be quite reasonable. This alkaloid is reasonably soluble in boiling water from which it can be nicely crystallized. It is less soluble in boiling methanol, and almost insoluble in boiling ethanol. And the extraction efficiency is optimum with methanol and almost as good with ethanol. With both, the less water present, the better. The compound is, after all, a perfect example of a zwitterion, the internal salt of a phosphoric acid and an amine base.
But the numbers with psilocin are strange. With aqueous ethanol, the optimum extraction was with a 70% ethanol concentration, and the extraction efficiency dropped almost to zero when there was no water present. But methanol was extremely inefficient regardless of the amount of water present in it. These researchers were apparently surprised by these findings, as they explored further and uncovered other clues. Time is a factor. Psilocin is extracted at a much slower rate than is psilocybin because it is contained intracellularly in the plant, and thus slower to be gotten out. They conclude that many of the low psilocin assays of mushrooms are due to this difficulty of getting the alkaloid out of the plant and into the extracting solvent. Using this information they determined that the levels of psilocybin and psilocin are substantially the same in Psilocybe bohemica, in conflict with the published literature values where very small amounts of psilocin were observed.
Efficient extraction apparently requires patience.
As to the identity of the crystals that were drifting around in the cooled Soxhlet receiver, from their being insoluble in ethanol, and white, and transparent, I would guess that you are seeing pure psilocybin.
-- Dr. Shulgin

GOTTLIEB

Then, after a little interaction at the web sites, PF found this extraction tek taken from a book by Adam Gottlieb at the EROWID web site.

THE PSILOCYBIN PRODUCERS GUIDE
by Adam Gottlieb 1976

Extraction
Crumble and pulverize the dried mycelial material and combine each 100 mg of this material with 10 ml of methanol. Place the flask in a hot water bath for four hours. Filter the liquids with suction through a filter paper in a buchner funnel with Celite to prevent clogging. Collect and save the filtrate liquids. Heat the slurry (the mush in the filter paper) two more times in methanol as before, filter, and accumulate the liquids of the three extraction's. To be certain that all of the alkaloids have been extracted do a small extraction with a portion of the used slurry and test with Keller's reagent (glacial acetic acid, ferrous chloride, and concentrated sulfuric acid). If there is a violet indication, alkaloids are still present and further extraction is in order.

In an open beaker evaporate the liquids to total dryness with a hot water bath or by applying a hair dryer. Be certain that all traces of methanol have been removed. The remaining residue should contain 25-50 percent psilocybin/psilocin mixture. Greater purification can be achieved, but would require other solvents and chromatography equipment and is hardly necessary.

Each 100 grams of dried mycelium should yield about 2 grams of extracted material. This should contain at least 500 mg of psilocybin/psilocin mixed or about fifty 10 mg doses. Theoretically psilocin should have the same effect upon the user as psilocybin. The only difference between the two is that the later has a phosphate bond which disappears immediately after assimilation in the body. In other words, in the body psilocybin turns into psilocin. Psilocybin is a fairly stable compound, but psilocin is very susceptible to oxidization. It is best to keep the extracted material in a dry air tight container under refrigeration. A sack of silica-gel can be placed in the container to capture any moisture that may enter.

Dosage
The standard dose of psilocybin or psilocin for a 150 lb person is a 6-20 mg dose. We will figure the average dose as 10 mg. The crude alkaloid extraction process given here yields a brownish crystalline powder that is at least 25 percent pure. Each mason jar should contain at least 50 grams of wet mycelium. After drying this would be about 5 grams of material. The crude material extracted from this should contain 25-30 mg of psilocybin/ psilocin or roughly 2-3 hits. This yield may very to some extent depending upon several factors. Many of these species contain less of these alkaloids than dose Psilocybe cubensis and the alkaloidal content of this species may very in different strains. Cultivation conditions have a lot to do with yield too. Higher temperatures (75 degrees F.) cause more rapid growth but lesser psilocybin content than do lower temperatures (70 degrees F.) One must test each new batch of extracted material to determine the proper distribution of dosages. Depending on the potency of the mycelia and how well the extraction was conducted the dose may range between 25 and 100 mg. Also bear in mind that the dose varies for different individuals.

STAMETS

Paul Stamets even mentions extraction in his 1996 book - "PSILOCYBIN MUSHROOMS of the WORLD". Quote - page 50-51 "Another method I have seen is to soak crushed mushrooms in 75+% ethanol. After two to three days, the roughage can be filtered, leaving a dark- blue elixir that can be decanted accordingly. For every fresh 5 grams of mushrooms, 25-30 milliliters of alcohol is recommended. Psilocybin and psilocin dissolve into this solvent, and the alcohol also acts as a preservative. I really don't have much experience with this technique, but have talked to people who say it is their preferred method. Some call this "blue juice."

Stamets tek is not very good for several reasons. He says to start with "fresh" shrooms. It is always the best way to first dry the material to be extracted. Water gets in the way of the solvent. "BLUE" is not good either. Bluing is evidence of the magic being broken down or compromised. I think it is the "fresh" material that does that. Dried material does not blue. Bluing is damage and occurs with bruising of the shroom flesh. Stamets again says on page 56 - "...the more the mushrooms are bruised (blued) the less potent they become."
But what is important about the Stamets quotes, is that he knows people that believe extraction is the superior way to go for the magic.

Mediocre Rating for Cubensis

The only criticism that has ever been directed towards the Psilcobye Cubensis specie is "On the psilometric scale of comparative potency, P.Cubensis gets a rating of "moderately potent," - P. Stamets. That is not the best. And it seems, that potency is the number one goal of all the seekers, accept the new cadre of shroom growers on the web that are more interested in the hobby of mushroom growing than any magic production.
This extraction technique is the answer to the serious seekers of the magic. What PF would recommend is to extract with easy to get liquor store 190 proof ethanol, and make magic shroom liqueurs and elixirs. The advantage of the liqueur is that it is a good way to preserve the magic crystals. Exposing magic crystals to the air is a quick way to breakdown. But in a freezer in an elixir of alcohol, the magic crystals can certainly last a lot longer. This way delivers potency far far beyond any natural magic shroom. When one considers the extract magic in doses of around .1 - .3 gram, no magic shroom can deliver that, unless extracted. So that puts the lowly Psilocybe Cubensis to the top, because of its one really great attribute - THE EASIEST TO GROW - by far.

This technique describes how to extract psilocybin from magic mushrooms with pure 190 proof ethyl alcohol and make a magic mushroom liqueur of concentrated psilocybin to effect a powerful psychedelic dose as potent as desired. The entire process involves only the shrooms and alcohol. The alcohol is untainted with chemicals and poisons because it can be easily acquired from a liquor store (United States) either over the counter (in some states) or with a special permit (most states - see end of article section - "procuring 190 proof ethyl alcohol from a liquor store").

Alcohol Extraction of the Magic Crystals

by Professor Fanaticus

Supply list:

1. Shrooms
2. 190 proof ethyl alcohol (GOLDEN GRAIN - EVERCLEAR ect)
3. Pyrex glass wide mouth slurry soaking vessel
4. Stove top boiling water pot (slurry vessel sits inside) "double boiler"
5. Funnel, and vacuum filtering set up or Dust-pollen masks
6. Small desk fan
7. Stirring tools - spatulas

Acquire quality psilocybe cubensis shrooms (harvested before or just as the veils open and cool dried with desiccant). The more shrooms used in the beginning, the more potent the concentration can be when finished. Use at least several grams of dried shroom material to make the process worthwhile and effective. The shrooms need to be thoroughly dry (rock hard) to allow pulverization. To pulverize the shrooms, put them into a small strong zip lock plastic bag (freezer bag), cover the bag with a magazine (for protection of the bag) and pound it with the rubber heel of a large shoe. Or, powder them in a small canister type coffee bean grinder.

In a heat resistant soaking vessel (Pyrex glass), combine the shroom powder with several times its volume with 190 proof Everclear (ethanol). This is the "slurry". Place the slurry steeping vessel in a pan of boiling water. Raising the slurry soaking vessel off the bottom of the hot water pan is a good idea for preventing serious sticking of the extracts. The slurry will start to boil. Turn the water boiling pan heat down and let the slurry simmer and steep for a few hours at a warm-hot temperature. Alcohol boils at a lower temperature than water. Watch the temperatures closely. Things can get totally out of hand and ruined very quickly without close attention paid. Stir the hot mixture periodically and often to keep things loose with no sticking.

After the hot steeping and while the slurry is still hot, filter it through filter paper. This is probably the most important part. A good filtration will be efficient and will keep most of the shroom material out, making for a clean extraction (clean of shrooms that is - but heavy on psilocybin). A small lab type vacuum pump powered bottle top filtering funnel with filter disk holder makes it all easy and fast, with little waste.

Collect and save the filtrate liquids. Heat the slurry (the mush in the filter paper) one or two more times with the 190 proof as before, filter, and accumulate the liquids of the extraction's. The photos at the top are of extraction's done twice.

If there is no vacuum filtering device at hand, inexpensive dust-pollen masks make good filters for the slurry. These are available at hardware, drug and paint stores. They are usually white or tan colored, fit over the nose and mouth and are held on to the face by a rubber band attached to the filter. Fashion the filter over the mouth of a drinking glass. Squeeze the filter and slurry to extract the alcohol. There are many details to deal with, but doing it once reveals them all. Experience is the best teacher. Store the extracted alcohol in a fresh bottle.

Evaporation and Concentration

Combine the filtered alcohol extracts into the Pyrex steeping vessel. Place a small electric fan near the vessel and point the air flow directly down into the vessel until the surface of the alcohol ripples. This will speed the evaporation and concentration. The process will take several hours. The more alcohol extract - the longer the evaporation time. As the alcohol evaporates and the level recedes down into the glass, wash the residue that adheres to the inside of the glass back into the solution. Any fumes that are generated will be harmless because the alcohol is a non poisonous drinkable spirit. Keep flames away from the solution - pure alcohol is very flammable.

One can also use heat to evaporate and concentrate the liqueur. Use a double boiler type of set up to heat and evaporate off the alcohol to concentrate the liqueur. At this point, with hot concentrated liqueur (no crystal precipitate) it is best to go immediately to the storage tek (see Dosage and Storage at the end).

The concentrated shroom liqueur will have a pungent mushroomy aroma (like fungi perfume). Also, a white crystalline kind of precipitate will form in the alcohol liqueur (see above photo) as it cools. Store it in small screw cap bottles or vials in the freezer. Alcohol doesn't freeze solid and will remain liquid.

Important Guidelines

1. Use warm-hot temps when steeping the initial slurry (shroom-alcohol). Use a double boiler for the slurry vessel. Avoid direct heat to the bottoms of the slurry soaking vessels. The extract has a tendency to bake on and stick very easily.
2. A good filter is a must. Lab quality filter paper helps for a cleaner extract (less shroom stuff). A small bottle top vacuum filtering funnel with a hand squeeze vacuum pump and fine slow flow filtering papers is perfect for this small extraction tek (look for the 47 millimeter filter sized set ups).
3. When filtering the slurry, do it while it is hot.
4. When heated in the initial slurry, the psilocybin alkaloid extracts are free base molecules. In the final liqueur on cool down, the free base molecules will coalesce and form crystals. It takes a day or two for the process to be complete. The less the final amount of liquid is, the easier it is for the free base psilocybin molecules to meet each other and coalesce into the whitish crystalline substance.
5. The crystalline extract can be completely dried by placing the liqueur container in front of a small fan to get most of the liquid out. To complete the drying, desiccant is recommended. Place the small vessel of liqueur into a larger jar with quality desiccant. It takes several days to complete drying. The final crystalline substance can be weighed, worked with and experimented with.
6. TEK personalization through experience is what happens to anyone trying this. Extracting plant material is an ancient art, and the ways are myriad.

Dosage and Storage

On cooling and with time, the free base psilocybin molecules coalesce in the liqueur and precipitate into a whitish crystalline extract which falls to the bottom of the storage vessel. The freebase Psilocybin molecules come together fast in the cool alcohol.

Storage and dosage prep is the same. If the liqueur has already precipitated the crystals, heat the final concentrated liqueur (for example - 20 grams of dried shrooms can be extracted to 50-100 milliliters alcohol) in its storage vessel in a pot of hot water. Boil the liqueur and stir and scrape deposits from the glass as the liqueur boils lightly. Alcohol boils at a lower temperature than water. Keep the storage vessel off the bottom of the boiling water pot. Direct heat is very bad for the liqueur, making it stick. As the liqueur boils, the crystals and extract will remelt with time. The large particles of the crystals can be crushed with a long needle probe to hurry up the process. When the crystals are dissolved, administer the magic liqueur while it is HOT. Using a syringe enables uniformity and accuracy of the dosages. Keep the liqueur stirred up to keep it uniform. The hot liqueur quickly becomes cloudy (precipitate) on slight cooling. A hot temperature of the liqueur with remelted crystals is important for accurate dosage administration.

While it is hot, dispense equal portions of the liqueur (10cc-20cc) into small storage jars with watertight caps. Each small jar is allowed to cool, the cap is put on and the jar is placed into the freezer for storage. Each jar is equivalent to an exact fraction of the original dry shroom weight so that dosage can be accurately controlled and determined.

When it is time to trip, the desired liqueur jars (with potency ratings) are removed from the freezer, allowed to warm to room temps, the lids taken off, a small fan is set up blowing air across the jars mouths and the liqueur is evaporated off to a manageable "hit" (variable alcohol). The small jars then become administration vessels where the entire contents (alcohol-water-crystalline extract) can easily be completely consumed.

Procuring 190 Proof Ethyl Alcohol (Everclear - Golden Grain et) From a Liquor Store

First, call a well stocked liquor store and ask if they have 190 proof ethyl alcohol. Full service liquor stores supply hospitals and laboratories with 190 - 200 proof ethyl alcohol. If a permit is needed, call the state liquor board (usually in the State Capital) and ask for an application to get an ethyl alcohol permit. The fee is 5 or 10 dollars. On the application will be a question asking what the use of the alcohol will be. Write what they more or less want to hear. State that the use of the alcohol will be for "non-toxic surface sterilizing plus herb extraction - preservation - tincture - and perfume making" (or something to that effect).

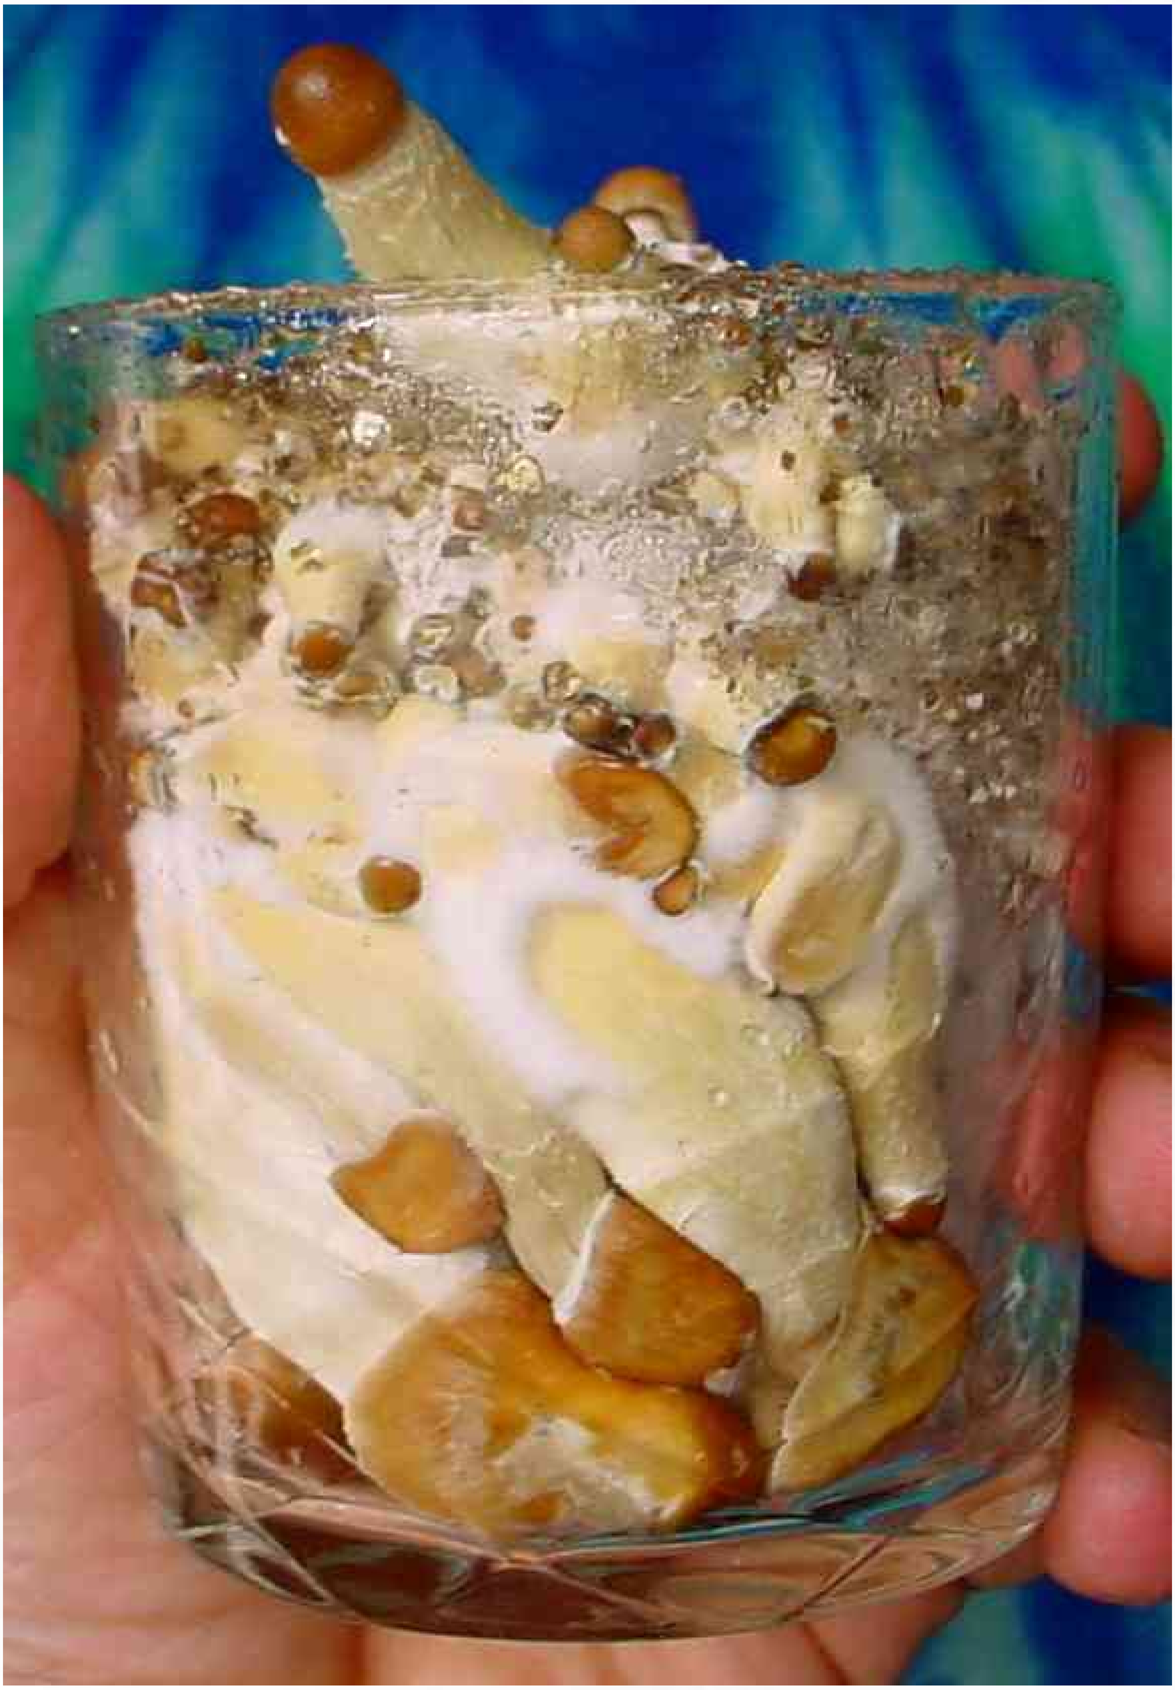
CHAPTER 11 - PF INVITRO TEK

original source: http://www.fanaticus.com/invitro.htm



This is a photo showing a cake grown in a glass jar that was allowed to fruit invitro. It is the standard PF TEK but with a little difference in the approach.

From the beginning (since 1991) of the essential PF TEK, PF has shown the importance of the appearance of primordia while the cake is still in the jar. Invitro "primordiation" is one of the fantastic attributes of the PF TEK. This invitro "primordiation" is not a feature of any other growing tek, but it is with the PF TEK.

Letting the primordia grow inside the jar (invitro) is a great way to grow these shrooms on the simplest level. Birthing is eliminated (accept for harvesting) and terrariums are eliminated. One of the really excellent attributes of PF INVITRO growing is what is being called "STEALTH". Stealthy growing is becoming very popular because one can hide the grow op. There was a posting on the net that someone did where he put the jars in an old dirty 5 gallon white bucket and on top of the jars, he placed old microphone cords and speaker cables, totally concealing them. An interesting thing he did, was that he birthed the cakes before they fruited or formed primordia invitro and cut them in half (1/4 pint sized cakes). He then filled the jar caps with vermiculite, soaked the vermiculite, placed the small cakes on the wet verm and placed the jar over the verm filled jar caps and cakes. He got a decent yield of quality shrooms, and he did it while they were all concealed in the white 5 gallon bucket and in the paranoid days we all live in, smart.

The Heartbreak of mega cultivation

When one is experienced in the different styles of shroom cultivation, a similarity of results is seen. A pile of dried and shriveled shrooms from a mega beautiful elaborately set up shroom cultivation, looks no different than a pile of dried and shriveled shrooms from a less than mega beautiful shroom cultivation. In other words, the beautiful full sized perfect looking specimens from a mega cultivation (trays - compost - ect), dry down and actually look no different than the little "ugly" convoluted shrooms from such a TEK as the PF invitro tek. The real difference is the emotional impact of "destroying" a shroom fruiting that one has worked on for a couple of months. When the shrooms begin to attain full size, there are two choices, either to pick them before they reach maturity (full size) for max quality, or to let them grow to maturity for spore printing. Whatever the case, the shrooms are doomed to be picked and then they aren't so pretty anymore, but become a pile of shriveled shrooms.

The real difference in this interpretation of the PF TEK and a mega cultivation (traditional teks) is that there is no "heartbreak" when harvesting the shrooms from a micro tek where the shrooms don't attain the magnificent stature of mega cultivation (traditional ways). When the shrooms appear inside the jar (PF invitro tek), it is easy to just take them and dry them. There is no "destroying" months of work or "ruining" a magnificent stand of shrooms before you get to even know them. There is only the harvesting of powerful psychedelic fungus, APPEARANCES BE DAMNED. That is really what the invitro PF TEK is all about. But then, if good looking specimens are desired, the PF TEK with a good casing procedure (PF double ended cake casing tek recommended) delivers the goods there also.

Dunking the Cake

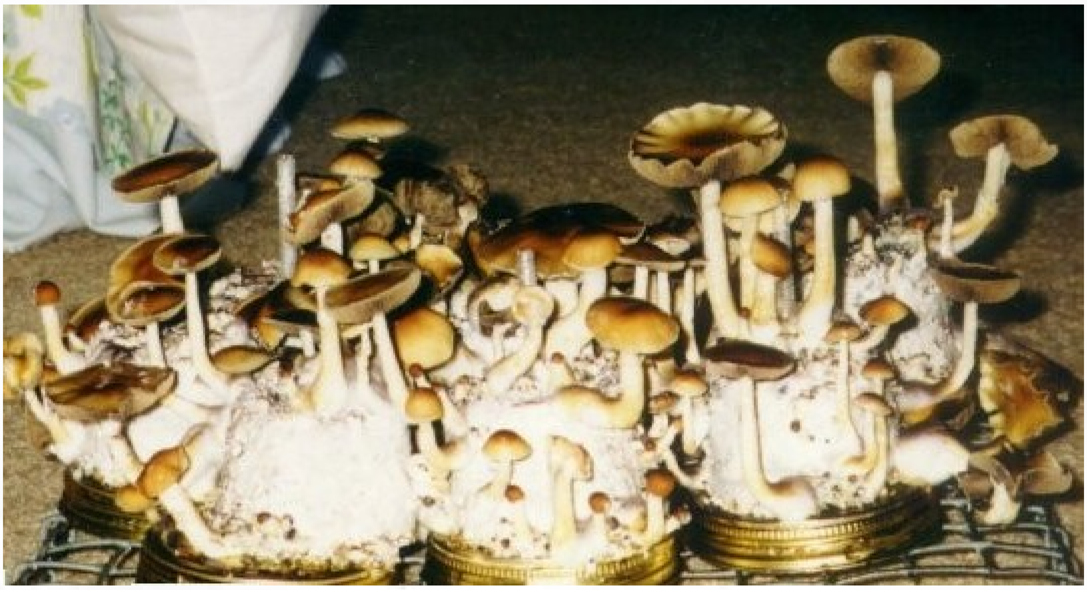
Another PF style grower added to the PF invitro style tek, and that is what is called "DUNKING". This is where the cake, after it is birthed and the invitro shrooms are harvested, is dunked in water for about a day or less. The cake will float and it has to be weighed down so that it goes under water all the way. The best way to do that, would be to take a cleaned cake (all shrooms and aborts harvested), fill the grow jar with water, put the cake in and put the lid on so that the excess water comes out. Let it sit for no longer than a day, and start the process over again by putting the dunked cake into a new jar for another flush. This can be repeated until the cake turns green with mold. Several flushes can be had this way and the yield can be about 6 dried grams total or more per invitro cake. This dunking technique is well established in the realm of growing normal shrooms. Shitake inoculated logs are routinely submerged in water to stimulate fruiting as well as other types of growing styles.

It is important to not let the shrooms grow to full size or even near full size invitro, but to take them before the caps TRY to open. Check the photo for what it can look like. It is not pretty, but the shrooms are of excellent quality and with good potency.

Table of Contents

CHAPTER 12 - THE DRINKING STRAW TEK

original source: http://www.fanaticus.com/7cakes.htm



This photo was sent to PF a few years ago and it was posted at the PF web site. It has also appeared at other web sites on the web. The sender was anonymous but I did know that the person used an ultrasonic humidifier with the straight PF TEK. This is an outstanding fruiting and I have never seen it bested. I have only seen this kind of fruiting at PF in large growing chambers with electric powered humidifiers in use.

Just recently I was notified about drinking straws being in the cakes. I looked harder, and there they were - drinking straws inserted into the cakes. (You can see one near the upper left coming out of a cake in the back) This is a TEK that has been going around the web for years, and even a good friend of mine said he did it and got great fruitings. I thought, great, but basically ignored it. What is done here, is that after the cake is birthed, an electric power drill is used and a clean hole is drilled into the cake in which the straw is inserted. And then during growth, water is injected into the straws which feeds into the cake, rehydrating it. That is why that fruiting is as good as it gets - casing or not, and only because of the pf substrates fruiting power and the growers water replenishment teks (humidifier and straws).

The number one element of any shroom fruiting is water availability. When the pf cake is birthed, the first thing that really starts to happen is moisture loss. That is because of the nature of vermiculite. Also, the fungi transpires plenty of water. So with two sources of water loss, evaporation and transpiration, cakes dry out. This reduces fruiting possibilites as it progresses.
So the answer is a way to input moisture to keep the cake fully LOADED with water as it gives off the water. It is clearly a kind of cycle - water in - water out - as the cake lives. It is apparant that many people are doing this various ways. Like--- burying the cakes in potting type soil mixtures. What this does is rehydrate the cake. Any type of moist soil like substance that can give off water can be used like this. It is a water feeding system. And that is exactly what the PF double ended cake casing tek is all about.

Here is a quote from the famous old cubensis growing book - "Psilocybin Magic Mushroom Growers Guide" by O.T.OSS & O.N. Oeric: page 49 - casing.

A variety of types of casing soils have been found to effectively promote fruiting. We have found the following mixture to be one of the best:

- 7.5 liters peat moss
- 3.5 liters fine vermiculite
- 4 liters washed fine sand
- 2 liters calcium carbonate (finely crushed oyster shell)

Powdered oyster shell is sold as a feed supplement by many feed companies. We have also found that a mixture of one part Mica-peat (50/50 vermiculite-peatmoss mixture) to one part potting soil will work, and even unadulterated rich garden loam has been found suitable, though its unsterile condition makes contamination a possibility.

There is room for further experimentation with other types of casing mixtures: one might try casing with finely granulated horse-dung or cow-dung, or a mixture of horse or cow dung and finely chopped wheat-straw. Casing with leaf-mold mulch might also effectively promote fruiting, and in fact might encourage the fruiting of smaller and more delicate species of psilocybe that do not seem able to fruit when the mixture given above is used. The object is to find a casing soil that is porous enough to allow air to reach the mycelium, and that at the same time is light enough to allow the young mushrooms to penetrate easily through the surface. Sterilization of casing soil is usually recommended but we found it unnecessary when relatively sterile commercially bagged materials were used.

This is the important sentence and idea of the Oss and Oeric info: "The object is to find a casing soil that is porous enough to allow air to reach the mycelium, and that at the same time is light enough to allow the young mushrooms to penetrate easily through the surface". And the purpose of it is to "effectively promote fruiting".
What does "effectively promote fruiting" mean or why does it happen? What is it about the casing procedures that "effectively promote fruiting"? What PF has found is it is not the casing the promotes fruiting, but the substrate. That is where the fruiting power is. The casing is a water input system. It allows the cake to take in water as it is outputed and replace the moisture that was lost, providing the cakes with plenty of water that encourages the fruiting.

The SECOND important factor to be reckoned with is the shroom races gestation period. The TC has a real slow poke of a gestation period. The reason the pf double ended cake casing tek with plain vermiculite works for that one, is just that the cake is kept fully "LOADED" with water while old slow poke decides to come out.
casing soils (peat verm ect)
wet vermiculite
wet perlite
intense humidification
Drinking straw teks

All these teks accomplish the same end - reloading the cake with moisture as it waits for the spore race to complete its gestation. And then when the shrooms begin to fruit, the fully water loaded cake can deliver the shrooms number one need - water. Water recharging is the purpose of all of these teks, and they accomplish more or less the same thing.

Psylocybe Fanaticus January 16 2000

CHAPTER 13 - DECONTAMINATION OF SPORE SOLUTIONS

original source: http://www.fanaticus.com/antibiot.htm

Antibiotic means "anti-life". But interestingly, fungi spores can withstand powerful doses of antibiotics while bacteria succumb easily. That is why "athletes foot" can't be cured with antibiotic creams. It could be that antibiotics come from fungi in particular. When a spore solution is made it can easily be contaminated with bacteria, the most common life form. We are surrounded by them. But with antibiotics, they are very susceptible, especially when in a solution of water and spores. The technique is quite simple. The Antibiotic is put into the spore solution where the bacteria are stopped in a variety of ways, either by cell wall destruction or protein synthesis inhibition, depending on what kind of antibiotic is used. I am no expert in antibiotics, but I know that antibiotics in concentrated form kills them dead, while leaving the fungi spores just fine. And over time, the fungi spores remain viable. And previously, it was bacteria contaminated (no spore germination - just a rotten smell and slime appeared).

But it is important to use the spore solution immediately. Over time, the cultures will still germinate and give a clean culture but you can tell something is not good. The culture is weak and it won't fruit, even though it is clean of bacteria. So use the decontaminated spore solution immediately and your results will work.

Step one: Acquire antibiotics. This is the easiest part. The best place to get a wide variety from Penicillin to Tetracycline is at your neighborhood pet store which has a good fish tank supply and of course, live fish for sale. In a particular section of the store, you can find rack fulls of a variety of antibiotics that are used for fish tank populations. They come in capsule form and are to be used directly into the fish tank water. But for our purposes, this won't work because these antibiotics are not sterile by any means. They are actually heavy with mold. Even Ampicillin you get from your doctor is heavily loaded with mold. The mold spores don't hurt you or the fish but they will destroy your attempt to culture fungi spores.

The antibiotics must be first sterilized before use in spore solutions. Heating the antibiotics is not the way, because it destroys the antibiotics. The antibiotics must be cold sterilized. This is accomplished by a very common micro biological technique ubiquitous throughout the Bio science lab world. The antibiotic is taken out of the capsule, placed into a small jar, about 10cc of water is added, the powder is mixed into solution, the solution is sucked up into a syringe and then finally, the antibiotic water is pushed through what is called a "SYRINGE FILTER". This is a small 25 mm round plastic device that sOcrews on the end of a standard leur lock syringe like the ones the Professor sells. These small round filters come individually packaged in what is called "blister packs" where they are sterile and ready to use. The antibiotic solution comes out of the syringe filter and it is sterile. The filter takes out anything bigger than .2 microns and that includes all spores, bacteria and viruses. The antibiotic molecules get through and are clean of all mold spores plus the bacteria that was in the water is dead already.

The antibiotics that I have used to great success are all available at the pet store fish tank section. Tetracycline is a powerful toxic antibiotic that colors the spore solution orange yellow. Kanamycin is a powerful antibiotic that is clear and does not show up in the spore solution. Neomycin is another clear antibiotic that has worked well. I think Tetracycline might be the best, but Kanamycin and Neomycin work just great. Penicillin is not near as good and usually fails. I have tried Streptomycin which fails half the time and gentimycin which is very weak, fails all the time. Gentimycin is an antibiotic that can withstand autoclaving and is used in agar agar (by such myco supply houses as Fungi Perfecti), but in comparison to Tetracycline, it is weak. In fact, a Doctor friend of mine says they don't use Gentimycin anymore. It's obsolete. I have used chlorpromazine and a few others, and I have found Tetracycline to be about the best, and it is always available at the fish tank store. Plus, it is the only one that colors the water yellow orange (not pretty) and it is the most expensive (less than $10 per pack of a dozen or so pills at the fish tank store).

The Tek

There are two sides of the equation. The first side is basically non sterile and the second side is sterile. In the first side, the antibiotic is put into non sterile water (distilled), which is sucked up into the syringe ready for injection through the syringe filter into the targeted spore solution. The second side is the clean side, which is the syringe filter itself, the needle if used and the spore solution (which is as clean as possible prior to the antibiotic treatment).

Supply list - non sterile side of the equation:

1. Tetracycline - Kanamycin - Neomycin capsules
2. 10 cc syringe
3. Distilled water
4. small mixing jar
5. mixing rod

Supply list - sterile side of the equation

1. 0.2 micron syringe filter (25 mm around) - available from science supply catalogs.
2. syringe needle (optional)
3. spore solution in jar (clean as possible

On the non sterile side, just start clean. All the contaminants will be taken out by the syringe filter. You needn't autoclave anything except the needle if it is used on the syringe filter in the injection of the sterile antibiotic fluid. First, open the antibiotic capsule, and empty the entire contents into a waiting small clean jar. With the non sterile syringe, inject 10cc of distilled water into the jar and with a rod mix the antibiotic until dissolved. It might not dissolve completely, but that is OK. The syringe filter will do the rest.

Suck the antibiotic water into the syringe. Leave about one cc of air in the syringe for good control of the outflow.

Now we go into the sterile zone. If you don't have your own spore print taken PF style according to the PF TEK, you will have to use a print gotten from somewhere. When this is the task, you must use an isolation hand box and using sterile equipment like a forceps (to handle the spore print) and a sterile exacto knife blade (to scrape the spores off the print) and a waiting sterile PF style jar with a little water in it (based on the syringe making tek in the PF TEK book). Many books already written describe how to do it, but they are all really the same. It is self evident how to do it. One just has to get the spores off the print and into a waiting sterile jar with water in it. The jar lid has already been fixed with the proper sized needle or access holes that are covered with good tape or tin foil.

Once that is done, have the jar with the hydrated spores ready. Follow the PF TEK on that (PF spore syringe making tek). Next, with the syringe loaded with the antibiotic solution (non sterile), peel off the back of the syringe filter "blister pack" (kind of like preparing a bandage). With the back peeled off, hold the syringe filter in the blister pack (by the sides) and screw on the syringe with the antibiotic solution and remove the filter from the blister pack holder. If a needle is to be fixed onto the syringe filter, remove the sterile needle from its tin foil and fix it to the syringe filter. Don't touch the needle tip, but you can handle the needle by the hub if you want to. Don't touch anything that the solution will come in contact with. Next, remove the tape covering the needle or access hole in the lid of the spore print jar, insert the tip of the syringe filter (or optional needle) into the hole in the lid of the spore solution jar and slowly but firmly press on the plunger. There will be a short pause while the solution begins to move through the filter, but then it will start dripping out the end of the syringe filter and into the waiting spore solution in the jar. The fluid will be a clear orange color (Tet) or clear (Kana or Neo). There will be no particles in the antibiotic fluid as it comes out of the syringe filter. Once you do this, this is actually fun to do and very easy.

When the antibiotic fluid is emptied out of the syringe, withdraw the syringe filter tip or needle, put some fresh tape on the lid hole, swirl the spore solution around a bit and put it safely on a shelf for a couple of days. Actually, once the antibiotic goes into the spore solution, the spore solution is ready to use, but to be sure, give it a couple of days of rest.

If the procedure is done correctly, and no mold contaminants are introduced during the procedure, the spore solution will be cured of bacteria.

To test the spore solution, inject a jar with an agar nutrient layer on the bottom or a slurry of brown rice powder. If the fungi appears a few days later and looks pure and clean, success is yours. But, there might be another problem, and that would be mold - green, blue etc.

If there is mold in your culture, it will be growing along with the pure white fungi mycelium, usually next to it. The next step is very easy. Go on to the PF micro peroxide brown rice cloning tek to clean up the mold through sub culturing with peroxide and on to the shrooms, PF style.

PF Peroxide and Brown Rice Cloning TEK

This photo is the PF albino mutant strain, cultivated PF style using the PF cloning tek (from anonymous experimenter).

The original idea comes from Rush Wayne's cultivation manual "GROWING MUSHROOMS WITH PEROXIDE". The following is a simplification of the idea down to the smallest degree, using brown rice powder, peroxidated water dilution's and small jars.

MATERIALS:

1. Small jars with lids
2. Brown rice powder
3. Regular store bought Hydrogen Peroxide (3%) antiseptic solution (usually in a brown bottle)
4. Dissection knife and long needle (exacto etc)
5. Living mushroom or fungus, or culture of fungus

If the previous antibiotic tek is used and there is mold growing along with the pure white good fungi, follow this tek using a small fragment of the desired fungi. The mold growing near the good fungi will shower it with spores, but this peroxide tek will usurp the contaminant spores and clean the good mycelium for further cultivation - PF style. This tek can be a follow up to the antibiotic tek, or can be used to clone a mushroom outright. Both purposes work just fine.

As a preliminary, start reasonable clean, but the following is to be done in the open air, without sterile implements or containers.

Mix the peroxide antiseptic and water at a 20% ratio. Example - 2cc peroxide and 8cc water. Place an amount of brown rice powder into the jar and add some of the peroxidated water to get a slurry, or very wet condition. The diluted peroxidated water sterilizes the medium. For extra experiments, you should try more potent peroxide contents in the brown rice peroxide slurry medium (30% - 40% - 50%). It is so easy, it can't hurt to experiment and you can benefit from it.

Tear the shroom apart and with an exacto knife, excise a small fragment about the size of a match head. With a long needle, knock or scrape the shroom fragment off the exacto blade and place the fragment on the surface of the peroxidated brown rice slurry. Or if you are using a culture of mycelium that may be contaminated with mold, cut out a small piece of the white mycelium with the exacto knife blade and do the same - scrape the fungi fragment of the blade onto the surface of the peroxidated brown rice slurry. If the culture grows back clean, that doesn't mean that it really is clean, because there will be contaminant spores in the mycelium (which is there anyway because of the open nature of this tek). When the culture is to be used PF style, when it is reslurried with fresh peroxide water, the contaminant mold spores and bacteria endospores will be killed while the growing fungi mycelium will survive to grow clean - PF style or any style you like.

Screw the lid tightly onto the peroxide slurry jar and put the jar in a warm place for growth. The culture can be opened and exposed for observation or experimentation without danger to the growing medium and culture.

Under magnification (10x), the fragment of mycelium appears to "melt". It also turns blue, as if it were killed. Within a few days, tiny white hair like tendrils (hyphae) will appear on the "melted blue" fungus. It will grow and fill the culture jar.

To use the culture for further inoculations, add 20% peroxidated water to the culture, mix the brown rice and fungus, and with a syringe, draw up water and inoculate PF jars, with the standard PF spore syringe technique. This is done nonsterily also because the peroxidated water will kill contaminant spores. But flame sterilize the needle before injecting into the sterile PF substrate. Instead of flaming the needle, an even better way to sterilize the needle (outside of the needle) is to wipe the needle with a tissue soaked with rubbing alcohol. Let the needle briefly dry of the alcohol before injecting. Use the culture well before it grows in. That way, it is much easier to get a usable slurry for the syringe without clogging.

As an addition, try more potent peroxidated water ratios. For instance, a 50% ratio works also. That would be half peroxide antiseptic and half water. Increase peroxide content until the mycelium doesn't survive. Then back off the amount of peroxide and use a near death peroxide load for guaranteed clean results. But a 20% peroxide to water ratio seems to be perfect.

If you are working with previously made plate or slurry cultures that have mold or bacteria slime growing along with the pure white good fungi, follow this tek using a small fragment of the desired fungi excised out of the culture. Make sure you don't have any growing mold or bacteria in the good mycelium because the peroxide won't kill it (as it doesn't kill the good fungi). If the culture grows back clean, that doesn't mean that it really is clean, because there will be contaminant spores in the mycelium (which is there anyway because of the open nature of this tek). When the culture is to be used PF style, when it is reslurried with fresh peroxide water, the contaminant mold spores and bacteria endospores will be killed while the growing fungi mycelium will survive to grow clean - PF style or any style you like.

TEK Problems

The only problem is syringe needle clogging. As a remedy, do not allow the culture to fully grow in or get thick. Keeping the culture "thin", allows a good breakdown of the mycelial fragments for use in a syringe. At first, doing the tek can be messy, but learning is quick and easy. Finding and using needles as big as possible is important.

But another route is very possible and actually preferable. Using long glass bulb pipettes are very good to use, but here, one must customize and "tweak" the teks a bit (one must be careful when injecting PF style jars with the bigger pipettes and not to breach the top vermiculite contaminant barrier). Also, flaming the glass pipettes can sometimes break the glass. In this case, always sterilize the outside of the pipette with the rubbing alcohol. Also, when releasing the bulb, it will inflow air. Do this inside the jar where the air is clean and protected by the vermiculite contaminant barrier. Or, after injecting, keep the bulb squeezed and withdraw it, and then refill it with fresh peroxidated mycelium for another injection, resterilize the outside of the pipette with rubbing alcohol, and inject, and so forth. When doing this, use small calculated amounts of mycelium slurry to keep from over doing it. Bulb pipettes are actually better to use than needles and syringes because they don't have much problem with clogging as compared to needles and syringes with mycelial slurries. But if the tek is followed closely and the cultures are not allowed to grow in and get thick, the 18 gauge needles with 10cc syringes work OK.

Principles of the Peroxide TEKS

Hydrogen Peroxide is a powerful antiseptic. The solution of Hydrogen Peroxide bought in a drug store is 3% Hydrogen Peroxide and 97% water. Even at this low concentration, and with further dilution's, the germ killing is potent. But that germ killing power only works for micro fungi spores and bacteria endospores. A micro-organism that has germinated into its secondary form (mycelium), is safe from the antiseptic power of diluted Hydrogen Peroxide. But the ungerminated spores, bacteria endospores, and microbes are all susceptible. If there is bacteria that is growing (germinated), it will not succumb to the peroxidated water (just as the fungi mycelium is not succumbing). Also, any mold that is growing will survive. A clean fragment of shroom flesh or mycelium from a mold contaminated culture has germs all over it, but only in the spore or endospore form. They won't germinate in the peroxidated medium and water or on the recovering mycelia.

The tek is like a tightrope act. The mycelium that is cultured in the peroxide enriched medium can survive and grow, but it is not clean. Any spores or bacteria that are "piggy-backing" on the mycelium and not in contact with the peroxidated medium can come to life if given the opportunity.

After the culture of mycelium grows, it can be rehydrated with more peroxidated water. The spores and bacteria endospores that are "piggy-backing" on the mycelium will die. The mycelium in its fully secondary form, will survive the new peroxidated solution, "cleaned".

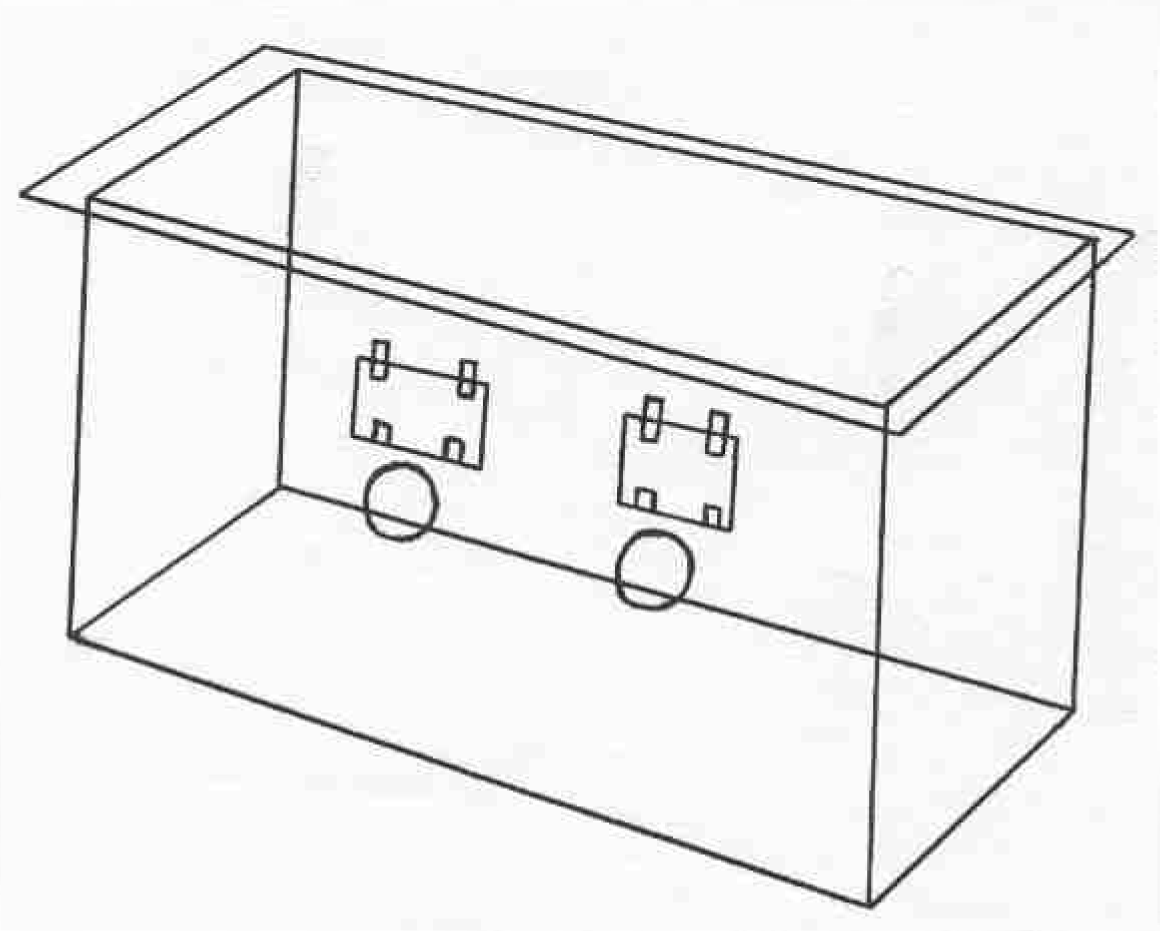
CHAPTER 14 - ISOLATION HAND BOX

original source: http://www.fanaticus.com/handbox.htm



Materials - plywood, plate glass and weather stripping. Be sure and make the box out of heavy enough wood so that it won't move excessively as you move your hands around. A little movement is OK.

This is the simplest design for a sterile air transferring hand box. It is four pieces of perfectly cut rectangular plywood, painted with a water resistant coating (preferably white enamel type paint). It has no top or bottom. The box sits on a flat table that serves as the work surface. A piece of plate glass (edged for safety!!) sits flat on top. The four panels of the box must be cut perfectly square so that when they are attached, the top and bottom of the box are flat and straight which insures draft free operation. The bottom of the box must sit squarely with the table with no leaks as well as the plate glass cover. If you want, you can line the top and bottom edges of the box with weather stripping for extra security against air drafts entering.

There are two round holes for your arms. When you cut the arm holes, determine your own particular movement needs (up, down, forward and sideways within the box) and place the arm holes to facilitate reaching and manipulating things. Cut the arm holes to size so that your arms (below the elbows) will close off and seal the holes to prevent contaminating air drafts from entering as you work. Cardboard squares are taped to the front of the box over the arm holes in order to cover the holes when the sterile spray is used to sterilize the interior air (shown in up position - undo the upper pieces of tape and the covers flip down).

How to Use the Isolation Box

Number one rule: Any surfaces or utensil's to be used in direct contact with the fungus are to be first covered or protected against the sterilant. You can cover closed dishes and jars with cut pieces of acrylic plastic.

To use the box, first place the things you will be working with into the box. Any surfaces or utensils to be used in direct contact with the fungus are to be covered or protected from the sterilizing spray. You can cover petrie dishes and jars with cut pieces of acrylic plastic for extra protection if you want and then remove the covers when you want to work. Tape the cardboard squares to the front of the box to cover the arm holes which will prevent air from entering the box during sterilization.

Slightly lift the glass plate cover and spray the interior of the box with 10% laundry bleach and 90% water or some kind of Lysol spray, or for the max killing power, you can use rubbing alcohol in a spray bottle. Let the spray vapors settle a minute or two. You don't need gloves, just wash your hands and arms. Remove the tape from the bottoms of the cardboard hole covers, lift or remove cardboard hole covers and with a MINIMUM of air disturbance or draft creation, insert your hands.
Sterile jars full of media can be opened and transferred without fear of contamination. Scalpels and dissection implements can be taken into the just sterilized (sprayed) box in your hands as you insert your hands through the access holes.

Don't seal any containers after working on them in the chamber. This allows whatever chlorine gas, alcohol vapors, ect, that has gotten into the jar or dish to naturally dissipate with normal gas exchange. To accomplish this, just slightly loosen the jar lids. They can be left in the box for added protection while they are exchanging any vaporous gas with good air. After a few days, then the jars and containers can be sealed for later use.

To be sure, things can be awkward, but with a good air tight box, you can knock things around and be sloppy and still have no contamination. That is why there is no bottom to the box. After working in the box, there will be strewn all over the bottom (table top), bits of agar, fungus, grain kernels or whatever might drop off of your scalpel, spoon, fork or knife ect. With no bottom, just take off the glass plate top, lift off the box and clean the table.

You can customize the box any way your creativity allows. For instance, you can rig up little hooks and dowel hangers and nails inside the box in proximity to your hands (reach) so that you can have a safe spot to hang your dissection tools as you work (away from toxic chemical droplets of the sterilant).
The Professor has used this type of box for many years before he got a HEPA filter blower. The Professor's very first cultivation employed an old 20 gallon aquarium with a Plexiglas cover (fits in the top of the aquarium) with two arm holes. It worked great the first attempt. Then the aquarium got broke and the Professor made a big box like the one pictured above out of heavy weight particle board. It also worked great. Then the third one was made out of lightweight plywood painted with white bathroom enamel (easy to tote around the house) and that one served the Professor for years. Then the Professor got into the HEPA filter blower (high tech). But, for hobbyists, the hand box design works as well and a lot cheaper and basically fool proof (low tech) but the disadvantage is that it can be awkward, but it has its good points to be sure.

CHAPTER 15 - PF SUBSTRATE FORMULA'S BIOLOGICAL EFFICIENCY

original source: http://www.fanaticus.com/ripsnort.htm

Photo and text from RipSnort
These are Treasure Coast spores from PF. I took a fully colonized cake, cut it in to 4 equal parts, and then cased the broken up cake quarters. Each one of thoes pans only has 1/4th of a cake in them.

Biological Efficiency (from Fungi Perfecti Catalog)

Biological Efficiency is a term frequently used in the mushroom industry to describe yield potentials of mushrooms from various agricultural by-products (straw, sawdust, sugar cane bagasse, banana fonds and coffee plant wastes, to name a few). This formula was first developed by the Button mushroom (Agaricus) industry.

Simply put, a yield of 1 lb. of fresh mushrooms from 1 lb. of dry substrate is considered to be 100% Biological Efficiency. Since mushrooms are approximately 90% water and the base substrate is typically raised to 75% moisture, 100% Biological Efficiency is equivalent to saying that 25% of the wet mass of the substrate is converted into fresh mushrooms.

Although such yield efficiencies are commonly achieved by experienced growers, many choose not to "chase the optimum", as their growing rooms can be better utilized by cycling in fresher material.

PF's comments

With some simple math and a little analysis, it can be readily seen that PF substrate is well over 100% "Biological Efficiency". RipSnort reports that his Treasure Coast shroom fruiting was had by quartering a PF cake and using the 4 pieces in seperate containers in which the quartered pieces were cased. This means that each fruiting tray above contains about 1/16 of a cup of brown rice powder and about twice as much vermiculite, plus the casing.

In a normal PF 1/2 pint cake, there is about 31 grams of brown rice powder (1/4 cup) and about 17-20 grams of vermiculite (1/2 - 2/3 cup) which adds up to about 50 grams dry weight. It can be conservatively stated that a properly cultivated PF 1/2 pint cake can produce (with several flushes) at least 10 grams of dry shrooms (100 grams wet weight). By using the above biological efficiency formula - this equals an easy 200% biological efficiency for that 1/2 pint PF cake (50 grams of dry substrate producing 100 grams of wet shrooms is twice efficiency - the wet shroom weight is twice the weight of the dry substrate, or in other words - 200%).

This amazing ability of cubensis shroom races to fruit on PF substrate has made the PF TEK the new fundamental of cubensis shroom cultivation. The PF TEK can be used straight PF style (mini culture) to get great fruitings of diverse cubensis races, or can be utilized in more mega style cultivations with trays or larger containers with more massive substrate amounts (compared to PF style Mini culture). What is being demonstrated at various mycophile web sites is PF substrate being mixed with various grains, soils and substrates with impressive fruitings on display. A certain percentage of PF substrate with any kind of cubie substrate results in big fruitings. AND, when PF substrate is used in these mega cultivation teks without the additional grain, fruitings are just as good, if not better. The RipSnort Treasure coasts are proof of the magic of the PF formula (brown rice powder and vermiculite).

The Discovery of the PF magic formula

Many years ago, PF grew cubies on many substrates and found brown rice to be the best grain for fruiting. The problems associated with using brown rice was that it was sticky when cooked up and unshakeable in quart style spawn jars. This creates many problems which thwarts the fruiting power of brown rice. In 1978, Dr Stephen Pollock published his book "Magic Mushroom Cultivation" and it featured a brown rice cake method using quart jars and growing the shrooms inside the jar. This tek has many flaws but had great potential.

Then in late October 1981, PF attended the Paul Stamets and Jeff Chilton Myco Media shroom conference at Orcas Island Washington. During a Stamets lecture, Stamets mentioned mixing vermiculite or perlite into grain substrates to get a better and easier shakeability. It was like a lighting bolt that hit PF, as he busily scribbled down some notes about this substrate mixing concept.

PF went home and began a series of experiments combining these two ideas (Pollocks rice cakes and Stamets vermiculite mixtures) which resulted in the PF TEK magic substrate formula, which has become the new fundamental magic mushroom growing and culturing medium.

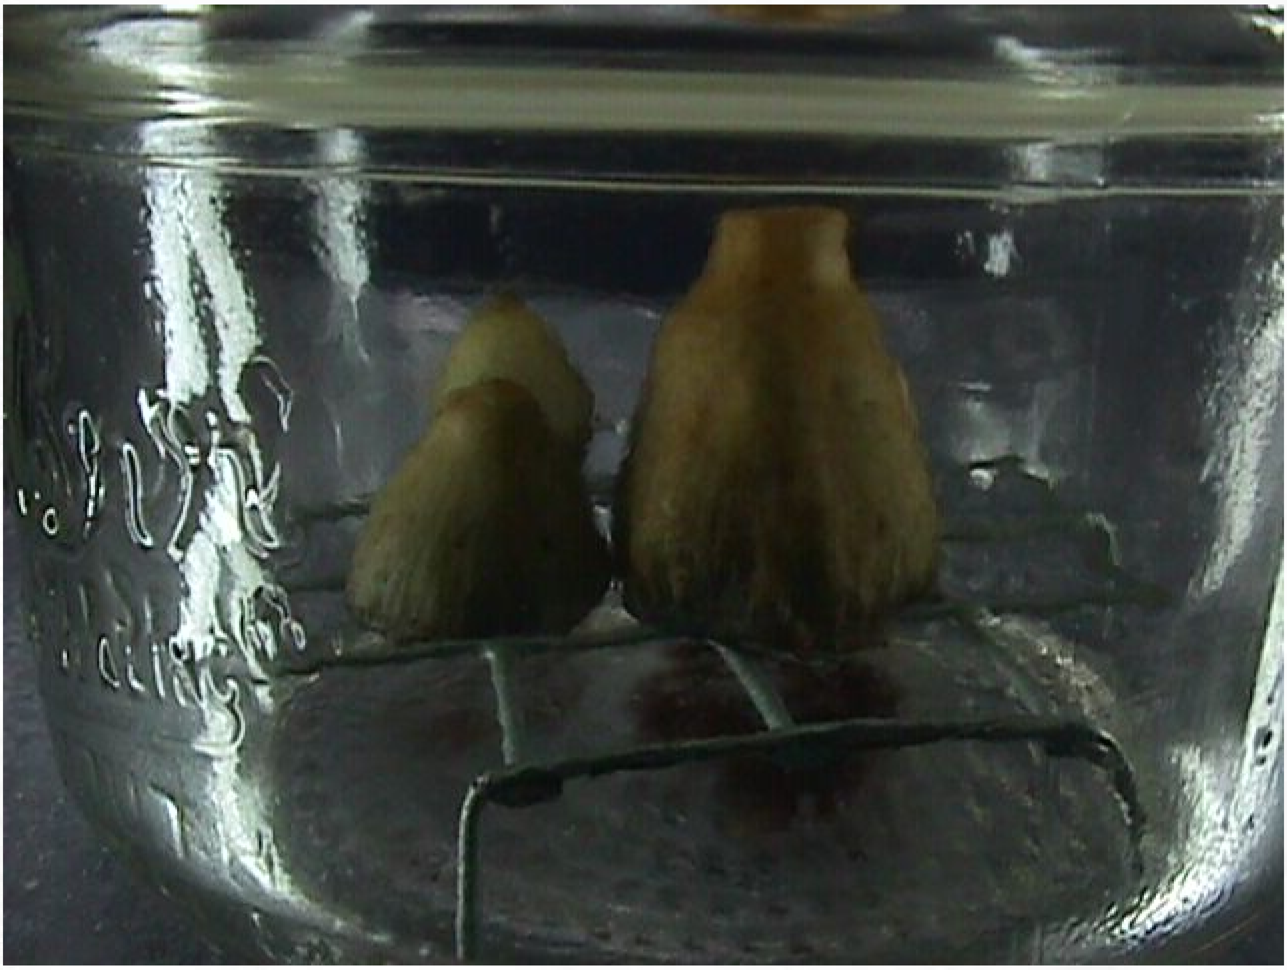
CHAPTER 16 - SPORE PRINTING IDEAS

original source: http://www.fanaticus.com/sporejar.htm



These are caps of psilocybe semilanceata (collected in the Olympic Rain Forest) in a 1/2 pint wide mouth canning jar.

The caps are resting on 1/2 inch galvanized wire screen. The 1/2 inch is related to the distance between the wire. The wire screen was cut up and fashioned into a screen support by cutting it with a wire cutter pliars and bending it into shape. The caps are above the glass surface which makes for a cleaner spore print (although printing directly on glass apparantly works as well).

The glass jar and wire support are presterilized in a pressure canner. Jars like this can also use the white sterile filter disks as lids held on by the canning jar lid bands. These are available from Fungi Perfecti in Shelton Washington. To find them on the web - just do a search with FUNGI PERFECTI.

CHAPTER 17 - MAJOR PF TEK SNAFUS FOR THE NEWBIE

original source: http://www.fanaticus.com/pitfall.htm

Water inflitration of the jars during sterilzation

There have been many isolated posts concerning delayed or stopped colonization. This seems to always concern the lower half of the jar. The simple explanation is water infiltration into the substrate during steaming.

This happens two ways. The first is that there is to much water in the pot and the boiling water can slosh into the jars. Then the water builds up in the lower part of the jar and the soaked substrate will not colonize correctly (or not at all - and stall) The second way is water dripping from the top of the pot down onto the jars. If you use regular canning lids, these do not seal the jar and water dripping down can go into the jars.

In the first incident - use a safe amount of water so that sloshing into jars doesn't happen.

In the second incident - cover the lids with tin foil to ward off dripping water.

Premature cake birth

Observe the photo of the in vitro primordiation in the PF TEK photo files. This photo is all you need to time the whole thing. Primordia appearing in the jar usually starts around the begining of the 3rd week after spore inoculation. But don't stop here. When you see the new primordia appearing, delay birth. Doing that influences more primordia to form. After about 3 to 4 days, birth the cake. The initial flush will be highly influenced by how primordia form in vitro.

Newbie humidifier uncertainty

The usuall case here is inexperience. Humidity is invisisble and humidifiers do almost to good of a job of humidification. The rule here is to avoid humidifiers when you are a PF TEK newbie. The pf tek does not need the extreme high humidities that you might think these shrooms need. A small terrarium will produce excellently - equaling electronic humidification (and that is no matter what the humidifier fans say). But of course, if you want to do the humidifier technique, the humidifier tek in the PF TEK photo files is the best because it is the cheapest and simplest and there is no sacrifice in effectiveness. Cool sprays are under $20 - available in the baby care section of a decent drug store and easy to rig up.

Improper water content in the jars

To determine the best water content, When you first do the pf tek, make a batch of jars with the same substrate amounts but variate the water, take notes, observe and go with what works best.

Pint jars verses 1/2 pint jars

When I first published the PF tek papers in 1991, I included a Pint jar pf tek chapter. And of course it was eagerly copied (a few years later) by the MMGG author as if it was the cats meow (because I had dropped it from the pf tek papers already).
In the beginning, All the subsequent letters from the myco customers with problems had to do with the pint jar. It was causing lots of trouble. 1/2 pints seemed immune to problems.

I already knew of the pint "trouble". So I dropped the tek. The "trouble" was "premature" fruiting (like thats bad?). What would happen, is that Pint sized cakes would commonly have the tendancy to begin putting out primordia and screaming to be released from in vitro BEFORE complete colonization of the cake, mainly caused by not enough spore solution delivered all around making for an uneven colonization.
So there you would have a tear jerking disaster on your hands; primordia all dressed up with no place to go. Because, birthing the cake would expose the exposed uncolonized cake surface (which sometimes is about half the surface) and you will not only have shrooms growing, but plenty of contamination (hence the absolutely ingenious MMGG technique of branding the cake.)

What is causing this is that the vermiculite in the mixture is the fruiting catalyst which stimulates fruiting whether the food is used up or not. The fruiting is clearly related to a food threshold and nothing to do with CO2 or oxygen - temperatures ect. And this is Because these primordia will appear just the same in a jar in which the lid has been on tight since the get go. (NO OXYGEN) strange but true.
To see the truth of this in demonstration: Try a pint jar of plain pre cooked (quite wet and soft is the way) brown rice in comparison to an equal pint jar of pf substrate mixture. (you don't have to go to the trouble to do this, but read on and trust PF)

When a pint of plain rice is colonized, and left to sit in vitro, Primordia will not appear and then the jar starts to yellow - die ect. The neglected pint jar of pf substrate will put forth plenty of primordia hot to get it on while in vitro. It is like two completely different substrate mediums but basically it is brown rice.
In these two examples is clearly shown what the pf tek is all about. The vermiculite is the catalyst for fruiting - similar to casing grain (but without the casing tek) - sort of an internal automatic casing.
That is why all of this stuff about casing pf cakes to make them work the best is from people that have no idea about the pf tek and its inner workings.

CHAPTER 18 - PF ALBINO MUTANT

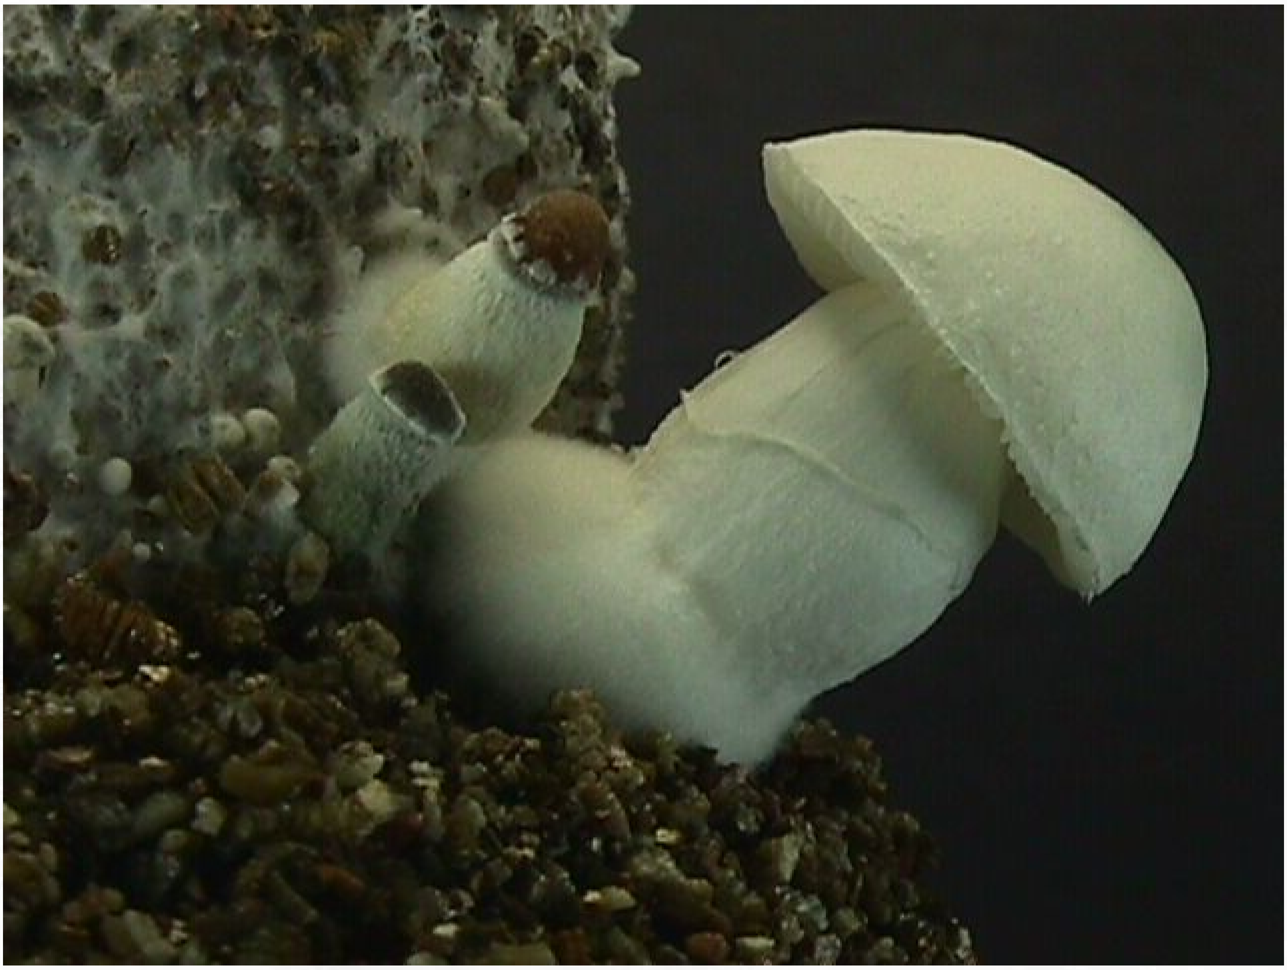
original source: http://www.fanaticus.com/albino.htm

ALBINO definition (Websters new world dictionary)
2. any animal or plant abnormally lacking in color

I once used a flourescent blacklight to grow PF strain shrooms. It seemingly worked as good as regular plant aquarium style flourescent lights. But something terrible happened as a result. The PF shrooms started to sprout out little white mushrooms without spores. Also along with the pure white sporeless mushrooms, normal looking PF's grew along with PF's that appeared to be part normal with albinoism traits (white patches and diminished sporulation).

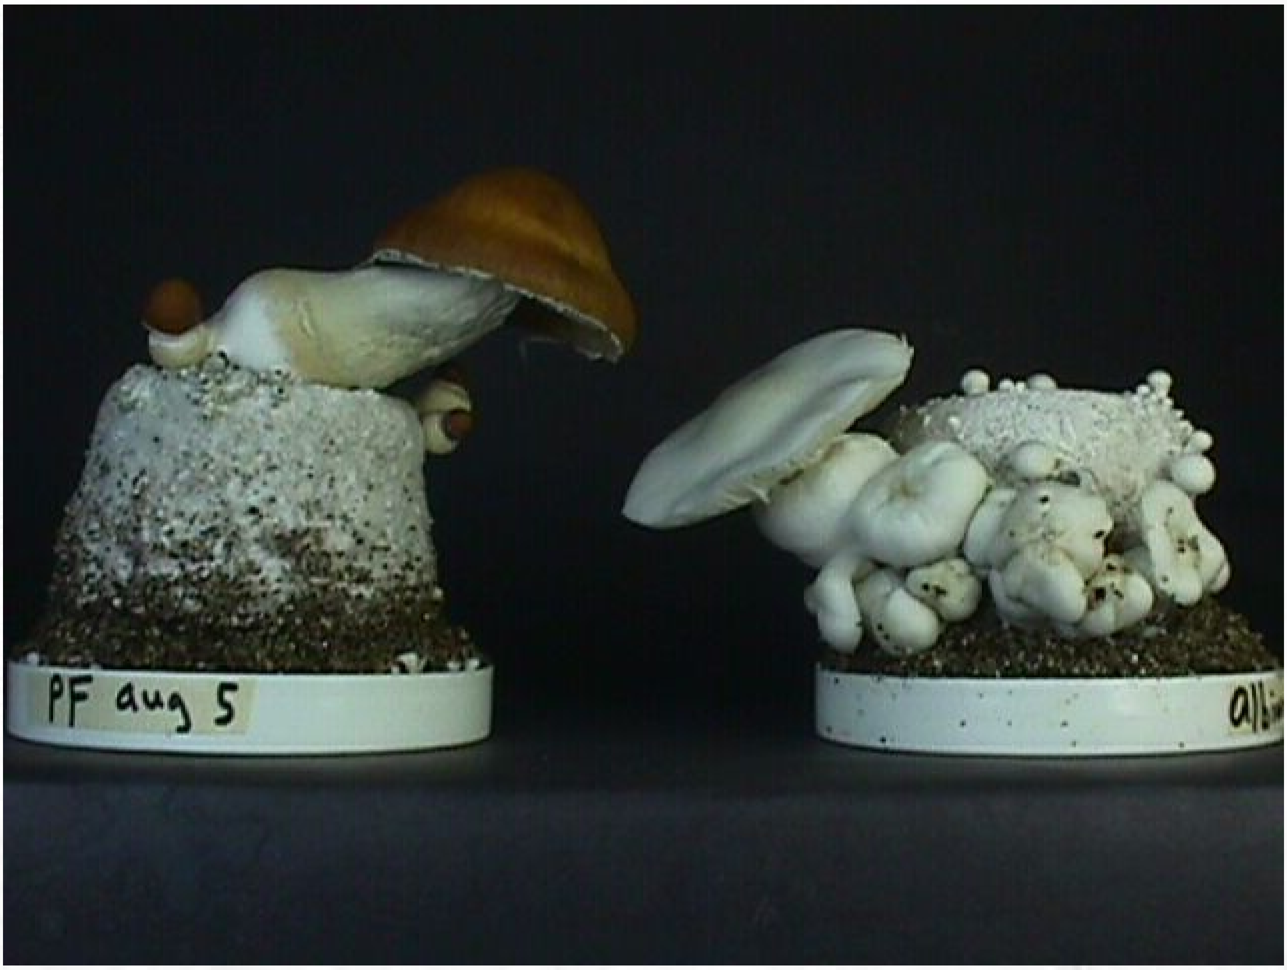
The shrooms were grown under the blacklights 24 hours a day and the lights were hung very close to the terrariums. What happened was that the intense constant glare of the UV rich light damaged the spores and caused the albinoism. Basically said, the UV killed the shrooms because eventually they stopped fruiting.

These following links [content included below] have the story. UV rich light is considered instrumental in mutation formation and it is never good.



For some unknown reason, a PF style cake of PF race shrooms developed strange white primordia. They grew into shrooms I have never seen before. They apparantely are ALBINO mutants. The gills are pure white and sterile (no spores or reproductive system). The above photo is a close up of the third flush appearance of the Albino, growing from the base of the cake in the bottom vermiculite layer. This is a good example of what a "strain" is. To the left of the albino is a normal PF race shroom primordia (abhorted). These are two seperate strains. This is a clear representation of different strain manifestations on a single cake.

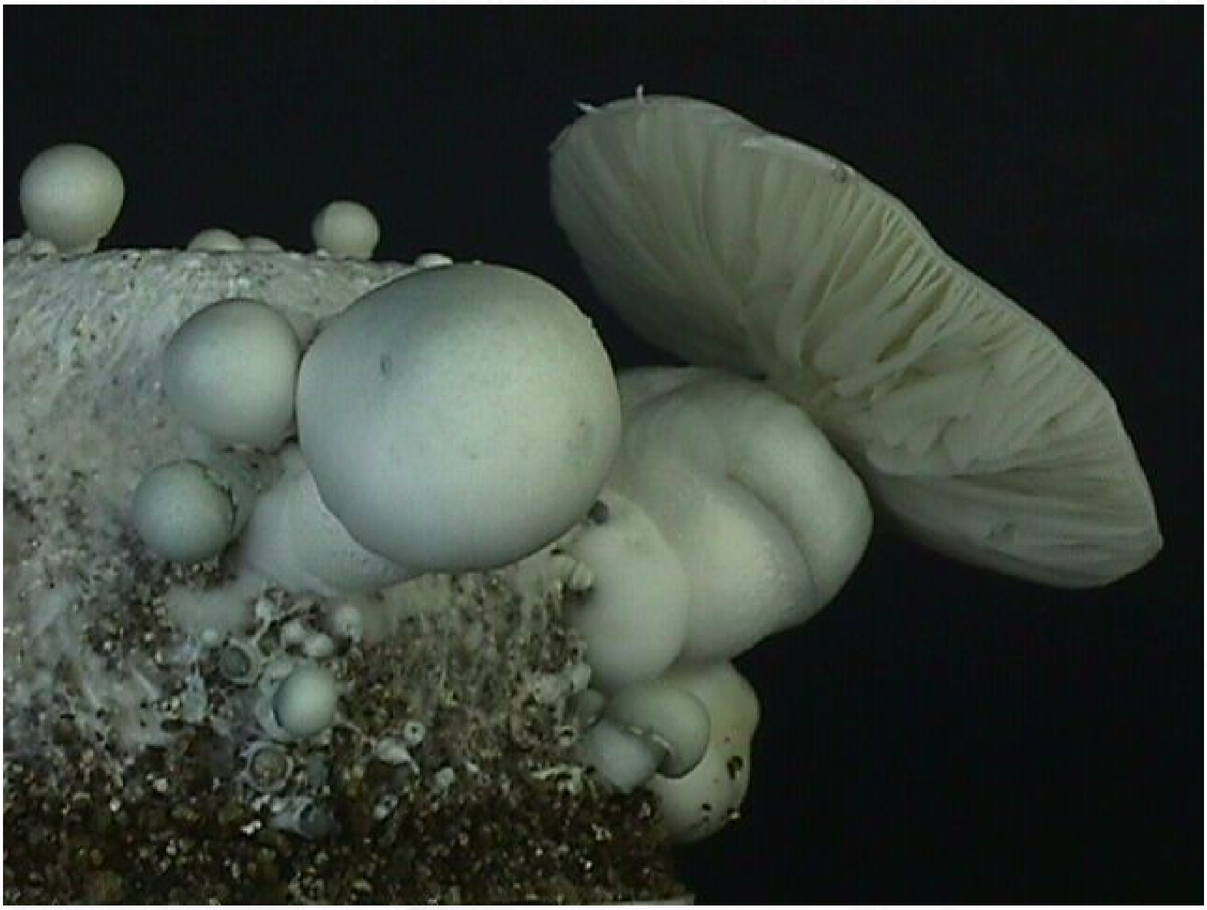
Cloned PF Albino Mutants



The shrooms on the left are a first flush of normal PF race shrooms. The shrooms on the right are the first flush of the Albino clone (taken from the single specimen in the above photo).

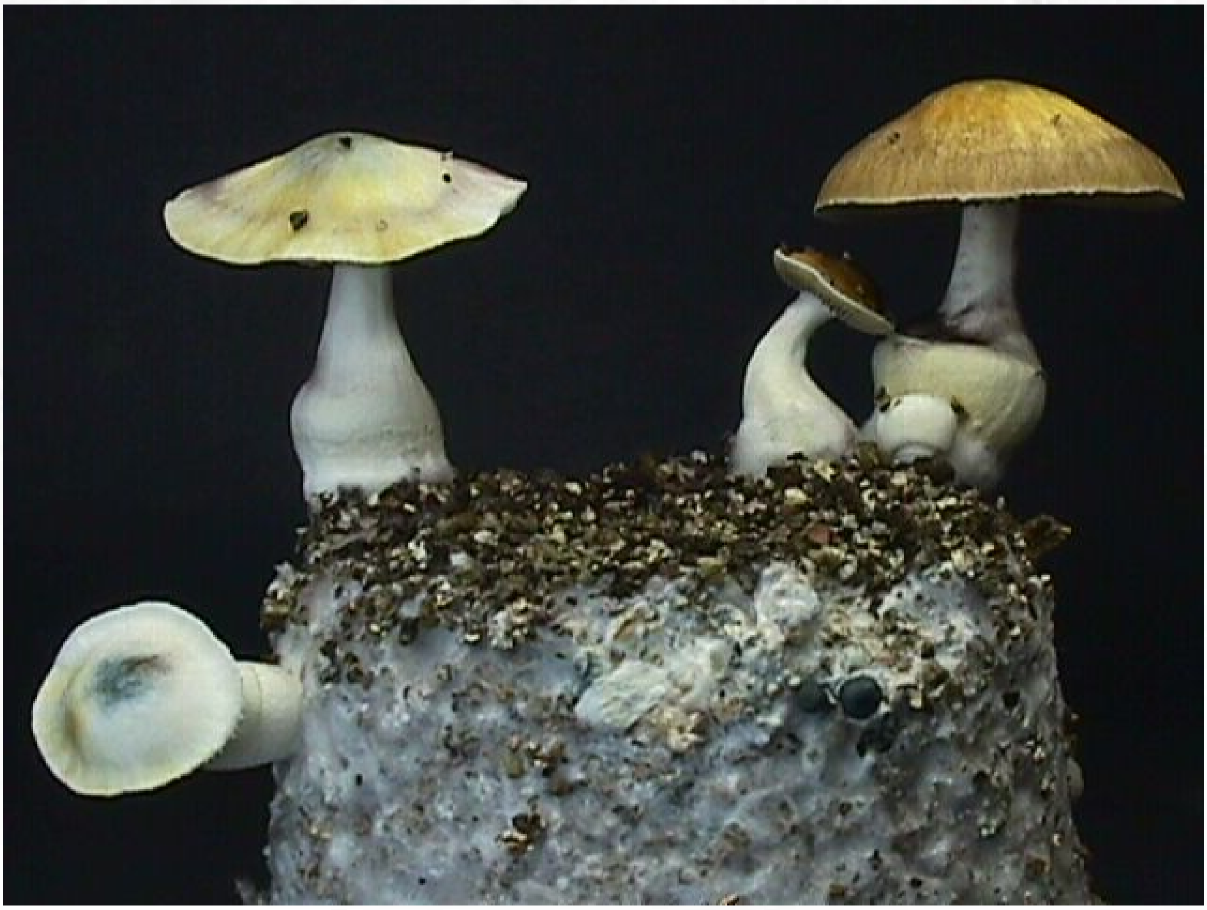
Albino Shroom Cloning Technique

As hoped for, the original PF Albino manifesting cake delivered a small third flush, and one Albino formed (the answer to a prayer to the great fungi from the beyond). This last appearing Albino was dissected and small fragments of inner flesh were excised and placed into a culture tube. As hoped for, it took and began to come to life. After the culture tube medium (Brown rice agar) was covered with the mycelium, sterile water was injected into the culture tube and the culture was broken up and mixed with a scalpel. The resultant mix was transfered to a small lab bottle (with a tight cap) and more water was added. The bottle was then violently shaken and with a 13 gauge syringe needle, mycelium rich water was injected into PF style jars. The Albinos invitro primordiated and grew like normal PF race shrooms. The bottle that was used for the injection solution was left with lots of remains. The bottle regenerated into a type of liquid culture with little floating "islands" of mycelium. This Albino is very resilient and spooks me. It looks like a ghost mushroom. The gills are sterile.



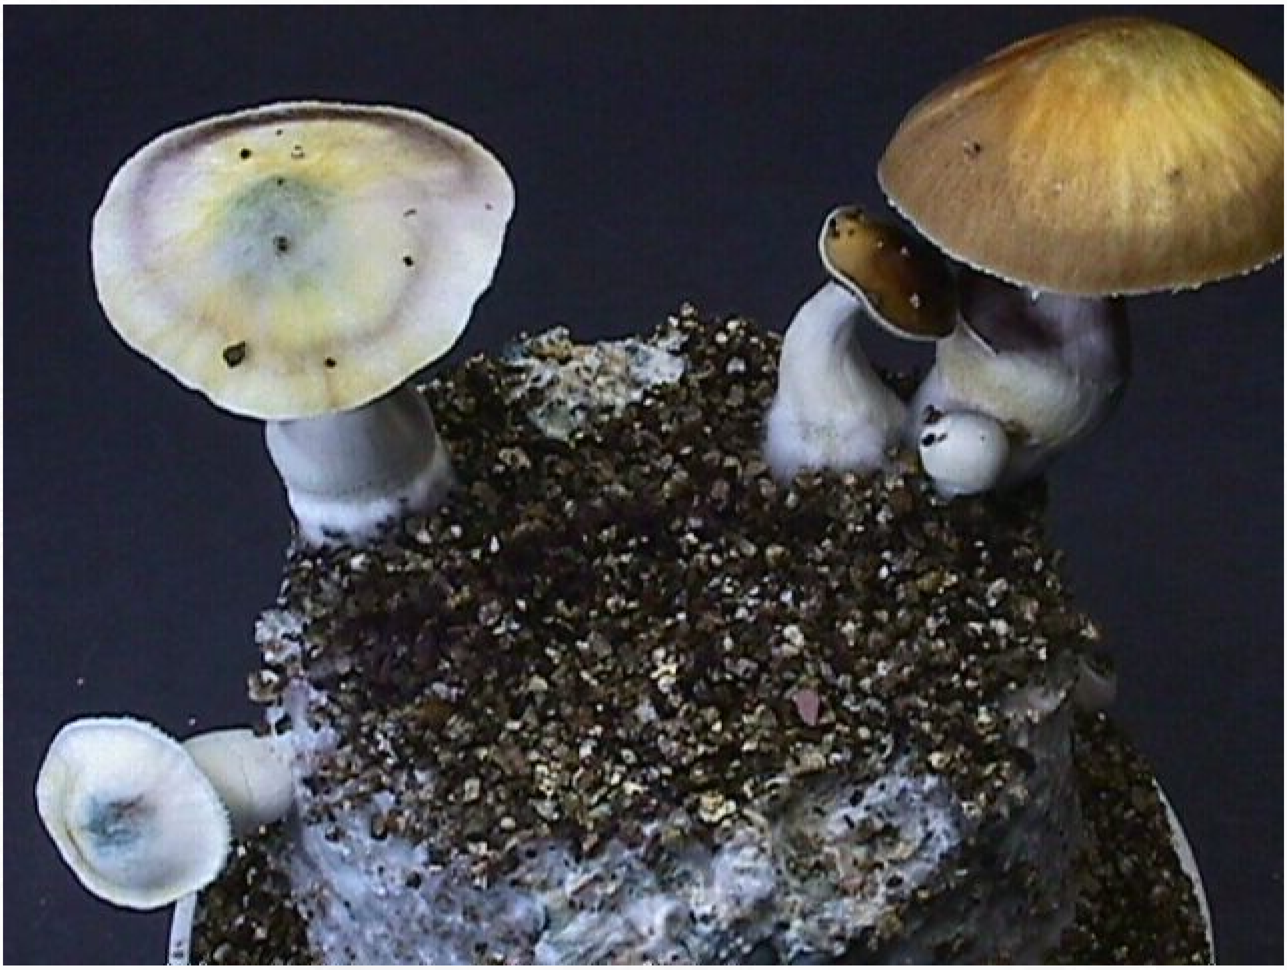
In this view, the sterile gills are shown.

PF Albino Mutant Strain



This is a photo of the PF Albino mutant strain. It is a cake that has been picked over. You can see tears where shrooms were picked for spore printing. The remaining shrooms are the stragglers in a first flush. The one on the far left is a pure Albino with a blue discoloration at the top of the cap and some purple spores from another shroom. The shroom in the center is a "half breed" in which some light sporulation is developing but the cap is strange in color - with light colors and greenish and blueish tints. The gills of this "half breed" are mixed up with some light colored gills that are lightly sporulating and white sterile gills. The shrooms on the right are more normal, but at closer inspection, there is something wrong with them also. The colors aren't "right" and they too have a greenish palor to them. The shrooms that were picked for sporulation (evidenced by tears in the cake), have definite GREENISH colors towards the center of the cap and an over all strange lightness in color. The sporulation is not spectacular, but they are giving plenty of purple spores.

This is a very unusual new creature. Very unusual in that it has never existed before. It came into being in the lab of PF. It can be said, that this shroom is truly PF's shroom - a creation of the PF TEK. What has happened, is that through reculturing and isolation of all the "normal" shrooms from the original Albino appearing cakes (pure Albinos at first), the Albinos have returned as a part of the spore race. What is happening is a first in mycology and after a little consultation, let it be known that this is a mystery of genetics and fungi reproduction. The only "explanation" that PF can come up with, is that PF shroom Albinoism is a kind of "refusing to grow up" syndrome. When primordia first appear, they are Albino and get color soon after. Pins (the precursors) of primordia are indeed pure white. So maybe the fact that pure Albinos don't sporulate or develope reproductive systems is related to not "growing up".



This a view from the top of the cake (above). The strange colors are a little easier to see, although the digital photo color rendition isn't perfect. The thing to do if one wants to explore the ultimate in growing the unknown, is to clone that pure Albino or any of them to see what will happen. The results of such an action has already shown to be astounding. And, according to a recent bio-assay, the pure Albinos are excellent potency (the strangest thing yet).

Disaster in San Diego Harbor Lagoons

Many years ago, a newspaper article described an alien plant invasion into San Diego Harbor lagoons in California. The plant has displaced the normal flora, making for an environmental degradation. Scientists have discovered that it is a common aquatic fern that is popularly used in home fish tank aquariums. The plant has mutated because of exposure to excess ultra violet light emanating from the low wattage fluorescent (15 watts) "plant & aquarium" lights. The lights are used in close proximity to the plants and the plants often float on the surface of the aquarium water making for a direct exposure. The plant escaped into the San Diego sewer system and wound up trapped and flourishing in the quiet inner lagoons of the harbor. They have taken over. UV (ultra violet) is well know in science to be a carcinogen and mutagen in plants and animals.

The Black Light Experiment

The disaster in San Diego harbor lagoons has a parallel with PF. Back in 2000, PF set up a phototropic experiment using 15 watt "black light" fluorescent tubes. The fungus cakes were growing in a simple terrarium. The lights were positioned almost touching the dome tops making the shrooms grow inches away from the lights. The lights were left on 24 hours a day. It is important to also mention that the plastic "richmans" domes are made out of polycarbonate clear plastic. UV does pass through the plastic.

The Albino Mutant Appearance

After a few months of fruiting under the blacklights, a couple of generations went by and then the PF Albinos appeared on two cakes. At first, PF didn't know what to make of them, but soon after, PF became worried, because Albinoism is a mutation, and mutations are a very bad sign genetically. PF then put away the blacklights knowing that the albinos and the blacklights are definitely connected in that they were synchronous. PF has never seen such a thing in over a quarter of a century of shrooming, plus, PF has never used blacklights - only plant type flourescents. PF remained worried.

The genetic mutation certainly occurred at the genesis of the spores, because the mutation changed the offspring that followed. The genes were damaged permanently and passed to the progeny. There were many cakes that seemed unaffected, so the two types; the Albino mutant spores and the "normal" spore race lines were separated. But unbeknownst to PF, invisible or unapparant damage did occur to the "normal" specimens.

The damage slowly crept into the spore race lines and by mid summer of 2001, PF had the sinking feeling of empending doom. The Hawaiian and Mazatec spore races were growing on the same PF formulations and in the same terrariums, but were doing great, with the customary excellent fruitings, but the PF which fruits at least equally as well, was doing frighteningly bad with no invitro primordiation, sparse fruitings, strange looking shrooms, off colors and a tendency for sterility (no spores or few forming). And in the worst case, no fruiting at all, even though the mycelium looked healthy. This degradation happened very gradually, over a period of several months. What happened, was that after the albino appearance and the cessation of blacklight use, PF continued to use PF spore race lines emanating from UV (blacklight) exposed specimens. Soon, all the PF spores PF was getting, were descended from the exposed and apparently damaged PF shrooms from the blacklight growing time. Or, the genetically damaged lines spread and gradually became dominant, taking over the PF race lines through spore mixing and spore solution making (PF's lab work).

PF knew exactly what to do - the obvious. PF then contacted a friend and got an old PF spore print from three years ago (not exposed to blacklight fluorescents) plus a fresh print that was propagated elsewhere. They were used with PF jars, and within two months, the proof was there. The "old" spores and the replacement spores were fruiting with total excellence - fast invitro appearing and big healthy (normal) flushes.
There is another recent experiment from TOKYO JAPAN with SHITAKE mushrooms that shows the power of UV (blacklight) light to mutate shrooms and make them sterile (not albino but sterile - no spores produced)).
Here are excerpts from a science paper from Japan describing mutating SHITAKE mushrooms with UV light to get sporeless strains (desirable in large mushroom farms to protect workers from spore allergies). What this means, is that what I did with the blacklight (UV intense) by accident is what these scientists did to SHITAKE on purpose.

Genetics and Breeding of Spore-Deficent Strains in Agrocybe Cylindracea and Lentinus Edodes

S. Murakami - The Tottori Mycological Institute, Tottori, Japan.

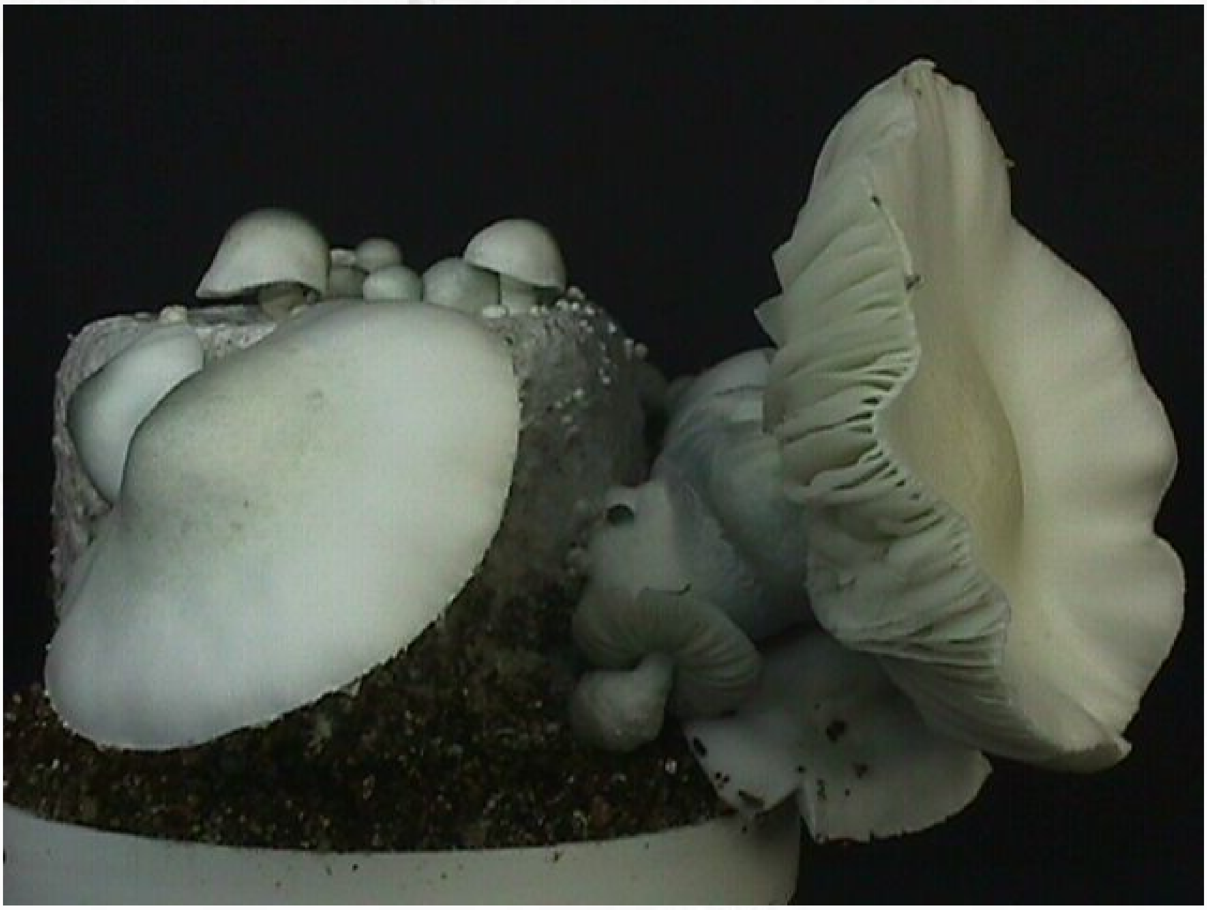
Dikaryotic hyphal fragments from a strain (2493) were irradiated with a Toshiba 10-watt germicidal lamp for 30-40 sec at a distance of 10cm. The irradiated fragments were then plated on CY-2 medium containing 20g glucose, 0.5g MgSO4, 7H2O, 0.46g KH2PO4, 1g K2HPO4, 2g polypeptone, 2g yeast extract and 20g agar per litre of water, and incubated at 25°C. The UV treatment and the incubation were performed in darkness. Lethal rate was more than 95%. Viable colonies were then isolated and transferred on to fresh CY-2 medium.

From 11,500 colonies treated with UV irradiation, 24 spore-deficient mutants and 233 strains with reduced sporulation were detected. Imbernon & Labarere (1989) reported that UV treated strains of Pleurotus ostreatus and P. pulmonarius exhibited some abnormality in morphology and yields of fruitbodies. In our experiment, pilei of the spore-deficient mutants were either very thin at the margin or small in size, or their stipes were slender and because bent.

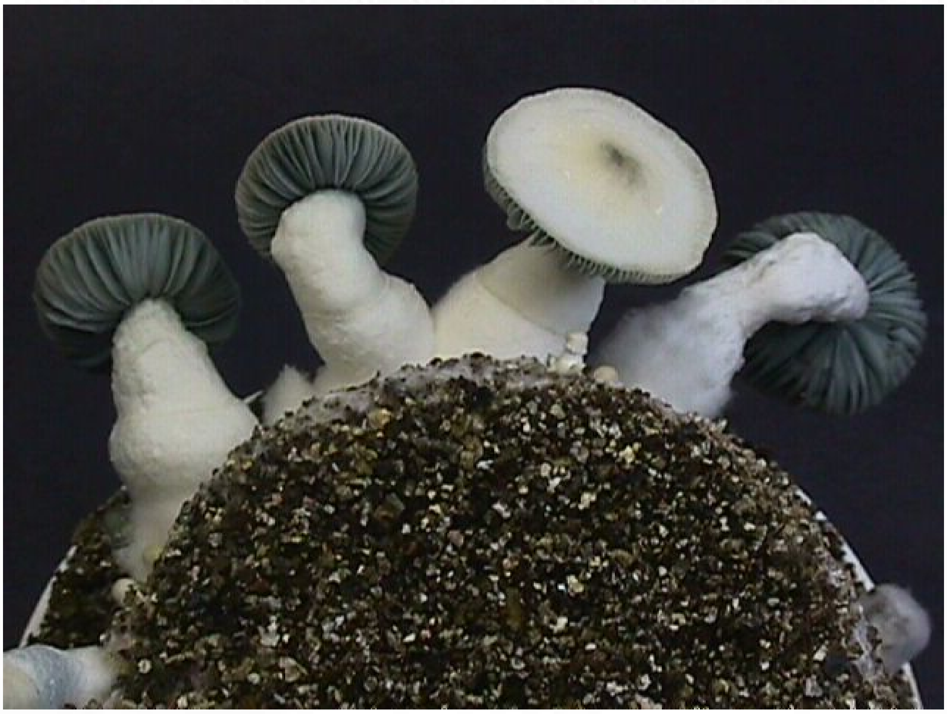
Thus less than 4% of the geminated spores formed colonies. The reduction in compatibility, spore production and viability in the basidiospore progeny stated above, may have an important implications for microevolution in fungi.

Professor Fanaticus
2004 A.D.

Cloned PF Albino Mutants



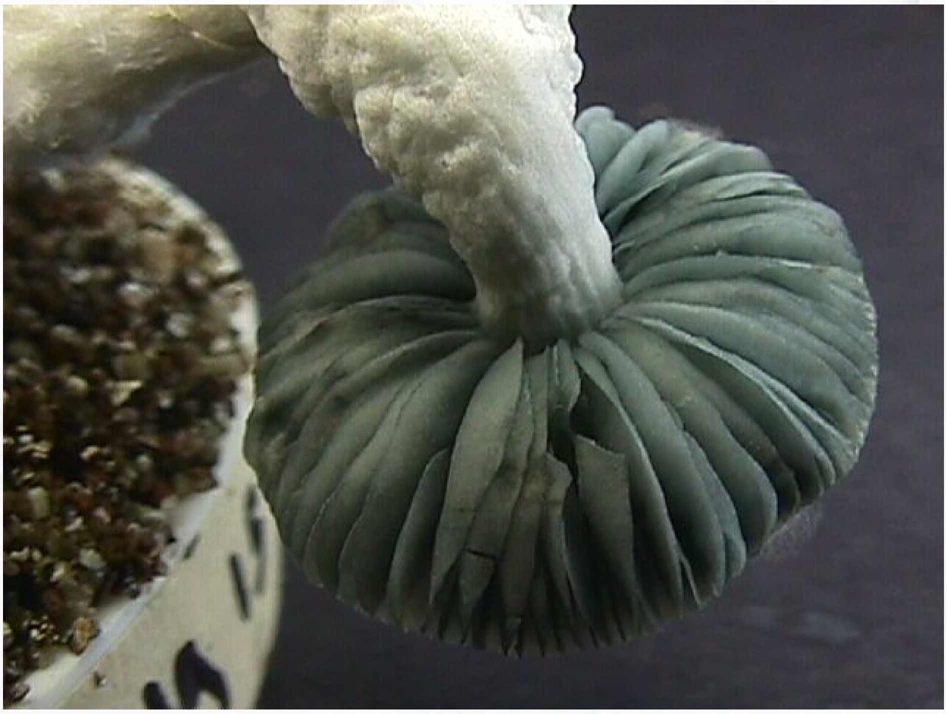
Full grown Albino mutant clone on the PF TEK.



Blueing of the gills.

These are some of the shrooms from the second flush of the clone cake. Another strangeness occurred. The gills blued heavily. On the first flush, blueing occurred with age but not nearly to this extent. Apparantely, the blueing shows the shrooms are psilocybian. On regular PF shrooms, gills will bruize blue very easily but not like this.

For this second flush, the terrarium was placed away from the light. As can be seen, several shrooms have oriented upside down. Regular PF shrooms will do this also when deprived of light. It appears that the Albino mutants are fully photo tropic by growing in an upwards orientation when exposed to light from above and growing in all directions when no light is given.



Closeup of the blueing gills.

CHAPTER 19 - PF RED SPORED MUTANT

original source: http://www.fanaticus.com/redspore.htm

Back when the Halle Bop comet was disappearing into the western sky (for a date only - nothing emplied), the Professor had a petrie dish with four normal looking PF shroom caps spore printing. After a few days, it was time to remove the caps and store away the spore prints. Three of the prints were normal purplish cubie spores but the fourth one was unique. The spores were a deep reddish brown color.

At first, the Professor thought that the reddish spore print was contaminated, but he let the dish dehumidify normally and then taped it up for storage. On close examination of the spores with a magnifier, the reddish spores were not contaminated but the color was with the spores themselves and nothing growing on them as first thought.

So next, the Professor made a spore solution with a streak of the red spores and injected a PF jar with them. They cultured normally and began to form primordia invitro just like a normal PF shroom. When the caps upturned, no spores were seen collecting around the shrooms. A couple of the caps were taken and placed in a petrie dish for printing. And as expected, the Professor hovered around the dish every few hours to see what would give. By the next day, color was detected around the periphery of the caps and low and behold, the color was RED! The Professor jumped with joy, a specie change! Spore color is one of the prime facets of what a specie is. In Mycology, if one has two mushrooms that look identical, grow identically and appear on the same substrate identically but have different colored spores, they are not the same specie.

Next, the Professor inoculated a PF cake on one side with normal PF purple spores and on the other side of the cake, the red spores. Fruiting occurred and on each side, the shrooms gave their respective colored spores. There was no mingling of the shrooms. They kept their own place. So as far as the Professor's opinion goes, the PF shroom some how and for some unknown reason split off into a new specie that ever since, has remained so - always giving the reddish spores and never any purple. Many cultivations of the red spore has been done, and it has remained the red spore - a new mushroom on planet earth.

Chapter one

JOURNAL OF FORENSIC SCIENCES
American Academy of Forensic Sciences (1948)
Volume 45 - Number 3 - May 2000 - JFSCAS 45 (3)513-754 (2000)

Susan T Gross, B.A.
Forensic Scientist, Minnesota Forensic Science Laboratory, 1246 University Ave. St. Paul, Minnesota.
This project was supported by the Federal Bureau of Investigation (FBI). Minneapolis Field Office.
Received 26 Feb. 1999: and in revised form 12 May 1999: accepted 23 Aug. 1999.
REFERENCE: Gross ST. Detecting psychoactive drugs in the developmental stages of mushrooms. J Forensic Sci 2000;45(3):527-537.
ABSTRACT: The following questions regarding the detection of psychoactive drugs in mushrooms are addressed: At what stage of the mushroom development can the psychoactive drugs psilocyn and psilocybin be identified, and what effect does light have on the growth of these mushrooms. To answer these questions, *Psilocybe cyanescens* Wakefield mushrooms were grown from their spores in a controlled setting. At various times of their development, samples were taken and analyzed for psilocyn and psilocybin. Knowing what stage of development the psychoactive drugs can be identified may be useful to law enforcement personnel and forensic chemists. Methanolic extracts of various samples were analyzed by TLC and by GC/MS. It was determined that the mycelium knot stage of the mushroom was the earliest stage at which the psychoactive drugs could be detected. It was observed that light affected the time of development and the appearance of these mushrooms.
KEYWORDS: forensic science. psilocyn. psilocybin. psychotropic mushrooms

Law enforcement agencies in Minnesota are beginning to see an increased number of mushroom growing operations. Knowing what stage of development the psychoactive drugs can be identitied may be useful to law enforcement personnel and forensic chemists. This information is important because in the state of Minnesota it is illegal to possess any material, compound, mixture or preparation which contain any quantity of psilocyn and/or psilocybin[1].

The word mushroom is a general term used to describe the relatively large and fleshy fruiting bodies of fungi, particularly all gill fungi. They are fungi that differ from plants in that these lack roots,stems, leaves, flowers, seeds and chlorophyll. Since mushrooms lack chlorophyll, they depend upon their surrounding medium for their nutrients. The vegetative portion of the fungus accumulates a reserve of food from the immediate surroundings in order to develop fruiting bodies[2-3].

Fungi are categorized as follows: kingdom, phylum, class, order, family, genus, and species. Mushrooms containing psychotropic drugs are classified in the kingdom Mycota, the phylum Basidiomycota, the class Hymenomycetes, and the order Agaricales. There are four families of mushrooms, Strophariaceae, Bolbitiaceae, Coprinaceae, and Cortinariaceae, that contain psilocybin, psilocyn, or related alkaloids with an indolic nucleus. The genus and species of Psilocybe mushrooms that were grown were identified as Psilocybe cyanescens. The pleurocystidia sizes noted in the keys describing the Psilocybe cyanescens mushroom varied slightly from the mushrooms grown. This may indicate a variant of this species (communication with Dr. David McLaughlin, Plant Biology Department, University of Minnesota)[2,4,5-8].

The four stages making up the life cycle of a mushroom are the spores, the mycelium, the primordia, and the mature fruit. The spores are the reproductive cells or "seeds" of the fungi (Fig. 1 - photo of spores under magnification).

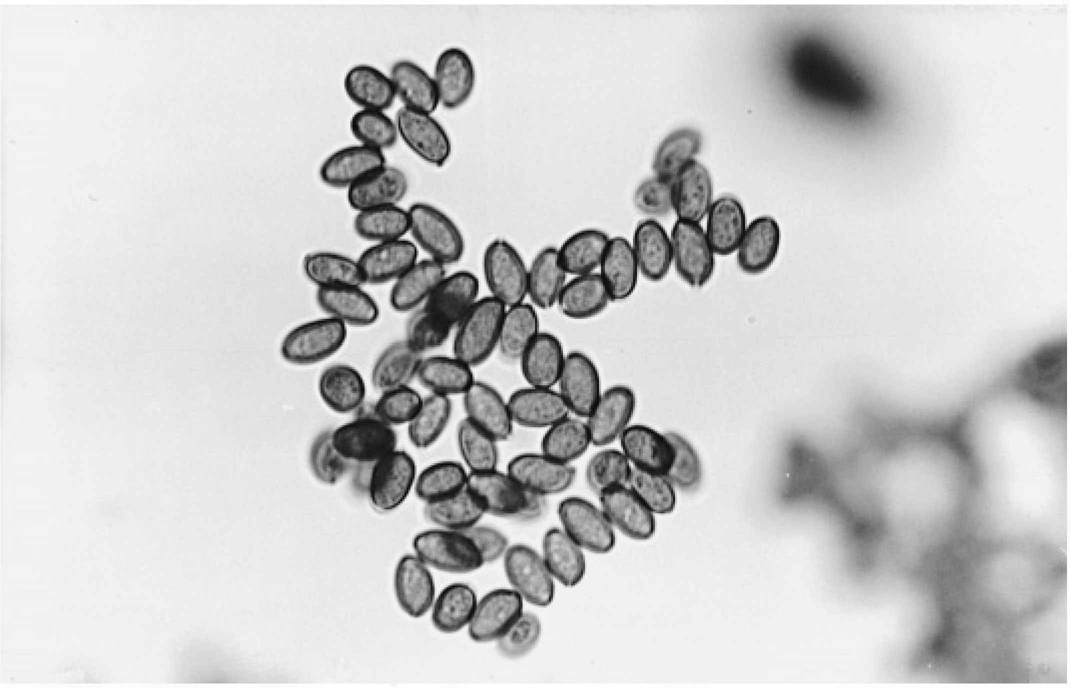

FIG. 1 - The aqueous spore solution viewed using a 1250x magnification microscope. The spores are the first stage of the mushroom's life cycle. One milliliter of spore solution was used to inoculate each 1/2 pint jar.

Germination of the spores takes place when a suitable substrate and correct environmental conditions are present. These spores grow outward seeking nutrients and branch out forming a complex "cob-like" system. This "cob-like" system is the vegetative portion of the fungus which is called the mycelium (Fig. 2 - photo of mycelium spreading in PF jar).

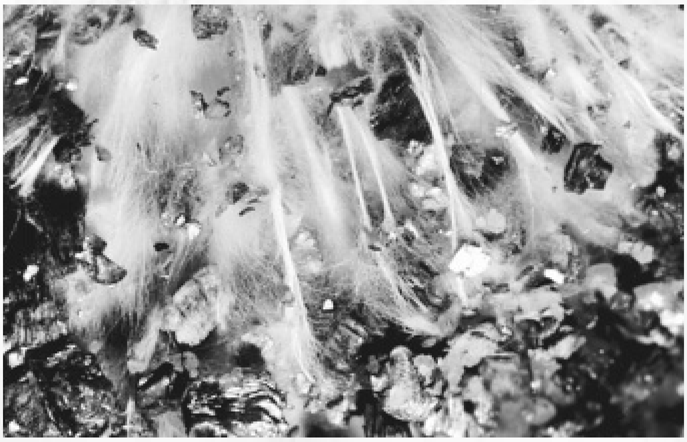

FIG. 2 - The vegetative portion of the fungus is called the mycelium. This is the second stage of the mushroom's life cycle. The first sign of mycelium growth appears 4 to 6 days after inoculation.

The mycelium absorbs water and nutrients from the substrate which is used in the production of the fruiting bodies. The ability of a fungus to begin fruiting is affected by genetic competence and various environmental factors including moisture, temperature, light, and aeration. The formation and growth of the fruiting bodies is known as primordia and has been referred to as "mycelium knots" and "pinheads." The "mycelium knot" is referring to the initial fruiting body that is formed when the mycelium clumps together and seems to form a "knot" (Fig. 3 - photo of birthed PF cake and pins).

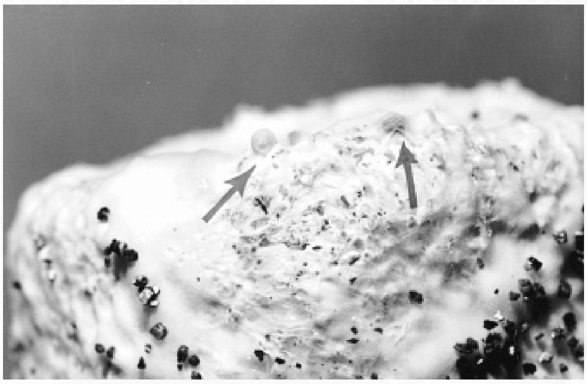

FIG. 3 - The third stage of the mushroom's life cycle is the primordia, and has been referred to as "mycelium knots" and "pinheads". The mycelium knots are the initial fruiting body that is formed when the mycelium clumps together and seems to form a "knot".

This knot eventually grows into the 'pinhead,' a plump growth, yellow in color and with a brown tip (Fig. 4 - photo of invitro primordia in PF jar).

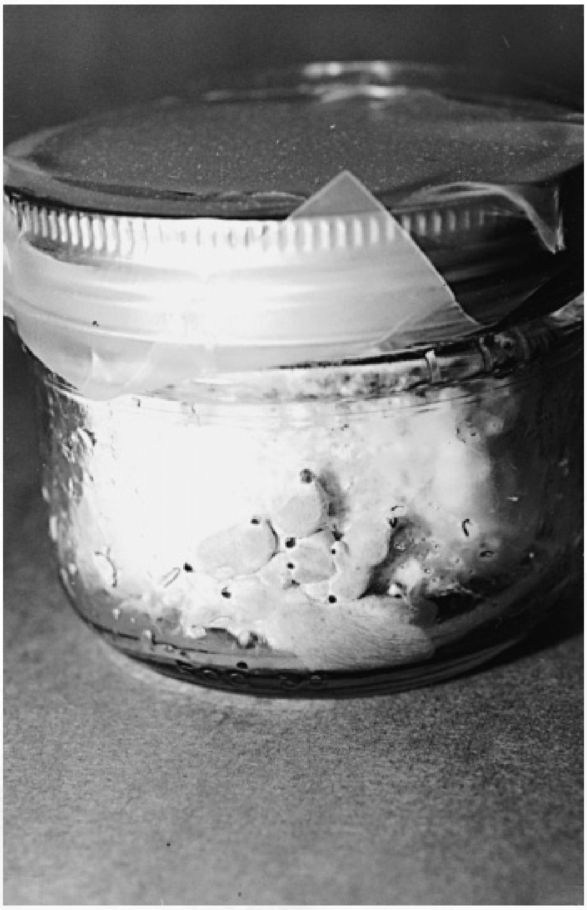

FIG. 4 - The third stage of the mushroom's life cycle is the primordia, and has been referred to as "mycelium knots" and "pinheads". The pinheads are plump growths, yellow in color with a brown tip.

The fruit is considered mature when it is able to disperse spores and begin this life cycle over again (Figs. 5-6 - photos of mature PF race shrooms on cakes)[2,9].

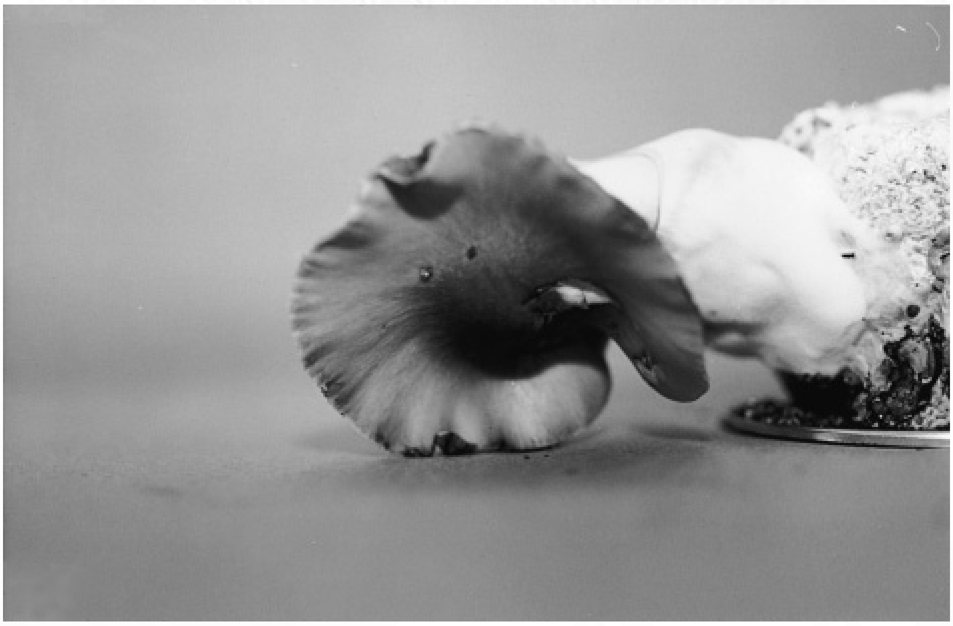

FIG. 5 - The fourth stage of the mushroom's life cycle is the mature fruit. Mushrooms are considered mature once they are able to disperse spores and begin the life cycle over again. Mature Psilocybe cyanescens Wakefield mushrooms.

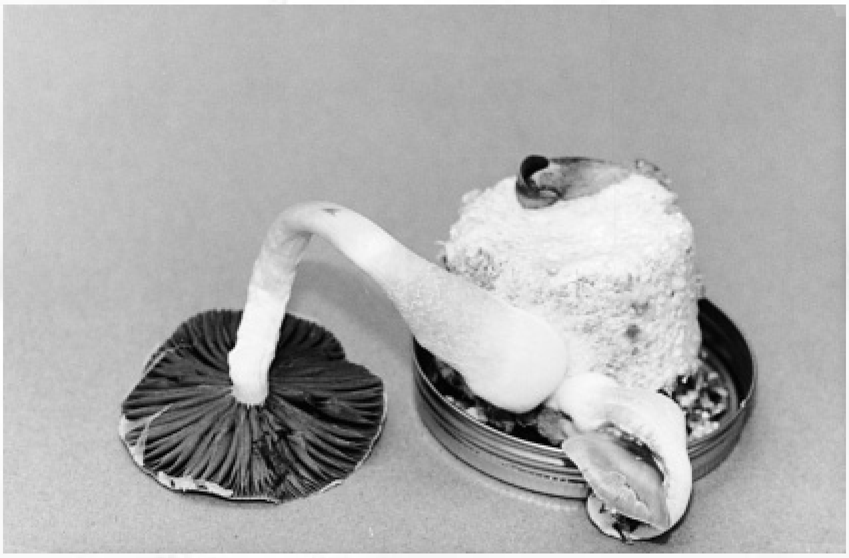

FIG. 6 - The fourth stage of the mushroom's life cycle is the mature fruit. Mushrooms are considered mature once they are able to disperse spores and begin the life cycle over again. Mature Psilocybe cyanescens Wakefield mushrooms.

Methods

The spores used in this experiment were obtained legally through an advertisement in High Times Magazine from Psylocybe Fanaticus (PFTek Seattle, WA). The spores were received in 10 mL syringes in an aqueous solution. The spore solutions were each viewed using a 1250X-magnification microscope.

Directions for preparing the growing media were received with the spores. Supplies used for the growing media were half-pint wide-mouth jars (KerrGroup, Inc. Jackson, TN), horticultural vermiculite (Schultz, St. Louis MO), brown rice powder and distilled water. The canning lids were prepared before the mixture was added to the jars. The rubber sealing edge of the canning lids were turned upwards and four holes were punched symmetrically around the outer edge. A mixture of one fourth cup brown rice powder, one half cup vermiculite and one fourth cup distilled water was prepared for each half pint jar. This mixture was placed into the jars and covered with dry vermiculite. The lids were screwed on tightly and aluminum foil was used to cover the lid to prevent additional water from entering the jars during sterilization.

Since growing media is susceptible to contamination, the top layer of dry vermiculite was used to keep airborne contaminants from the wet substrate and absorb and regulate moisture transpiration and condensation[10]. The jars with the growing media mixture were sterilized at 120°C for 20 minutes. The jars were cooled before inoculation. Contamination was detectable through various colors from pastels to black. The growing media that became contaminated was observed but was not analyzed.

Eight jars per week were inoculated with 10 mL of spore solution. This was done for 9 weeks for a total of 72 inoculations. In addition to the eight jars inoculated per week, one jar per week was not inoculated and was used as a control blank. During the first four weeks, all samples were allowed to grow under indirect light. The last five weeks, half of the samples were allowed to grow under indirect light while the other half were kept in the dark. The jars kept in the dark were exposed to light only when samples were taken. Each jar was covered with parafilm after inoculation to keep airborne contaminates from the substrate.

The samples were transferred to terrariums after the pinheads became too large for the jars they were growing in. Two different terrariums were used for this experiment. The first one consisted of a styrofoam cooler with a piece of plexiglas inside of it. The second terrarium consisted of a 2-liter pop bottle with the middle portion cut out. To maintain a high level of humidity, both terrariums were sprayed with distilled water two to four times a day. Fanning the chamber with the lids two to four times a day also kept the terrariums well ventilated.

The growth and colonization was monitored for the samples grown under indirect light. The mycelium was sampled 13 days after inoculation. Samples were also taken from each jar at various stages of growth of the mycelium, primordia and the mature fruit. The growth of the mycelium, primordia and the mature fruit was monitored and compared for the samples grown under indirect light and in the dark simultaneously.

Sample Preparation

Samples were allowed to soak in methanol overnight. The methanol was decanted into a shell vial which was then condensed to near dryness (<1/2 mL) using a stream of air. An aliquot was removed for thin-layer chromatography (TLC). The mycelium knot samples were analyzed by TLC and by gas chromatography with a mass spectrometer (GC/ MS) in this methanolic extract state without any clean-up.

The extracts were cleaned up with an acid solution for GC/MS analysis. A 0.2 N solution of sulfuric acid was used to resuspend and acidify the extract. This solution was washed twice with chloroform to remove the neutral organic compounds. The samples were made basic with sodium bicarbonate and the psychoactive drugs were extracted twice with chloroform. The chloroform was evaporated and the sample was reconstituted with methanol for GC/MS analysis.

Thin-layer Chromatography

TLC was carried out on 5 X 10 cm silica gel plates (Analtech Newar, DE). Psilocyn (Alltech State College, PA) and psilocybin (Alltech State College, PA) standards were spotted on each plate along with the sample extracts. The plates were developed to 6 cm at room temperature in a covered development tank with a 9:1 chloroform/methanol solution. A beaker containing 3 mL of ammonium hydroxide was placed in the tank to assist in development. The plate was dried with low heat and visualized with a para-dimethylaminobenzaldehyde (p-DMAB) spray reagent. (The p-DMAB reagent consisted of 2g of p-DMAB in 50 mL of ethanol and 50 mL of hydrochloric acid.) The relative R_f value of psilocybin is 0.00 and the relative R_f value of psilocyn is 0.85.

The lower limit of detection was determined by serial dilutions of the psilocyn standard and spotting/developing it until the spot associated with the standard was not seen. The lower limit of detection for the TLC method was determined to be approximately 0.03 mg/mL.

Gas Chromatograph/Mass Spectrometer

The Hewlett Packard gas chromatograph 5890 Series II interfaced with the Hewlett Packard 5970 series mass selective detector (MSD) and the Hewlett Packard G1800A gas chromatograph detector system (GCD) were used for the detection of the analytes. These two instruments are equivalent and samples were run on specific instruments depending upon their availability. An HP-1 12 m column (film thickness 0.33 µm, column id 0.2 mm) was used for the gas chromatography (GC). The parameters for the GCD were as follows: injection port 250°C and detector temperature 280°C. Method SCAN70-Low mass 35, high mass 425, initial temperature 70°C, ramp rate 25°C/min and final temperature 300°C hold for 3.0 minutes. The parameters for the MSD were as follows: injection port 265°C and detector temperature 280°C. Method SCN90-Low mass 35, high mass 400, initial temperature 90°C, ramp rate 25°C/min, and final temperature 300°C hold for 4.0 minutes. Sample volume was approximately 3 µL with the split ratio of 30:1.

Lower Limit of Detection

The lower limit of detection for both instruments was determined by serial dilutions of the psilocyn standard and analyzing it until a peak at the correct retention time containing the prominent ions 44, 58, 77, 159, and 204 was not detected. The lower limit of detection was determined to be approximately 0.1 mg/mL for both instruments.

Results and Discussion

Identifcation of the mushrooms grown in this project was made by examination of the spores, fruiting bodies and the mature mushroom. Spores were examined for their color, shape, and size. The spores were purple to brown in color and elliptical to oblong elliptical in shape. They ranged in size from 6.7-8.2 µm by 12.6-15.0 µm. The fruiting bodies were examined mainly for color. The mature mushroom was examined for shape, size, color, texture, gill characteristics, and general appearance.

The original spore solutions were analyzed by TLC and by GC/MS. No psilocyn or psilocybin were detected in any of the spore solutions.

Mycelium growth was observed from 4 to 6 days. Fruiting bodies were observed from 24 to 48 days. The average amount of time for the primordia to appear was 32 days. Samples of mycelium were taken after 13 days of growth, 20 days of growth, and at various other days of growth. A total of 29 samples of the white mycelium growth were analyzed. No psilocyn or psilocybin was detected in any of these 29 samples. Nine of the 29 samples were confirmed by GC/MS, and again no psilocyn was detected.

Samples were analyzed after the first sign of growth of mycelium knots. A total of 22 mycelium knot samples were analyzed by TLC. Samples were considered to be consistent with a standard if their relative R_f value and their color matched the standard also spotted on the plate. Samples were considered to indicate a standard if their relative R_f value matched the standard but the color was not as dark as the standard spotted. Of the 22 mycelium knot samples, 17 were consistent with psilocyn. Of these 17 samples, 8 were also consistent with psilocybin and 1 indicated there was psilocybin in the sample. Four samples were consistent with the psilocybin standard spotted on the TLC plate, and one of these samples also indicated there was psilocyn in the sample. There was no psychoactive drugs detected in one of the samples.

Samples were analyzed after the first pinheads of the fruiting bodies were observed. A total of 25 samples of the pinheads were analyzed by TLC. All 25 samples were with the psilocyn standard spotted on the TLC plate. Of these 25 samples, 3 were also consistent with the psilocybin standard spotted and 3 indicated there was psilocybin in the sample (Table 1).

The 22 mycelium knot samples were also analyzed by GC/MS. In the inlet system of the gas chromatograph, thermal dephosphorylation of psilocybin occurs. As a result of this degredation of psilocybin to psilocyn, one is unable to differentiate the two by GC/MS. With this inability to differentiate psilocyn and psilocybin, it is unknown if the starting material contains psilocyn, psilocybin, or a mixture of both drugs. For this project, only a psilocyn standard was analyzed by GC/MS (Figs. 7-9 see source). Samples were considered to be consistent with psilocyn if their retention time and mass spectral fragmentation pattern matched that of the psilocyn standard. Samples were considered to indicate psilocyn if their retention time was consistent with the psilocyn standard and contained the prominent ions, but were lacking ions in the total fragmentation pattern. Of these 22 mycelium knot samples, 12 were consistent with the psilocyn standard. Seven samples were found to indicate psilocyn, and there were three samples where psilocyn was not detected.

TABLE 1 - Results of thin layer chromatography (TLC).*

Sample Types	Total of Samples Analyzed	c/w Psilocyn and c/w Psilocybin	c/w Psilocyn and Indicates Psilocybin	c/w Psilocyn Only	c/w Psilocybin Only	c/w Psilocybin and Indicates Psilocyn	Not Detected
Spores	4						4
Mycelium	29						29
Mycelium knots	22	8	8	1	3	1	1
Pinheads	25	19	3	3			
Mushrooms	11	9	2				

* Results of thin layer chromatography (TLC) on the various stages of development of the *Psilocybe cyanescens* mushroom. TLC was carried out on 5 x 10 cm silica gel plates and developed with a 9:1 chloroform/methanol solution. Plates were visualized with p-DMAB spray reagent. Samples were considered to be consistent with (c/w) a standard if their relative R_f value and their color matched the standard also spotted on the plate. Samples were considered to indicate a standard if their R_f value matched the standard but the color was not as dark as the standard spotted.

The 25 "pinhead" samples were also analyzed by GC/MS. Of these 25 samples, 19 were consistent with the retention time and mass spectral fragmentation pattern as psilocyn. Three samples were found to indicate psilocyn and psilocyn was not detected in 3 samples (Table 2).

TABLE 2 - Results of gas chromatograph/mass spectrometer (GC/MS).*

Samples Types	Total # of Samples Analyzed	c/w Psilocyn	Indicates Psilocybin	Not Detected
Spores	4			4
Mycelium	9			9
Mycelium knots	22	12	7	3
Pinheads	25	19	3	3
Mushrooms	11	11		

* Results of gas chromatography/mass spectrometer (GC/MS) on the various stages of development of the *Psilocybe cyanescens* mushrooms. Samples were analyzed on Hewlett Packard gas chromatograph 5890 Series II interfaced with Hewlett Packard 5970 series mass selective detector (MSD) and the Hewlett Packard G1800A gas chromatograph detector system (GCD). Samples were considered to be consistent with (c/w) psilocyn if their retention time and mass spectral fragmentation pattern matched that of the psilocyn standard. Samples were considered to indicate psilocyn if their retention time was consistent with the psilocyn standard and contained the prominent ions, but were lacking ions in the total fragmentation pattern.

Samples of the mature mushroom were also analyzed. Eleven samples were analyzed by TLC and by GC/MS. All eleven samples were consistent with the psilocyn standard spotted on the TLC plate. Of these 11 samples, 2 also indicated psilocybin in the sample. All 11 samples analyzed on the GC/MS were consistent with the psilocyn standard (Figs. 10-12 see source).

There were some noticeable differences in the samples grown under indirect light versus the samples grown in the dark. All samples started to show mycelium growth at 4 days. The first signs of fruiting bodies were observed to be from 19 to 25 days in the samples that were grown under indirect light with the average being 21 days. The first signs of fruiting bodies were observed from 23 to 45 days for the samples that were grown in the dark, with the average being 26 days. The samples that were grown under indirect light had primordia which grew faster and larger. They were plump, yellow in color with brown tips. The samples that were grown in the dark had small white primordia that were skinny and long. The coloring was off-white with only a few having dark brown tips. The mushrooms that were grown under indirect light had thick stipes with yellowish to chestnut colored caps. The mushrooms that were grown in the dark had lighter stipes that were much skinnier than the mushrooms grown in the light. The caps of the mushrooms grown in the dark were also lighter in color than the mushrooms grown under indirect light. Psilocyn and/or psilocybin was detected in the mycelium knots, the pinheads and the mature mushrooms of all samples grown either in the dark or the light.

Conclusion

The psychoactive drugs psilocyn and psilocybin were not detected in the mycelium, the earliest stage of development of the mushroom. These drugs were identified in the mycelium knots, the earliest stages of the fruiting body of the mushroom.

Light affects the growth of the Psilocybe cyanescens mushroom. This affect is apparent in the time of development and the appearance of the mushroom. Light affected the color and size of both the fruiting bodies and the mature mushroom. Light did not affect the presence of psilocyn or psilocybin in the early stages of the primordia or the mature mushrooms, nor did it affect the ability to detect these psychotropic drugs. It appears that the Psilocybe cyanescens mushrooms are not photosynthetic, but are photosensitive.

Acknowledgments

The author wishes to acknowledge Dr. David McLaughlin, Plant Biology Department, University of Minnesota for his time and assistance in identifying the mushroom, and his explanations about the classifications of fungi and the development of the mushroom. This project was supported by the Federal Bureau of Investigation, Minneapolis Office which generously provided the supplies.

PF comments

There are several interesting points in the first article, "Detecting Psychoactive Drugs in the Developmental Stages of Mushrooms".

1. The article was the result of a full FBI investigation of PF in 1998. What saved PF was this; "The original spore solutions were analyzed by TLC and by GC/MS. No psilocyn or psilocybin were detected in any of the spore solutions". If these drugs would have been detected, PF would certainly be history and the new spore syringe phenom would be over.
2. The article gave PF credit for the source of the spores, "The spores used in this experiment were obtained legally through an advertisement in High Times Magazine from Psylocybe Fanaticus (PFTek Seattle, WA)". This is quite amazing because the FBI did not have to give any credit for this research, but they did. Most likely, it was because a lot of money was invested for the research and they achieved valid results. They even spelled Psylocybe Fanaticus correctly incorrect with a Y, and not an I. Also, the FBI performed the PF TEK exactly as written (credit given in the references section and footnotes) and because they followed the PF TEK, even they were able to get a first time success, making their research project and money spent, successful.
3. The paper identified the shroom grown (PF race) as a Psilocybe Cyanescens. Everyone knows that the PF race is Psilocybe Cubensis and not Psilocybe Cyanescens. Why then identify it as a wrong specie? The clue is here, "The genus and species of Psilocybe mushrooms that were grown were identified as Psilocybe cyanescens. The pleurocystidia sizes noted in the keys describing the Psilocybe cyanescens mushroom varied slightly from the mushrooms grown. This may indicate a variant of this species (communication with Dr. David McLaughlin, Plant Biology Department, University of Minnesota) (2,4,5-8)". For the last few years, PF has taught the concept of "spore race". What the scientists did was to ignore what PF said about the identity of the shroom and went to the books and keys to do an objective ID, and what they obviously saw was that the PF race shroom looks more like a Psilocybe Cyanescens than a Psilocybe Cubensis. They refer to it as a "variant of the species". This is more vindication of PF's new concept of spore race as opposed to the common designation - "strain", which falls short of describing these various races that do not mate, but stay unique and separate.
4. They found no drugs in the young mycelium. This is very surpising, because after ingestion of "tea" made from boiling down mycelium engulfed grain, a slight "psilocybian buzz" can be felt for a brief time. The answer is that the lab equipment could not detect an amount of psilocybin that the human psyche can!

PF comments chapter two

Extreme variations in potency of a given collection of magic shrooms has been reported ever since reports have been done about these shrooms. And similarly, this report also shows the extreme variability of psilocybin content amongst the dried samples. So if one wants potent and satisfying Cubensis magic shrooms, they should be grown for potency. And that is done by harvesting them in their young stage, before sporulation begins. When that is done, even the most different appearing spore races look about the same. When the caps aren't fully expanded, all of the races look similar. The visual differences emerge when the shrooms mature, but then when they mature, they are only good for spore printing. These are weak in potency and unsatisfying for tripping. So the word of wisdom is, grow them PF style, harvest them when they are young and cool dry them with desiccant. When this is done, they are an entheogen of the highest nature.

Table of Contents

PSYLOCYBE FANATICUS MUSHROOM MUSEUM

original source: http://www.fanaticus.com/museum2.htm

All of these shrooms in the PF Shroom museum were grown identically - PF style in the "Richmans terrarium" - basically the PF neglect tek. No humidifiers or perlite layers were used to increase humidity. Only a couple of airings and mistings were done per day and sometimes less (neglect tek). Some have vermiculite casings on the tops and some are without. All have a "bottom" casing of wet perlite covered with vermiculite (in a jar cap) which keeps the cakes hydrated and adds to the humidity of the terrarium.

PSYLOCYBE FANATICUS

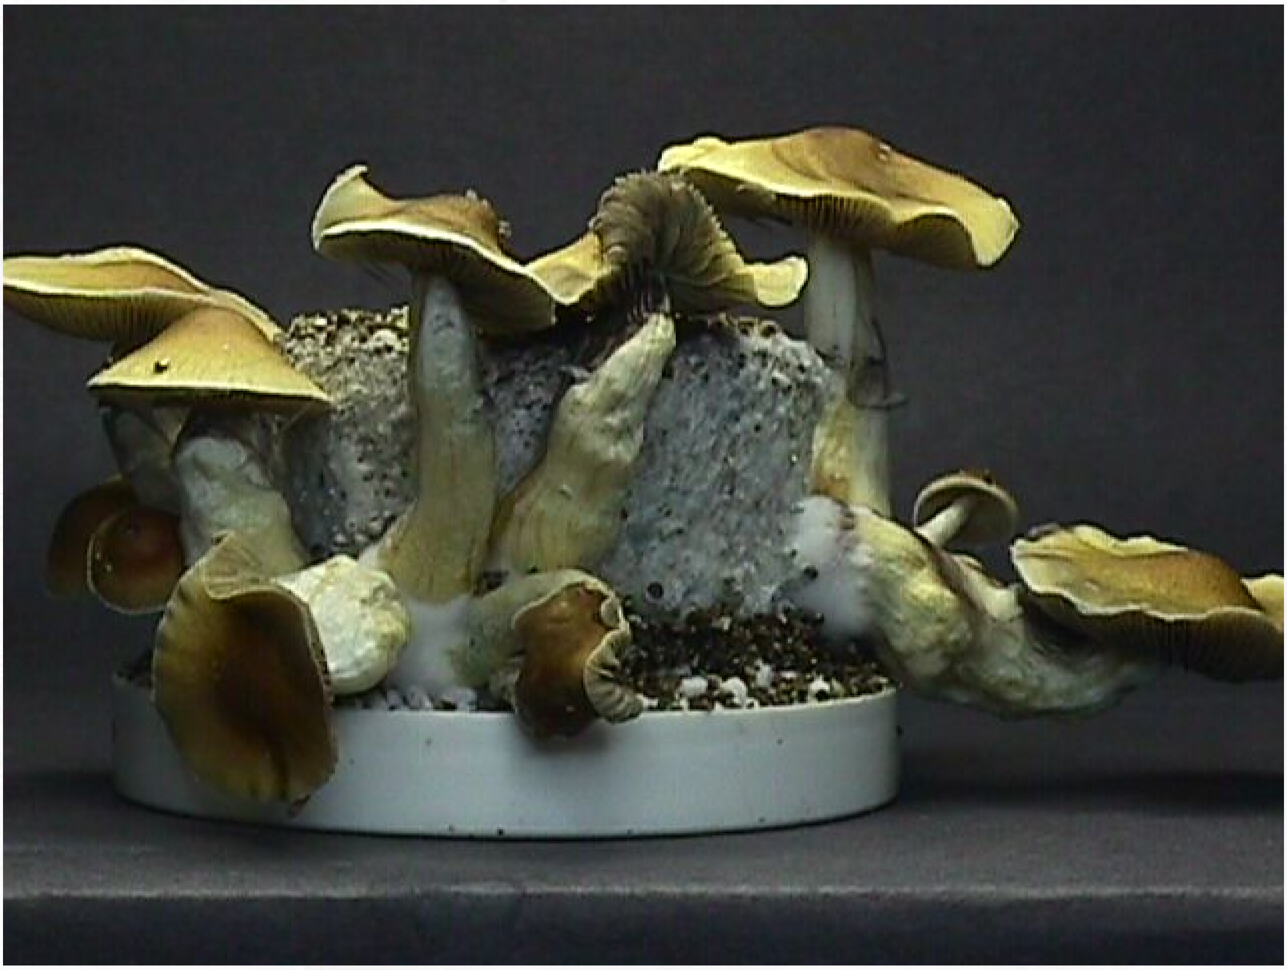
CHAPTER 21 - PSYLOCYBE FANATICUS RACE PHOTOS AND DESCRIPTIONS

Psilocybe cubensis - Matias Romero



This is the PF spore race. It is also called "Matias Romero" at other spore sellers sites or Amazonian. It lately has picked up the name "PF CLASSIC". This photo is of a second flush. The first flush was done and the cake was cleaned with a very sharp hunting knife (like peeling an apple - only with a very sharp large blade). The cleaned cake was placed on a jar cap of soaked and drained fresh perlite and vermiculite. Then a fresh dry vermiculite layer was applied to the top and soaked by dripping water on it from an eye dropper.

DESCRIPTION:

1. CAP (size - shape stages - colors)
   The primordia start dark reddish. The cap is a fairly dark reddish (deep colors) and thick. It starts dome like and goes to plane at maturity and continues to grow until it is upturned and convoluted, with the gills a very deep brown, with streaks of purple (spore deposits) across and around the cap.

2. STEM (length - girth - flesh - colors)
   It can be short and fat or long and hefty. It depends on the air and humidity. The PF race responds to this seriously. With lots of air and humidity, the PF stem is long, slender, thick fleshed and white. The flesh of the PF race is unique amongst all the races. It is very much like soft moist BREAD. But sometimes there can be a bit of fibrousness here and there.

3. VEIL (deliquescent - partly deliquescent - persistant anulus)
   The PF race has a definitely deliquescent veil. When the veil breaks during growth of the shroom, it usually breaks off from the stem and breaks up around the gills, leaving veil remnants all over the gills and mainly on the edges. But, sometimes there is a veil that becomes like an anulus (around the stem) but at close inspection, the veil will not be attached securely and usually might just hang in part. Also, there is serious differences amongst the races at how the gills attach to the stem under the cap. The PF gills attach closely. Whereas the Malaysian gills have a rather large gap where the gills attach to the underside of the cap. Gill stem and cap attachment is a definite trait of races, but unfortuneatly, further observations and notes are required for any in depth descriptions. But note that all these races have distinct gill attachment traits that adds to the differences!

4. SPORULATION (at what developement stage does it begin?)
   The PF race is a slow maturing shroom. It can grow large and the cap expand, but the gills will still be biege or light colored. Then, after about a day or two, the purple deposits of the spores will appear on the stem, and the gills will be darker brown. But sometimes, sterile specimens will appear. These are shrooms that don't develope spores and the gills remain distinctly light colored (biege - tan - yellowish). They have no spores. I once knew someone who cloned this type of sterile strain and claimed it to be the best in potency, overall. This fits with the observation that potency diminishes as sporulation developes. So without sporulation ever starting, the potency doesn't diminish in relation.

5. TENACIOUSNES (Strength of attachment of the stem base to the cake)
   The PF is the champ at this. Usually the PF shroom has a large base (big foot). In fact, "BIG FOOT" should be the sur name of the PF race. This makes the PF race the most tenacious to the substrate of them all. When harvested, it is common to pull off large chunks of cake in the process.

6. SHAPE SHIFTING (shapes and changes of flush to flush - strain to strain)
   The PF race is the champ in this also. It goes from ugly little abhorts and convoluted dwarfs, to tall robust white thick stemed specimens with large deep reddish colored caps that go to plane and then wildly upturn at full maturity.

7. SIZE TENDANCIES (overall size of the mushroom at maturity)
   Small to about as big as they get.

8. GESTATION PERIOD (generalized time of primordia appearance after inoculation)
   The PF might be the champ here also. It is the first of any of these shrooms observed to form primordia invitro. The others can, but the PF is a speed demon in comparison. And the PF invitro primordiation is far more numerous if allowed to develope and not birth so quick. But also, many if not most of the primordia will abort. The PF shroom is the champ at aborting shrooms also. That is why it has such a love hate relationship with the hobbiests.

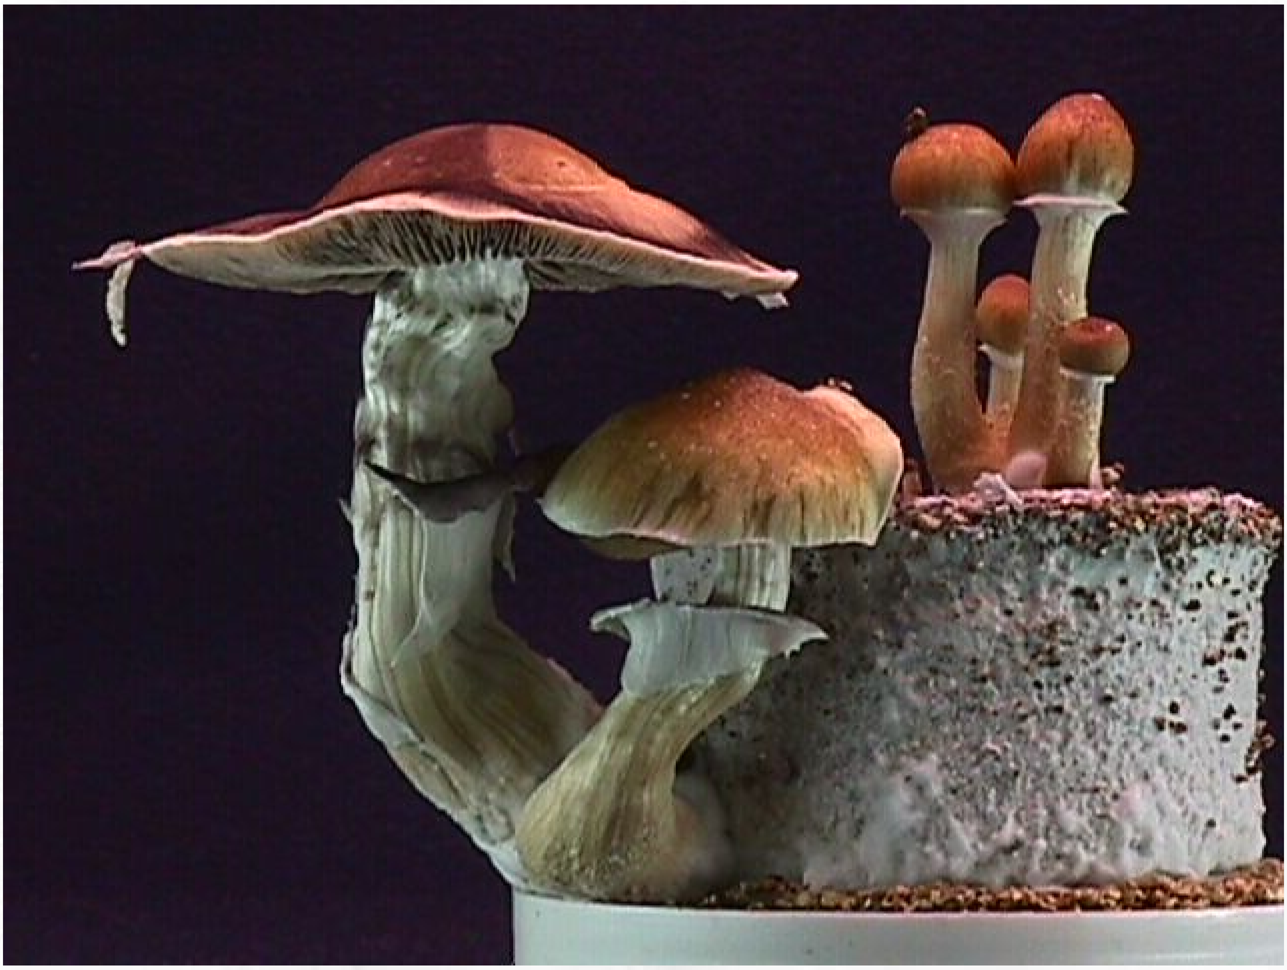
9. POTENCY (This simply comes down to how fast the shroom loses its latent potency - relating to the advent of sporulation)
   The PF potency gets a big thumbs up from everywhere. Its advantage is that is a slow maturer, so it

gives a wider envelope for the shroom to be harvested in its peak potency. A lot of hobbiests rate the PF race number one in potency. But that is not written in stone.

10. FLUSHING (Ability to repeat flush)
    The PF race usually flushes rather poorly on the first flush, giving mostly abhorts. And it can flush nicely the first time. But with a recasing treament. The second flush will be totally different and be excellent. The third flush is always decent and one can squeeze the lemon for nice looking healthy third flush stragglers. But all in all, it is good for three interesting flushes, PF style.

It appears that the PF spore race garners a love hate affair. People either hate it or love it. Even after enduring a severe flogging from the 1999 spore wars (PF copy cats and spore sellers claimed that it was actually a poisonous mushroom - which was believed by the unitiated for a short while). Now, it has regained its favored position amongst a host of mycophiles as either their favorite or at least near the top of the list. Interestingly, there are many who claim that the PF race is the most potent. But then there are many who don't. But whatever the judgement call would be, it is not a bad cubie, so that makes it as good as any, and in my opinion, DAMN good.

Psilocybe cubensis - Hawaiian



This is a photo of a first flush PF style. The cake was birthed without invitro primordiation, given the PF double ended cake casing treatment, and delivered to the basic PF neglect Tek. This spore race actually should be called the "classic". From what PF knows, it was the number one Cubensis cultivar in Holland for many years. There was a fiasco in Holland having to do with a grower (Tim Cyanse - psuedonym) who was supplying shrooms to Dutch head cafes but he went to far. He made cakes and candies with shroom powder (left over from harvesting and drying). This didn't go over to well with the Dutch authorities and a big bust and scandel erupted, even involving the famous German mycologist, Dr. Jochen Gartz.

DESCRIPTION:

1. CAP (size - shape stages - colors)
   Dome shaped to plane. This one doesn't upturn much in extreme maturity. The colors are the usuall flesh (caucasion) color, deep.

2. STEM (length - girth - flesh - colors)
   Slender to thick - whitish when young and mature. It is fibrous and sturdy with a medium length.

3. VEIL (deliquescent - partly deliquescent - persistant anulus)
   The veil is persistant leaving a well defined Stropharia type of anulus. It breaks clean off of the gills and forms a "turtle neck sweater" type of anulus.

4. SPORULATION (at what developement stage does it begin?)
   Sporulation is rampant and begins soon after the veil breaks. And it might even begin as the veil breaks leaving a decidedly purple colored anulus. This shroom is a fast maturer.

5. TENACIOUSNES (Strength of attachment of the stem base to the cake)
   Good tenaciousness, stable during growth and easily picked clean of substrate hanging on.

6. SHAPE SHIFTING (shapes and changes of flush to flush - strain to strain)
   The Hawaiian is a serious shape shifter. From large thick stemed specimens to small petite delicate stemed shrooms.

7. SIZE TENDANCIES (overall size of the mushroom at maturity)
   Small to almost as big as they get.

8. GESTATION PERIOD (generalized time of primordia appearance after inoculation)
   Slower than the PF race. Invitro primordiation is usually unsatisfactory, and birthing and casing are required about after a month.

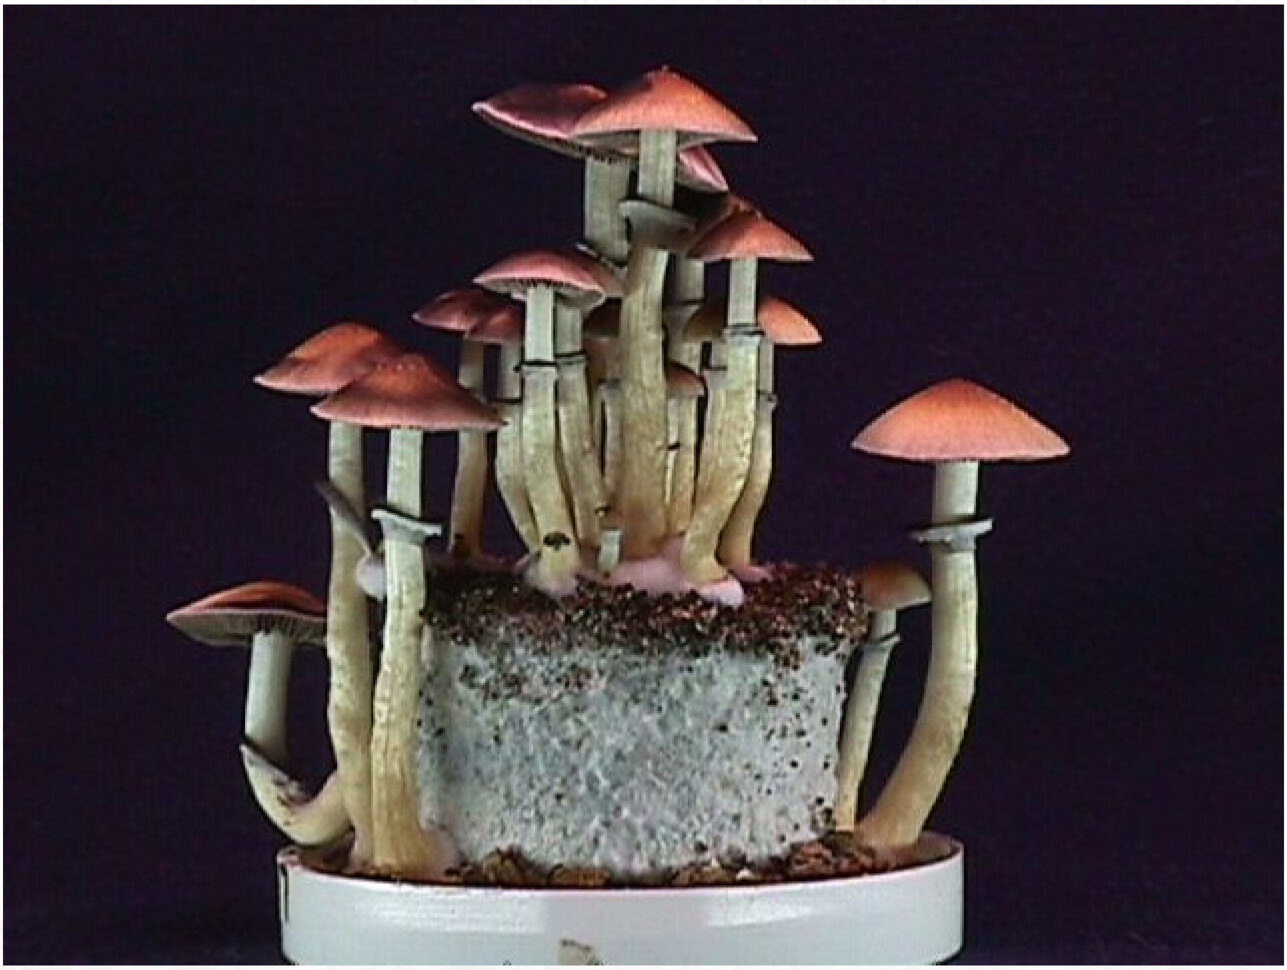
9. POTENCY (This simply comes down to how fast the shroom loses its latent potency - relating to the advent of sporulation)
   As long as this shroom is picked before any purple is observed, it is a good shroom.

10. FLUSHING (Ability to repeat flush)
    The Hawaiian might be the champ at this. First second and third flushes are easy and always look great. They change radically from strain manisfestaion to strain manisfestation, flush to flush. Very few aborts develope with the Hawaiian.

PF got it from a hobby mycologist in Holland (PFE) who was supplying it as a spore sample to Amazing Nature and Smart Botanics (Dutch Weed folks and items for sale). PFE named it "Golden Teacher". He did this because sometimes right before the veils break when the primordia are at their largest size before becoming mature, the entire shroom can have a golden yellowish color which vanishes when maturity starts to set in.

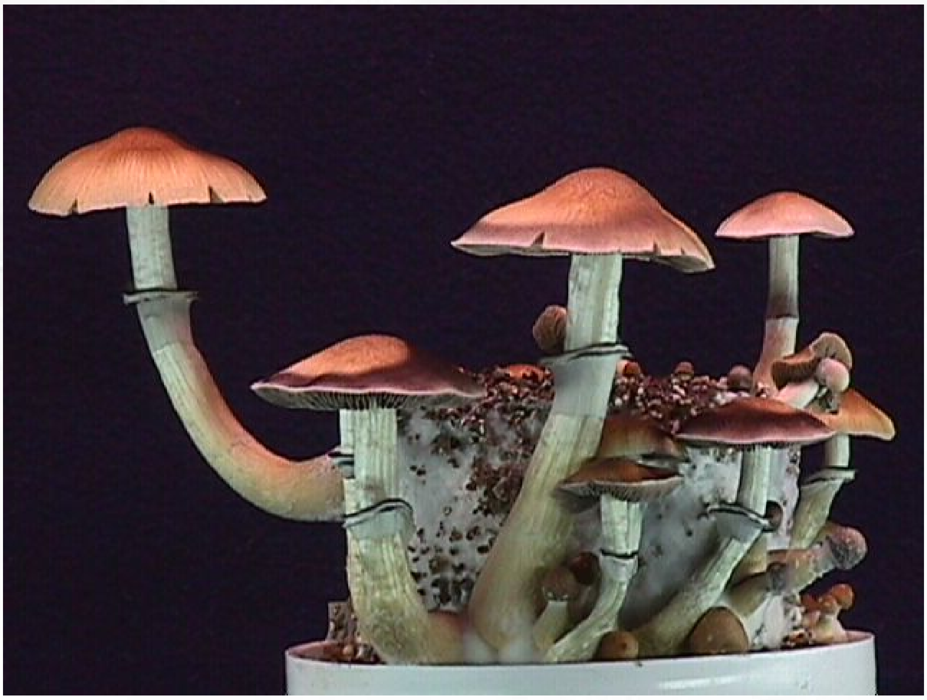
Strangely, the "Golden Teacher" being sold by other spore sellers is being claimed to be different from PF's "Golden Teacher". PFE claims that the Dutch growers got it from Pacific Exotic Spora in Hawaiia. It really doesn't matter where it came from. The reallity of it is that it is a superb Cubensis cultivar, one of the best ever found. It does look like the Cubensis used in the old OSS and OERIC (Mckenna brothers) shroom growing book.

So given the confusion about PES and the so called PES Amazon, PES Hybrid, or PES Hawaiian (all supposedly different), PF is dropping the "PES" from the title and just leaving it, "HAWAIIAN". Actually, Cubensis does not appear in Hawaiia (according to certain "experts"), so then it makes sense for PF just to call it the "Hawaiian", because after all, it is the only shroom spores marketed under a title having anything to do with HAWAIIA. So "Hawaiian" it will be.



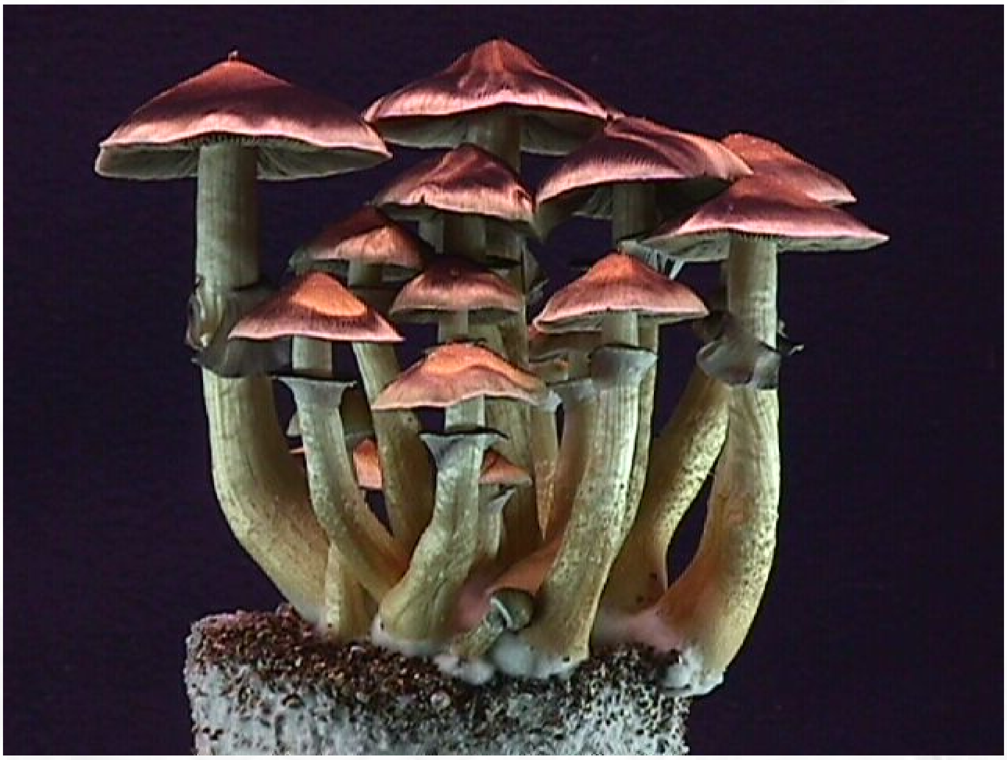
This is a second flush of the Hawaiian. Notice the smaller and thinner stems on this flush as compared to the large white stems on the flush pictured at the front. This could be a cause of the silly confusion about what the "PES Hawaiian" or the "PES GOLDEN TEACHER" or the "PES HYBRID" really is. Methinks they are the same. The Hawaiian is a mighty shape shifter. All in all, PF considers this Hawaiian to be the best cultivar of all (no darts please).

Psilocybe cubensis - JLF Amazon



This spore race was sent to PF on a trade and the sender said it was JLF's "AMAZON". It looks and acts just like the HAWAIIAN of PF. It probably is. This is an example of how these excellent spore races wind up everywhere with different names. But it keys out to the Hawaiian by all of its distinctions. It has the distinct persistant anulus and it is attached "turtle neck sweater" like. It has a white fibrous stem, and the cap and gills look identical.

Psilocybe cubensis - Equador



This is one of the best cultivars. It has appeared for many years. Its first appearance is a cover photo. Paul Stamets first book, "Psilocybe mushrooms and their allies" has the Equador on the cover. This is a very nice second flush and this shroom is a fav of many because of its incredible stature and growing ability.

DESCRIPTION:

1. CAP (size - shape stages - colors)
   dome shaped - doesn't go to plane at maturity but becomes convex. It never upturns. The primordia caps are sometimes a deep purple reddish with white spots.

2. STEM (length - girth - flesh - colors)
   Fibrous, sturdy, thick and whitish.

3. VEIL (deliquescent - partly deliquescent - persistant anulus)
   The veil is persistant, leaving a skirt like anulus attached to the stem.

4. SPORULATION (at what developement stage does it begin?)
   It begins quickly, maturing fast after veil break.

5. TENACIOUSNES (Strength of attachment of the stem base to the cake)
   Moderately attached and easy to pick cleanly.

6. SHAPE SHIFTING (shapes and changes of flush to flush - strain to strain)
   Very little shape shifting - a very stable appearing shroom from strain to strain.

7. SIZE TENDANCIES (overall size of the mushroom at maturity)

From small to about as big as they get.

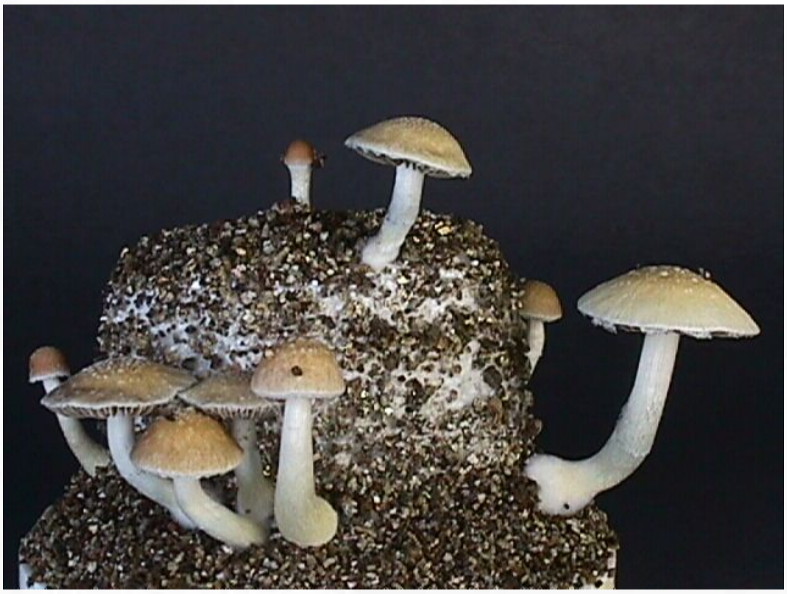
8. GESTATION PERIOD (generalized time of primordia appearance after inoculation)
   Like the Hawaiian, longer than the PF, and not a very good invitro primordiator. It can primordiate and give some perfect specimens, but it does better to birth after about a month and give it the PF double ended cake casing treatment.

9. POTENCY (This simply comes down to how fast the shroom loses its latent potency - relating to the advent of sporulation)
   This is a fast maturer, so the specimens must be picked in advanced primordia stage right before veil breakage for good potency.

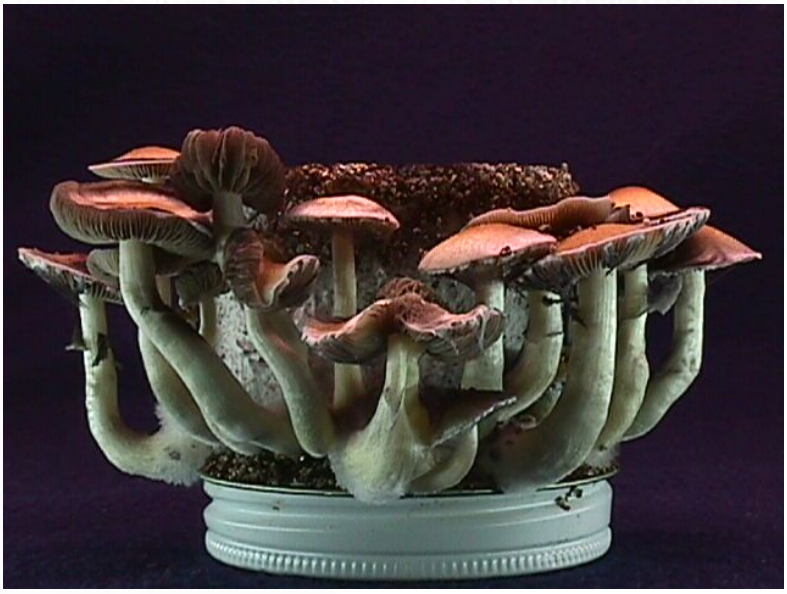
10. FLUSHING (Ability to repeat flush)
    It is a great flusher, giving three really good PF style flushes and more if the lemon is to be squeezed.

And, like the Hawaiian (Golden Teacher from PFE), it glows a yellowish hue from top to bottom right before the veil breaks. Then it quickly loses the gold color.

False Mexicana

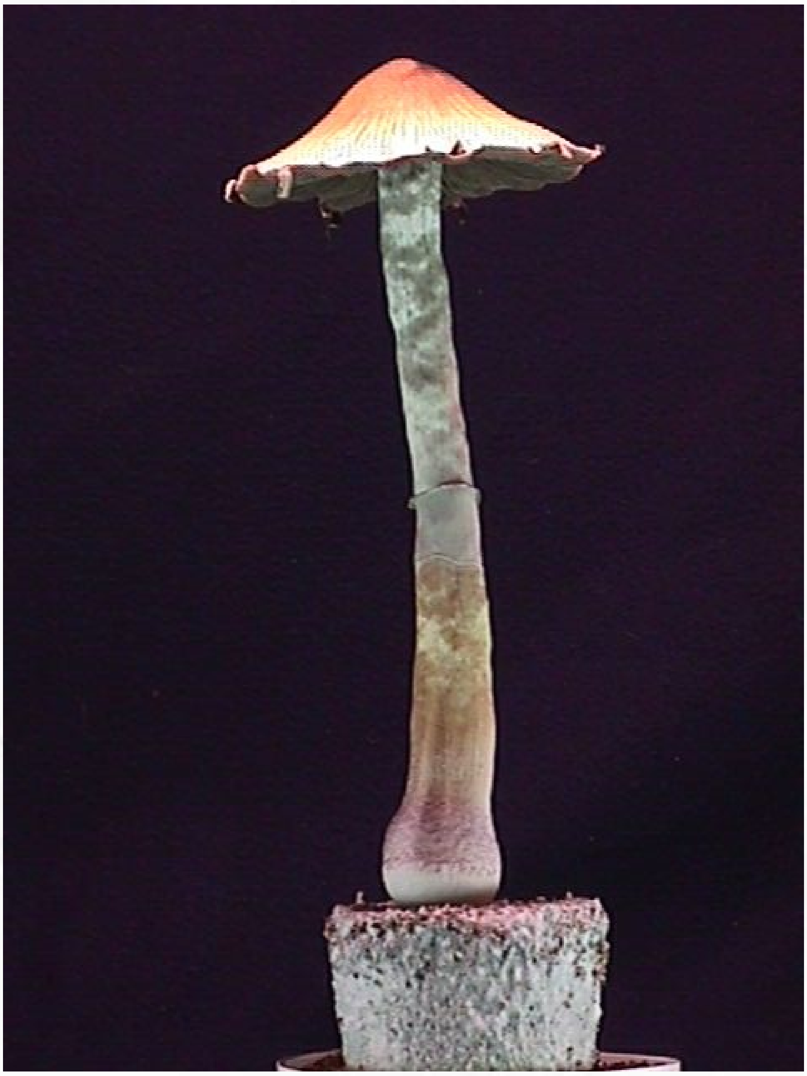


This mushroom started a real fury in the beggining of 1999. On the alt.drugs.mushrooms newsgroup, a spore seller appeared called FOGGY MOUNTAIN FARMS. They advertised a PSILOCYBE MEXICANA spore syringe and prints. Along with PANEOLOUS TROPICALIS and others, they offered the absurd "Azurescens Cubensis B+ hybrid". PF posted that it was a rip, and then the beginning of the 1999 spore wars took off. It turns out to have been a cubensis (as PF insisted). Then it was named MEXI-CUB.
This is an interesting little cubensis. That is exactly what it is, a small cubie. That is what they call it in Europe. The PF style flushes are small, but they are numerous over time. It likes to flush several times and each flush is incredibly different then the last. This is a surprising little shroom. Sometimes, it looks just like a pan cyan with no anulus, smooth slender white stem and dome like cap. But then, it can be medium sized with a large cap that goes to plane at maturity. The larger appearing strains have a cap color that is light with an orangish center. With PF style growing, this shroom never seems to want to get very big.



This is the photo PF uses for the PF ad in High Times magazine. As can be seen, this flush is much different from the above flush. It's a shape shifter.

Psilocybe cubensis - B+

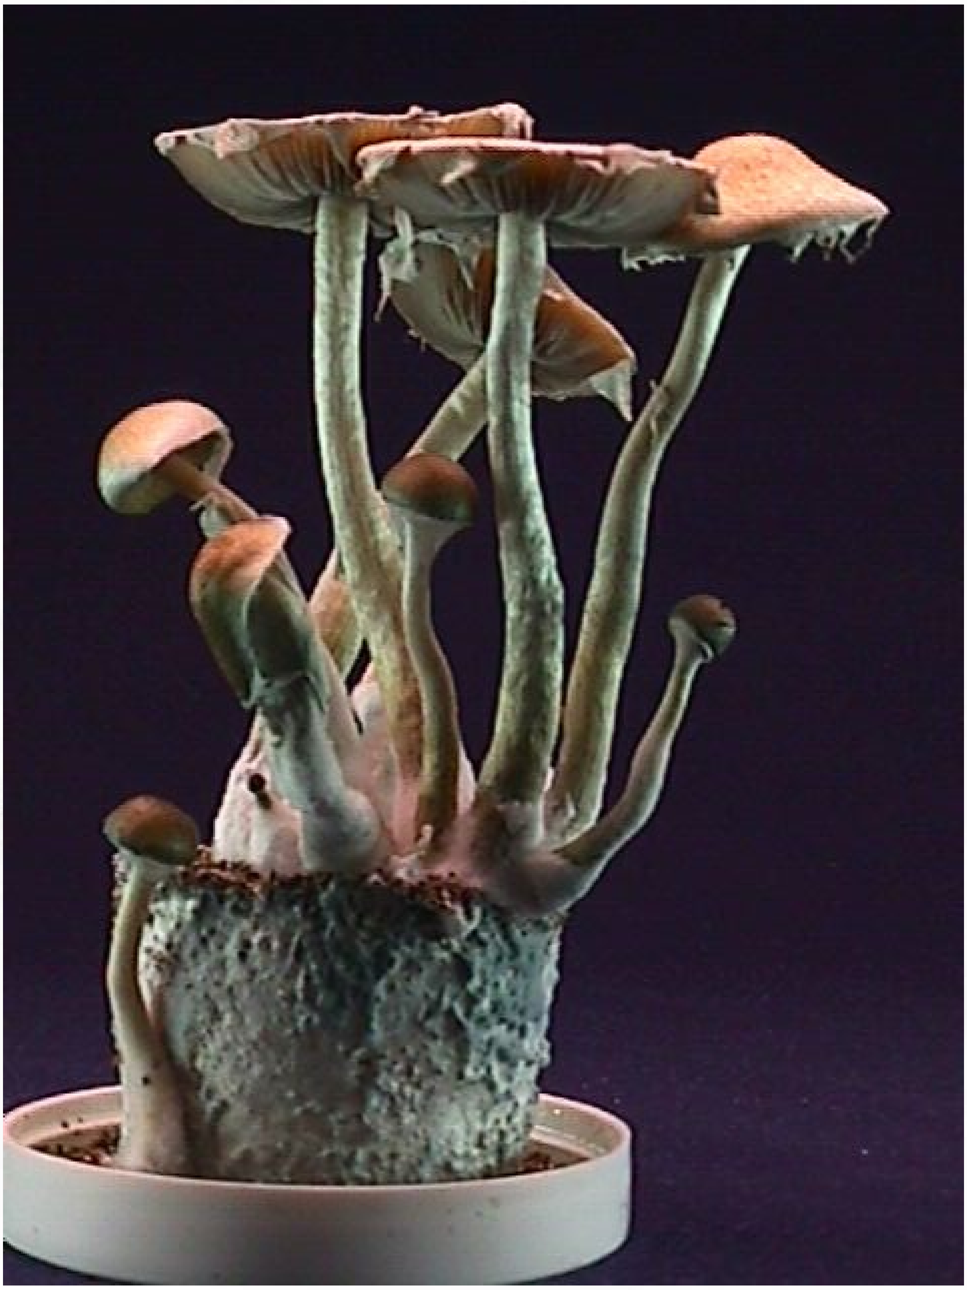


This cubie has been around the web for a few years. It is the favorite of certain spore peddlers. The original is called "Herbens B+ strain". From what I have seen, B means big and the + means very (very big).

Also, this shroom is the most hyped cubensis in history. There are many youthfull pop mycologists around the internet that are still debating about this shroom being some kind of Psilocybe Azurescens cubensis "HYBRID". And there have been various spore sellers that advertise it as that. But of course, it is just a cubensis. The shroom in the photo is growing on a 1/2 pint PF cake. The cultivation procedure was identical to the others. Temperature ranges are the same and it likes to be birthed and cased. Invitro primordiation seems fairly nil.

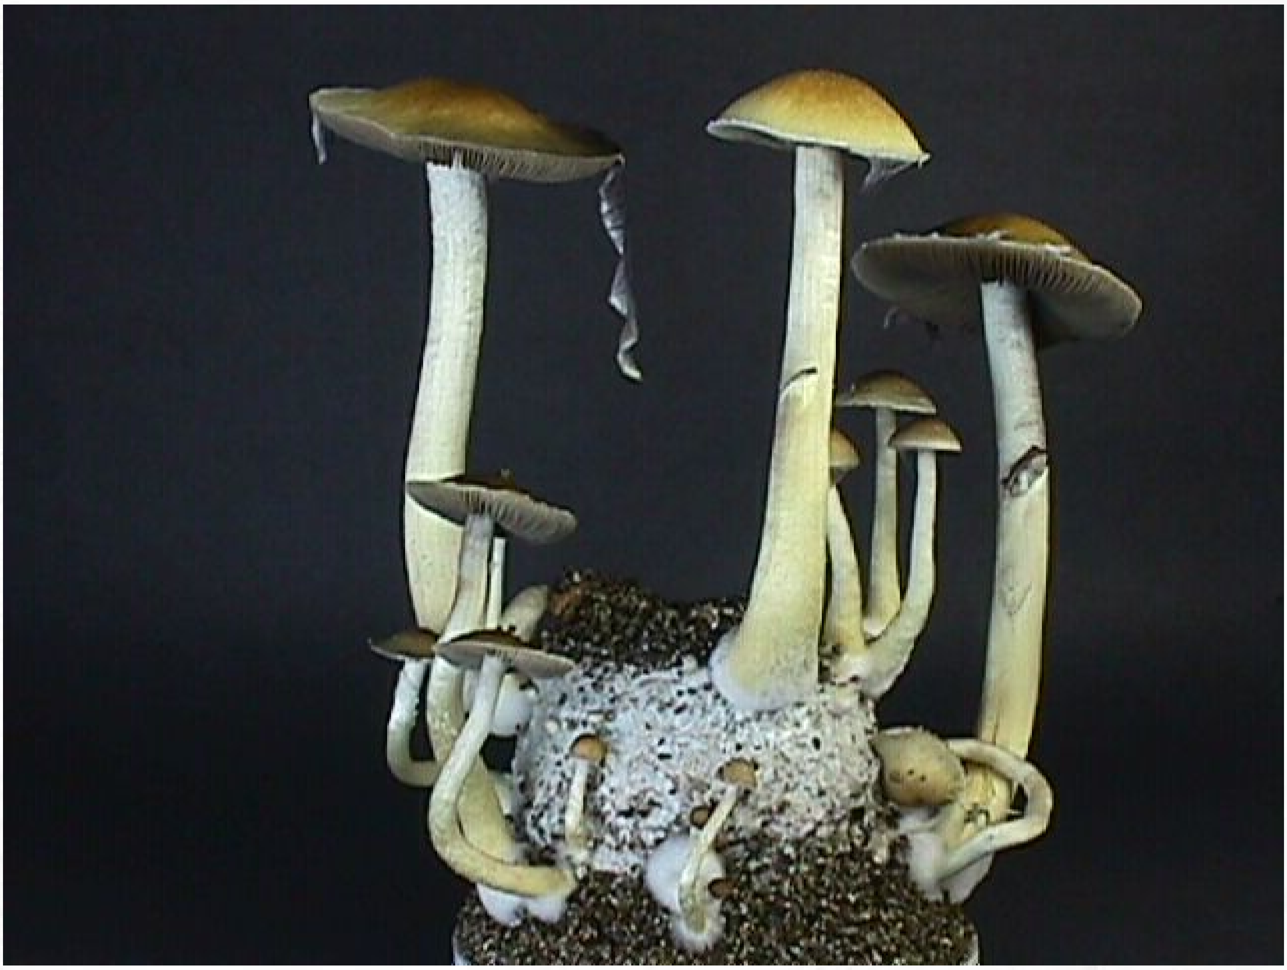
In comparing this one to the others, its size can be determined by using the cakes as a reference (all 1/2 pint size). Its veil becomes a persistant anulus, attached to the stem "turtle neck sweater" style. It has a fibrous slender long stem, and large cap that doesn't seem to go to full plane and never upturns. It seems to clearly to be the champ at long stems and specimen height. It is not tenasciously attached to the substrate, so it has a tendancy when grown PF style, to grow tall and fall over (tip the cake or just break off from the substrate when in the wrong position). It is the tallest growing cubensis around, and it has many fans. But just because it is the biggest, doesn't mean it is the best. It had a fierce reputation as being the most potent, but after time has passed and this shroom got around, it turns out to be no better than any other Cubensis in potency. And since this too is a fast maturing shroom, it must be picked presporulation for max potency. It should be picked in its advanced primordia stage, with the veil still unbroken.

Psilocybe cubensis - Treasure Coast



Psilocybe cubensis - Cambodian

This spore race was sent to PF on a trade and the sender said it was MYCO TECH (Seattle) Cambodian.



DESCRIPTION:

1. CAP (size - shape stages - colors)
   Becoming plane in age and not upturning. The cap seems to have dark colors in it as well as the usuall purplish streaks from wandering clouds of spores.

2. STEM (length - girth - flesh - colors)
   Whitish, fibrous and hefty slender with a medium length.

3. VEIL (deliquescent - partly deliquescent - persistant anulus)
   The veil is decidedly deliquescent.

4. SPORULATION (at what developement stage does it begin?)
   Not a real fast maturer, just a little slower than the EQ or HA.

5. TENACIOUSNES (Strength of attachment of the stem base to the cake)
   Well secured to the cake. It is not big enough to want to fall over.

6. SHAPE SHIFTING (shapes and changes of flush to flush - strain to strain)
   Stable.

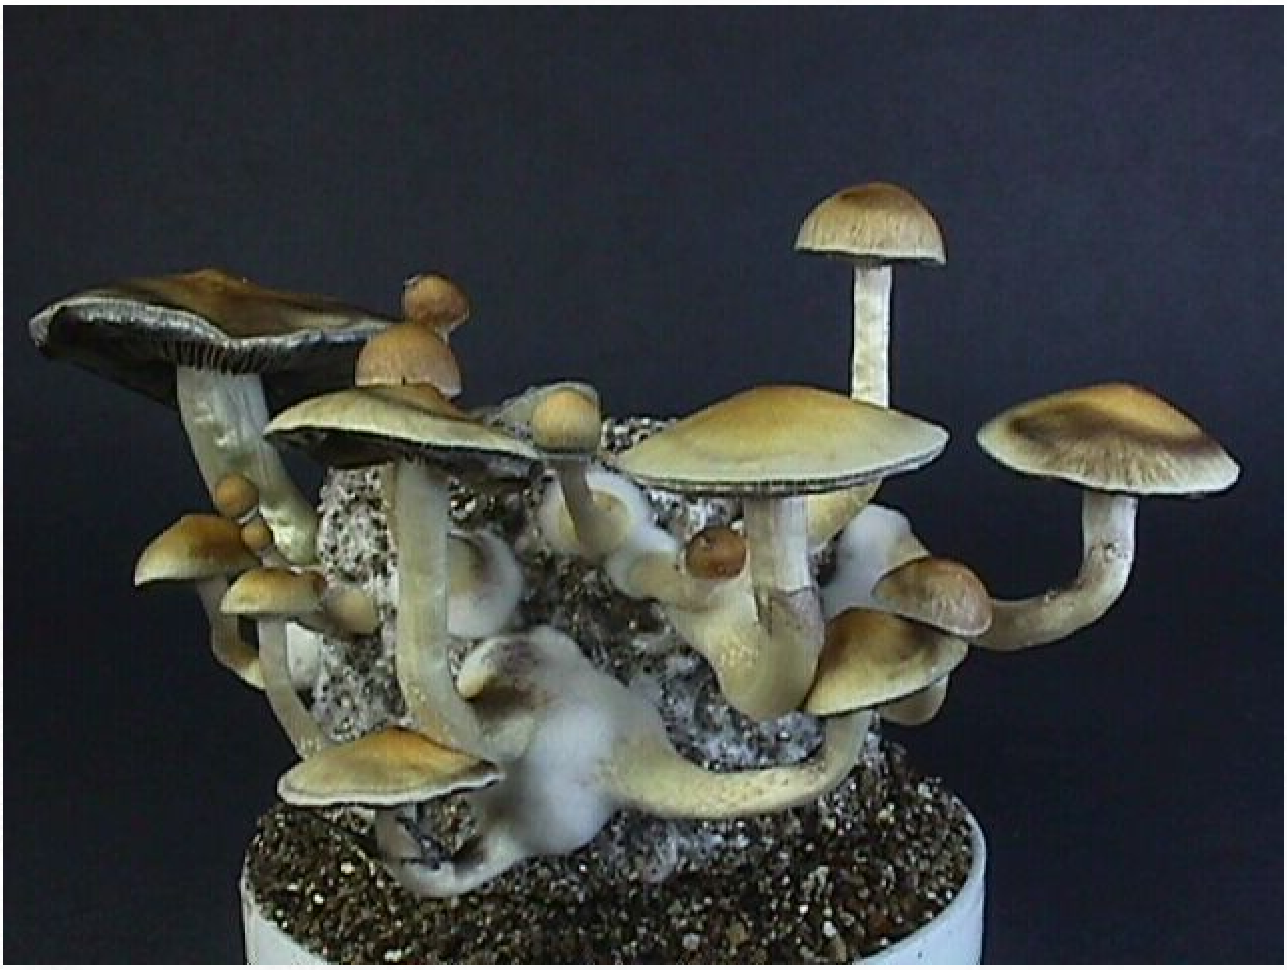
7. SIZE TENDANCIES (overall size of the mushroom at maturity)
   From small to as big as they get.

8. GESTATION PERIOD (generalized time of primordia appearance after inoculation)
   Similar to the EQ or HA.

9. POTENCY (This simply comes down to how fast the shroom loses its latent potency - relating to the advent of sporulation)
   Probably as good as any. Just pick it presporulation.

10. FLUSHING (Ability to repeat flush)
    Unknown, but probably as good as any.

Psilocybe cubensis - Thailand



This spore race was sent to PF on a trade and the sender said it was MYCO TECH (Seattle) THAILAND.

DESCRIPTION:

1. CAP (size - shape stages - colors)
   It goes to plane on maturity and doesn't seem to want to upturn. It is lighter than a lot of cubies.

2. STEM (length - girth - flesh - colors)
   Slender white and fibrous. Medium length at most.

3. VEIL (deliquescent - partly deliquescent - persistant anulus)
   Veil is deliquescent.

4. SPORULATION (at what developement stage does it begin?)
   The Thai is kind of like the Treasure Coast. It is a slow maturer and a weak sporulator.

5. TENACIOUSNES (Strength of attachment of the stem base to the cake)
   Moderate with good stability PF style.

6. SHAPE SHIFTING (shapes and changes of flush to flush - strain to strain)
   Appears stable.

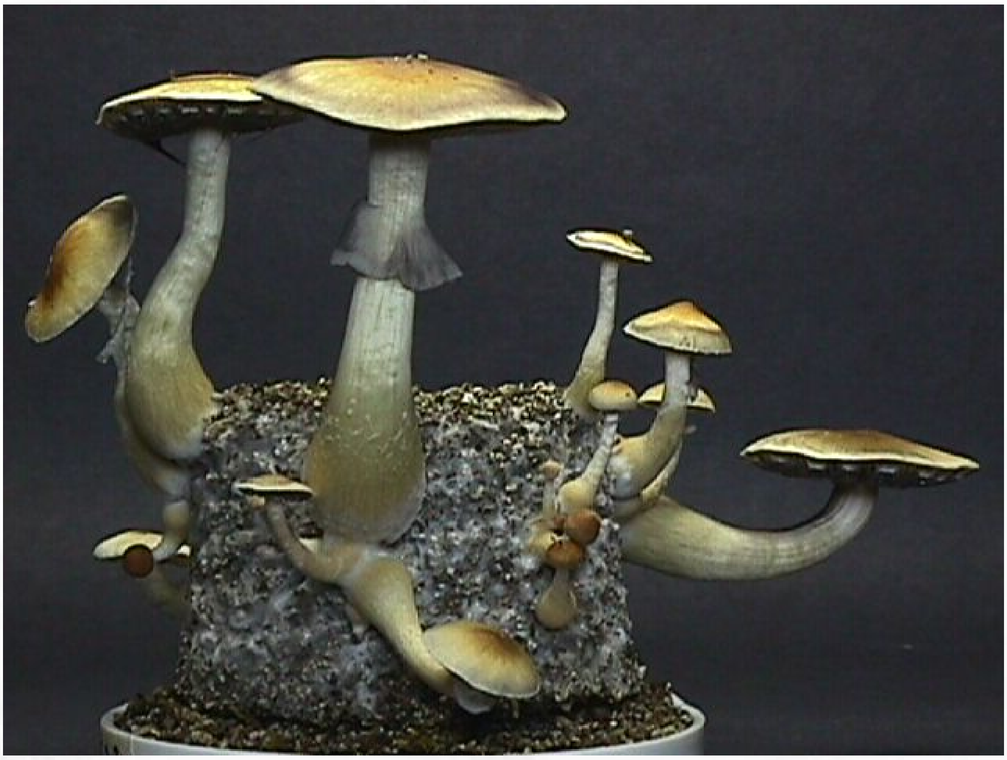
7. SIZE TENDANCIES (overall size of the mushroom at maturity)
   Tiny to moderate.

8. GESTATION PERIOD (generalized time of primordia appearance after inoculation)
   Average - like the HA.

9. POTENCY (This simply comes down to how fast the shroom loses its latent potency - relating to the advent of sporulation)
   Due to its late maturing, the envelope is wide to get quality potency before maturing.

10. FLUSHING (Ability to repeat flush)
    Unknown but probably as good as any.

Psilocybe cubensis - Malaysian



This spore race was sent to PF on a trade and the sender said it was MYCO TECH (Seattle) MALAYSIAN.

DESCRIPTION:

1. CAP (size - shape stages - colors)
   It doesn't upturn at full maturity, but goes to plane. The colors are the usuall.

2. STEM (length - girth - flesh - colors)
   Whitish, fibrous and hefty slender.

3. VEIL (deliquescent - partly deliquescent - persistant anulus)
   This one is a combo. It has a fully deliquescent veil and also can leave behind an EQ style "skirt" persistant anulus. Very mystifying.

4. SPORULATION (at what developement stage does it begin?)
   Not an early maturer.

5. TENACIOUSNES (Strength of attachment of the stem base to the cake)
   Moderate.

6. SHAPE SHIFTING (shapes and changes of flush to flush - strain to strain)
   Stable - few aborts.

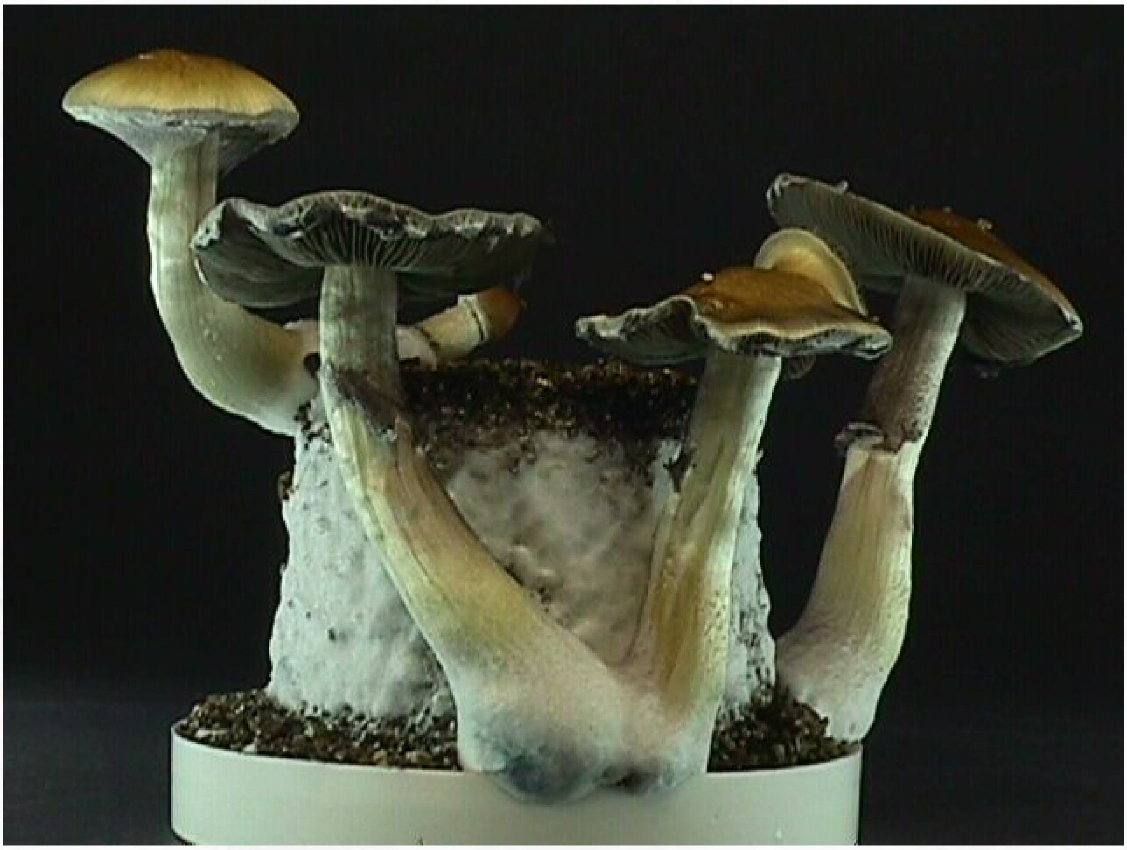
7. SIZE TENDANCIES (overall size of the mushroom at maturity)
   Tiny to moderate.

8. GESTATION PERIOD (generalized time of primordia appearance after inoculation)
   Similar to the EQ or HA - moderate.

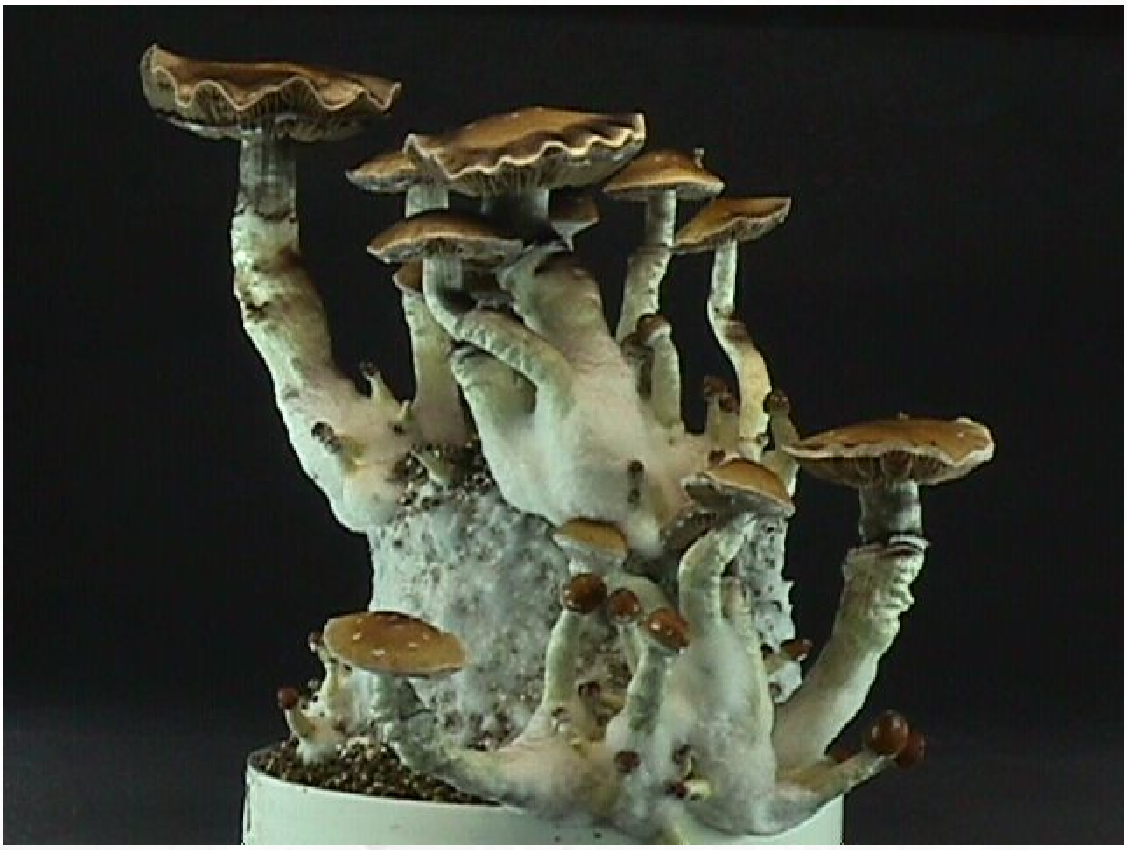
9. POTENCY (This simply comes down to how fast the shroom loses its latent potency - relating to the advent of sporulation)
   Pick presporulation.

10. FLUSHING (Ability to repeat flush)
    Looks good and probably will flush several times with proper care.

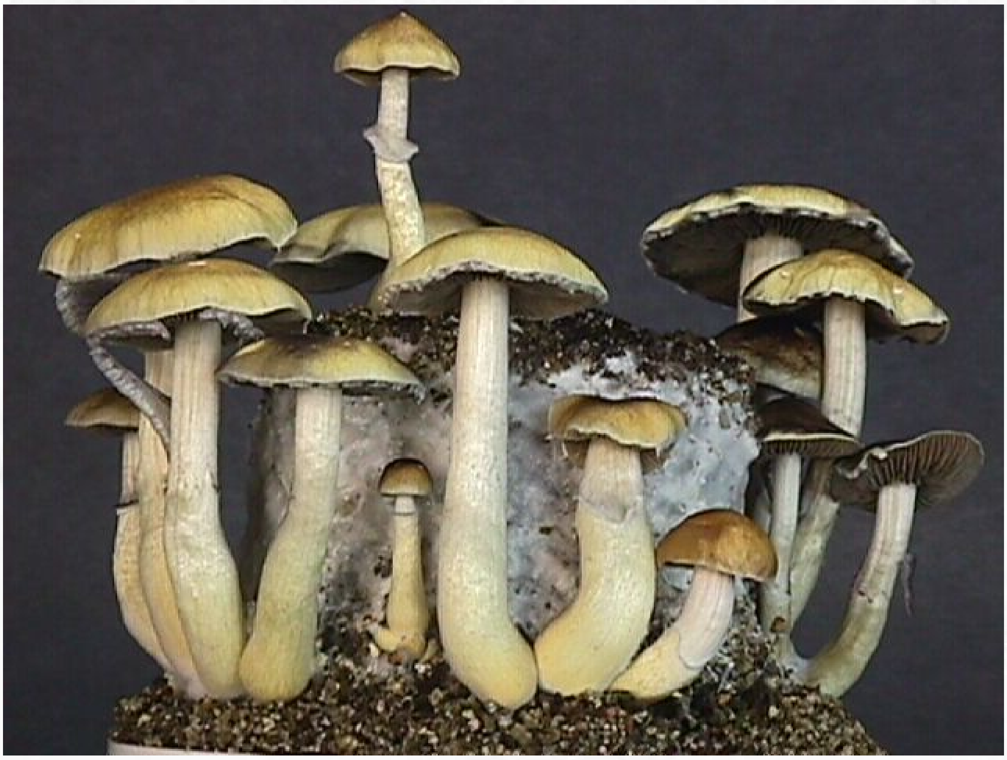
Psilocybe cubensis - Australian



Psilocybe cubensis - India

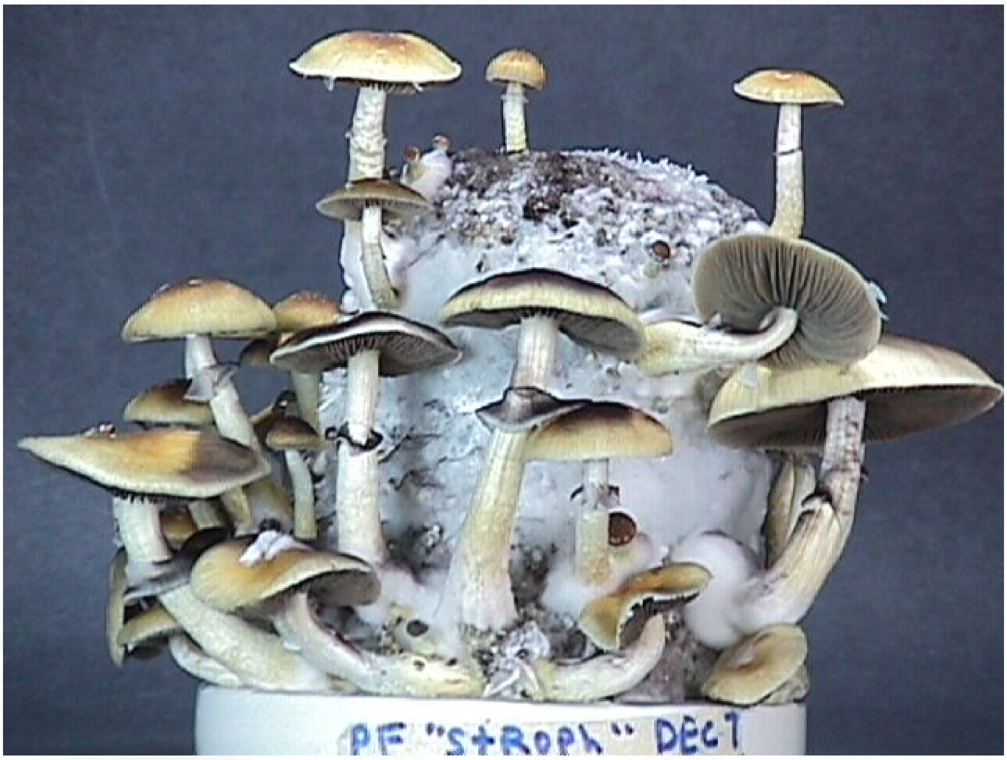


Psilocybe cubensis - Mazatec



This cubensis race looks like a cross between the Mexi-cub (false Mexicana) and the Equador. When the stem is cut, it seems to consistantly bruize deep azure. The Maz yields very well. This is one of the best PF has tested. The Mazatec is a small but refined cubie with whitish smooth stem flesh, apparantly more "dense" and less watery than the larger growing races (Equador, B+, Cambodian ect). A big thumbs up for the Maz!

Psilocybe cubensis - PF Stropharia



Yachaj describes the PF Stropharia

The PF Stropharia combines a great sporulation capacity with an easily printable cap (no slimey veil remnants hanging from it), an extremely agressive mycelium, strong blueing of the flesh, a solid stem and a top notch harvest on PF Substrate (usually in bouquets of smaller potent mushrooms instead of a few weak large ones). It is a winner on all qualities which are important for a cubie except for its pinning speed (PF Classic is faster).

Please help to preserve this unique Psilocybe cubensis race. Spread its spores as prolific as possible but - do not change the name PF Stropharia. This genotype was a present from me to PF. Everybody may distribute its spores, but the name stays. - do not change the substrate. This is a PF TEK / hippie tek only cubie!

The origin of the PF Stropharia

At this moment there are two versions of the story. According to my notes the PF Stropharia was born in January 1997. It came up in a jar of PF Substrate which was gamma ray sterilized instead of steam sterilized. The difference between cold and hot sterilization is that in cold sterilizations (with gamma flash) the substrate remains raw. The mycelia have a slight difficulty in colonizing it and pinning is delayed. This is not an advantage so I terminated the gamma flash experiments, but according to my notes the PF Stropharia came up from one of those jars - from PF Classic spores obtained from PF in 1995.

But as anyone can see, the PF Stropharia looks very different from the PF Classic. It has scales on the cap while the PF Classic is smooth. It has a ring around the stem, the mycelium is much denser. It doesn't look like a PF Classic offspring at all.

So PF's explanation of this that I made a mistake. That the PF Stropharia is a genotype I received from someone else and that I mislabeled the jars.

When I look at the mushroom I would say that PF is right. His explanation is the most simple one and in science the simplest explanations are usually right. The Stropharia is too different from the Classic to be offspring. But at the same time this explanation is difficult for me to accept because I didn't have so many different cubies back then. I had only 2 cubies which liked PF Substrate (the PF classic and the 'Amazonian' from the Hawaiian vendor Pacific Exotic Spora which PF now distributes under the name 'Hawaiian'). So if I mislableled the jar then still the origin of the PF Stropharia is a mystery.

The meaning of PF "Stropharia"

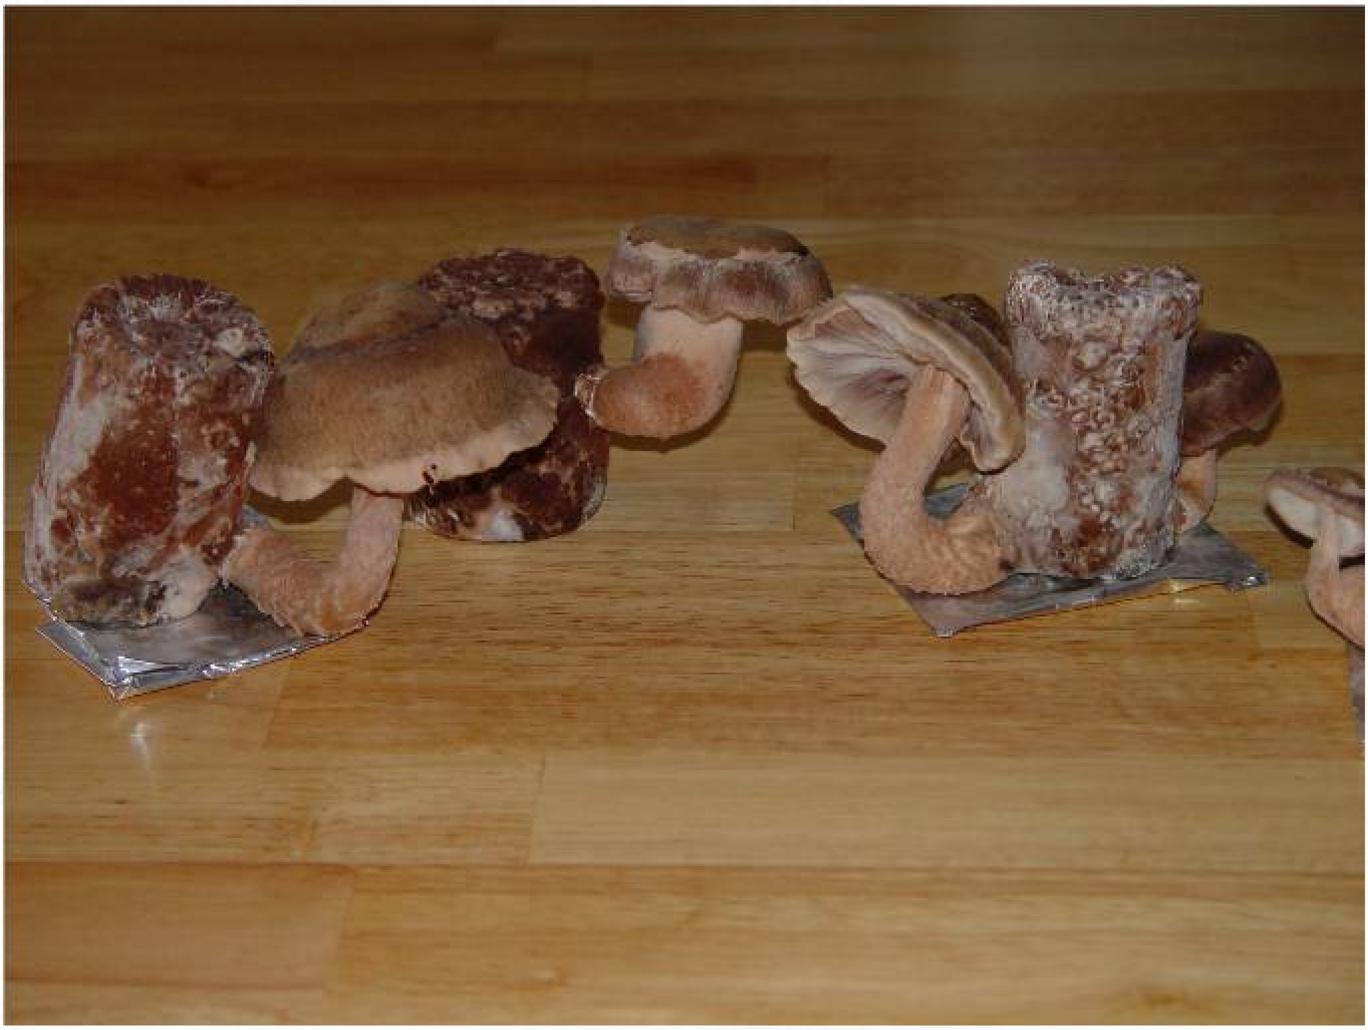
The name PF refers to Psylocybe Fanaticus, the inventor of the substrate which this cubensis race seems to like best. Stropharia refers to the appearance of it. The veil which protects the spores during the first stage of the mushroom growth sticks to the stem when the cap unfolds, leaving a ring. This looks like a belt. Stropharia means Swortbelt in Greek.

Yachaj (RENE of Perfect Fungi Europe - PFE)

PF Style Shitake

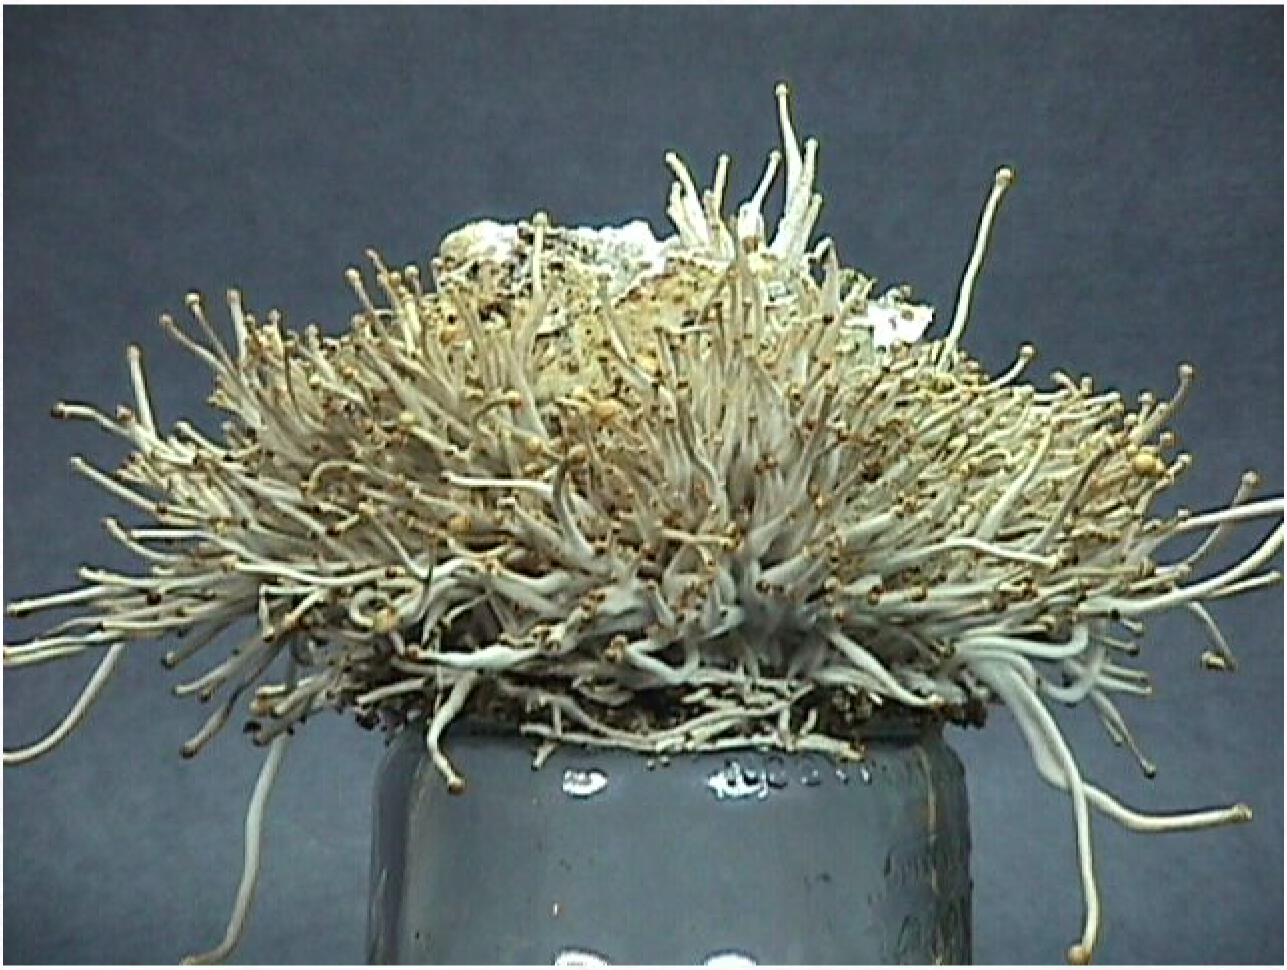
I lost my photos of shitake on BRF cakes (B is brown, R is rice, and F is flour) - aka PF TEK cakes. Here is a post and photo by a dude called Bluecat, someone who I have talked to on the Mycotopia web site. The photo follows the post. They are pretty ugly huh? That is the mycelium with the ugly discolorizations, but it isn't contaminated. That's the way the shitake mycelium acts. Bluecat uses half the amount of brown rice flour (1/8 cup) instead of the usual 1/4 cup. 1/8 cup of brown rice flour (BRF) works very well with the magic shrooms.

By bluecat (Bluecat) Member Username: Bluecat Post Number: 34 Registered: 05-2003 Posted on Tuesday, May 11, 2004 - 01:24 am:
I tried the same experiment hundreds of times.the regular pf half pints with no sawdust are always the best.both faster,and more productive.you really only need one plug per jar,right down the middle.i get the best results with just over 1/8 cup brf.if you use much more than that,they get sticky and grow slower.good luck,have fun.



This is the "gourmet" edible mushroom - SHITAKE (Lentinus Edodes). It was cultivated with the straight PF TEK. Instead of spores, SHITAKE spawn "plugs" were inserted into the jars substrait. After about 3 months, the cake turned black and the mushrooms formed. The black looking cake is actually just the outer surface. This is where the mycelium dies back but under the black "skin", the cake was a normal whiteish colored mycelium.

Stropharia Melanosperma



This is a mushroom from ISRAEL. Spores of it were sent to me and I cultured it with an altered PF substrate formula. Instead of brown rice powder, I used wheat grain powder. All the ratios were the same as in the standard PF formula. It is not a magic shroom but it is considered to be an edible. I couldn't get any spores from this mushroom. It doesn't grow normally with this tek, but it sure looks strange.

EXTERNAL UPDATES

PF-Tek for Simple Minds

original source: http://www.fungifun.org/English/Pftek

Introduction

The whole grains and dung.

The PF-Tek for Simple Minds uses ½ pint (~240ml) canning jars or drinking glasses and a growing substrate made of vermiculite, brown rice flour and water. The substrate is mixed, filled in jars, sterilized and inoculated with mushroom spores. After the substrate is fully colonized the substrate cakes fruit in a humid container.

On the subject of cleanliness

By growing mushrooms indoors on a nutritious substrate you create conditions than not only favor the growth of the mushrooms, but also the growth of a large number of other organisms (molds, bacteria), many of them potentially hazardous to the health. To ensure that only the desired mushroom is grown, it is very important to assure cleanliness in all of the cultivation related procedures.

Before you work, wash your hands with (antibacterial) soap and warm water. Afterwards, wipe them dry and rub with Lysol or isopropyl alcohol (iso-propanol). Keep the place where you do the inoculation and fruiting dust free and clean and don't bring in dirty clothing or shoes. Personal hygiene is equally important. Dirty hands and even dirty hair are a hotbed for all kinds of unwanted microorganisms which can destroy your cultivation project.

Materials

Most materials are easily avaliable at the local shops.

Vermiculite

Vermiculite is made from a naturally occurring mineral - mica.
Crushed mica containing water is heated and expands to a volume several times greater than that of the untreated mica.
Vermiculite is able to hold several times its own weight in water and it gives the substrate an airy structure.
Vermiculite is available in several grades, the middle and the middle-fine grade are most suitable for cultivation purposes.

Ebay:

Canada - www.auroralighting.ca

United Kingdom - www.gro-lite.co.uk

Australia - users.bigpond.net.au/nutriflo/

Generally you can get vermiculite in garden and hydroponic stores, in some regions also in pet shops.

Brown rice flour (BRF)

BRF is available in health food shops either already ground, sometimes though there is only whole brown rice available. In this case you can grind the rice either in the shop or if this option is not available, grind your own using an electric coffee grinder.

Brown Rice
Brown Rice Flour

Bob's Red Mill
WHOLE GRAIN
BROWN RICE FLOUR
STONE GROUND

Bob's Red Mill Rice Flour Brown

BRF is also available at Ebay:
BRF is best kept cool and dry for prolonged periods of time, since it can easily become rancid because of the fat content of its husk.
If you are unable to find BRF you can also use whole rye flour, ground millet or ground millet based birdseed with similar results.

Water

Water used for the substrate preparation should have drinking water quality. Tap water is usually OK, but if you're not sure about it, better use bottled drinking water or mineral water.

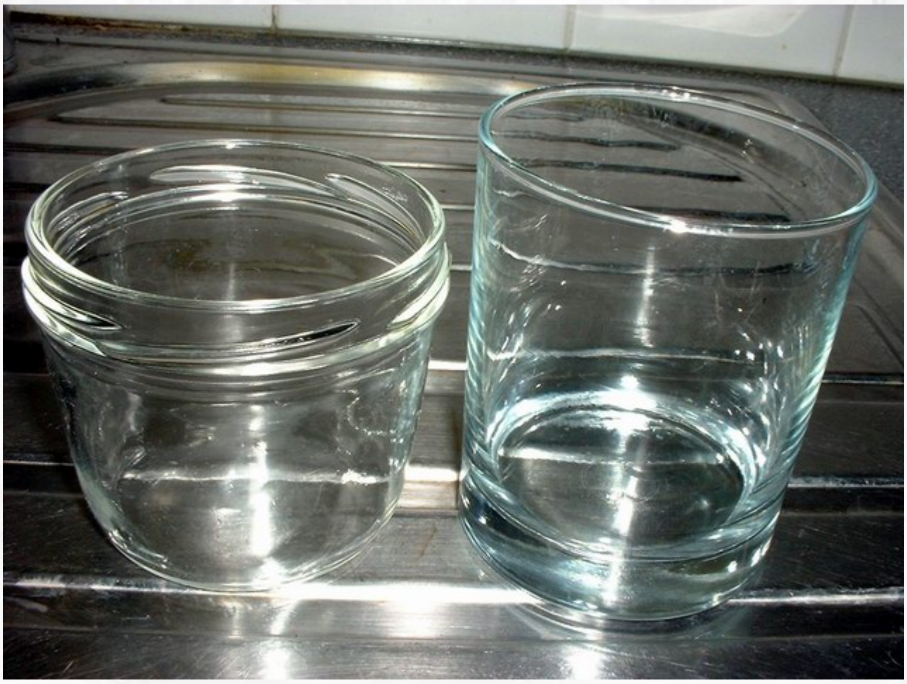
Spore syringe

A plastic syringe with needle attached containing 10cc-12cc suspension of mushroom spores in water.
The color of the suspension varies from completely translucent to slightly violet depending on the quantity of the spores in the solution.
Spores are microscopic so as long as you see at least a few specks in more or less clear water the syringe should have plenty of spores.

Available through the internet, for instance
www.sporeworks.com
www.thehawkseye.com
and many more.

Jars

The jars should have a content of around ½ pint (~240ml).
You can use either canning jars (Ball, Kerr...) or drinking glasses, the only requirement is that they are tapered and without shoulders, so you can slide the cake out of it in one piece once it's colonized. Bigger jars take much longer to colonize and are not recommended.



Kerr 0500 wide mouth mason jar
half pint, 8oz

Shroomery FAQ: Where can I find supplies in the USA?
Shroomery FAQ: Where can I find supplies in the UK?

Substrate preparation

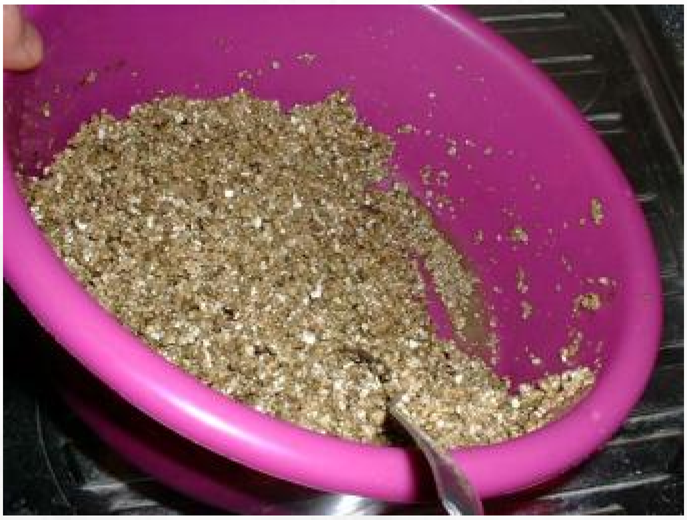
For **one ½ pint jar**(~240 ml) you will need:
=> 140 ml vermiculite
=> 40 ml brown rice flour
=> some vermiculite to fill the jar to the top (app. 20 ml)
=> water

For **6 jars**, this amounts to:
=> 3.5 US cups vermiculite
=> 1 US cup brown rice flour

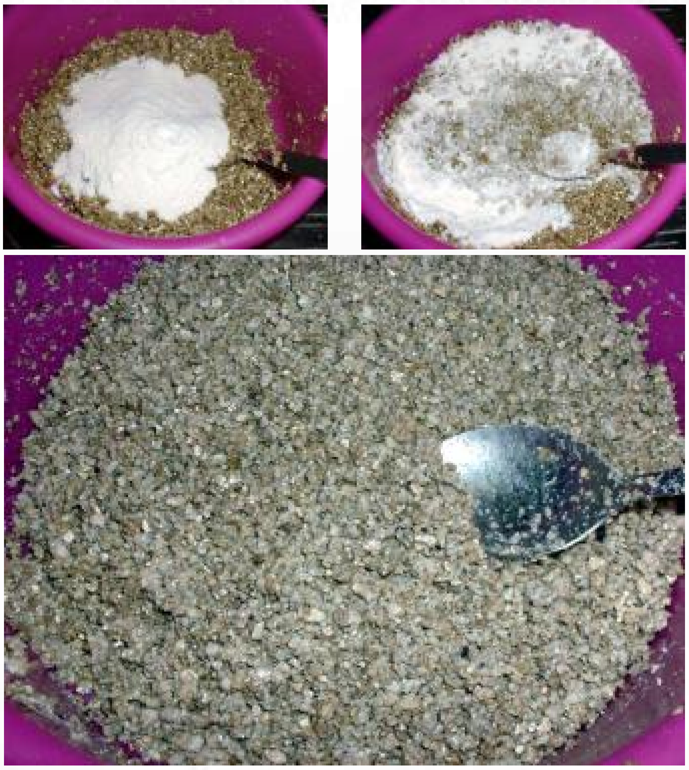
Note:
½ pt (US pint) = 1cp (US cup) = 236ml (milliliter) = 236cc (cubic centimeter) = $^1/_4$ qt(US quart)

Put the required amount of vermiculite for all the jars of one batch (for instance 6 jars: 6 x 140 ml = 840 ml ~ 3.5 US cups) in a bowl.

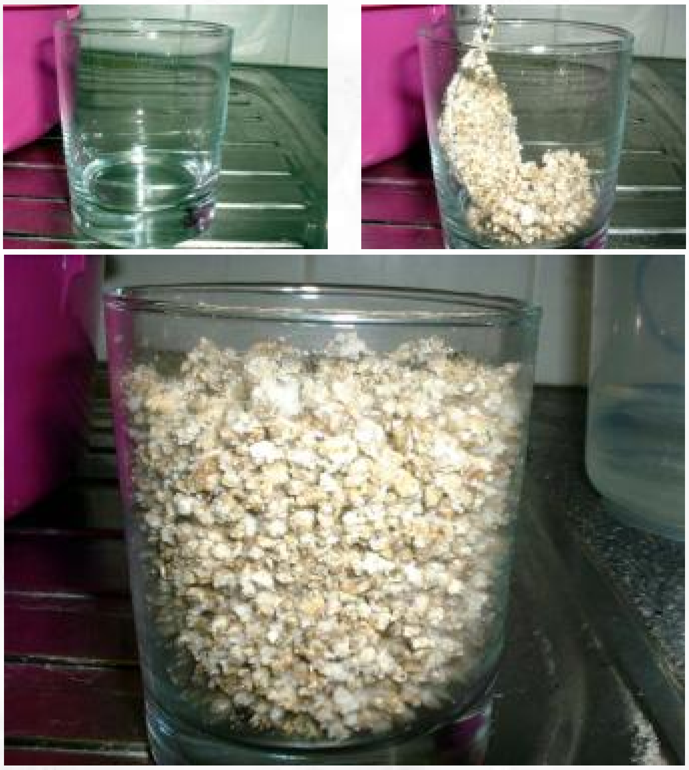
Pour water slowly over the vermiculite while stirring with a spoon. Be careful to only put that much water in as it can be absorbed by the vermiculite. Stir it well so all the vermiculite is uniformly soaked with water.



When you tilt the bowl you should see just a little water starting coming from the vermiculite. This is when the correct water content is achieved. If there is too much water in the bowl, pour the wet vermiculite in a strainer and let the excess water drain for a minute. Then the vermiculite will be at the field capacity, which is perfect.

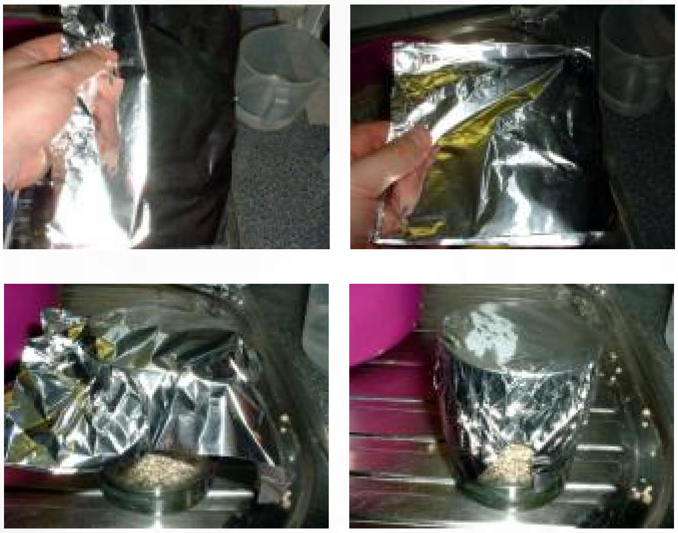


Now put the required amount of the BRF (for instance 6 x 40 ml = 240 ml = 1 US cup) into the wet vermiculite at once and mix it in with the spoon. The goal is to uniformly coat the wet vermiculite particles with a layer of BRF.

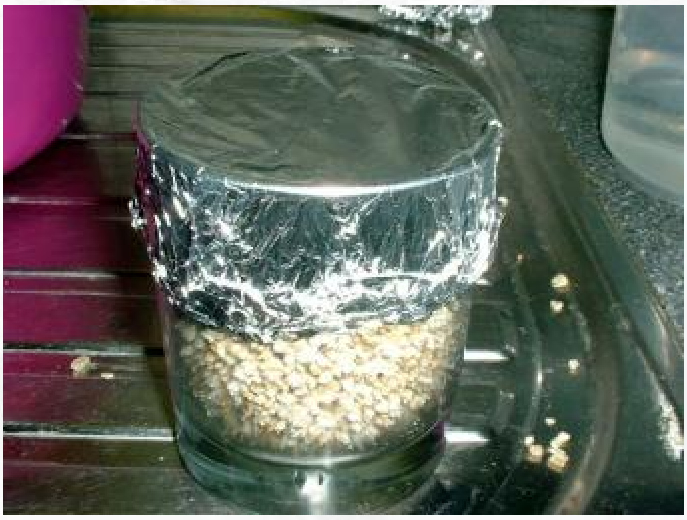


Fill the mixture in jars $^1/_2$ inch (1cm) under the top. It's very important to fill the substrate in the jars without tapping it down at all. It should stay very airy and loose to provide optimum conditions for the growth of mycelium. Be careful not to leave any substrate on the upper edge of the jar. If you weren't careful enough and there are some substrate specks at the edge take a clean moist cloth and wipe the upper portion of the jar clean. Otherwise contaminants can start at those spots and work their way down into the jar.

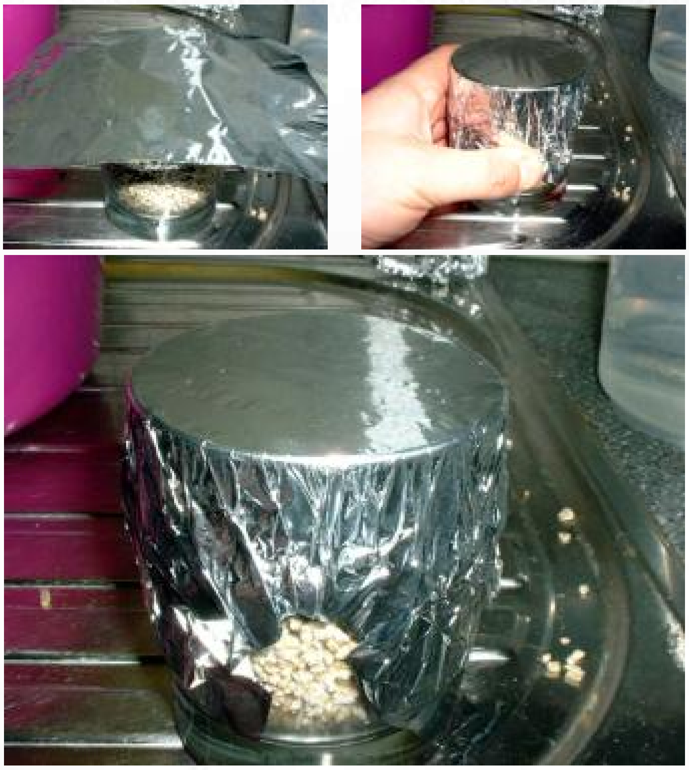
Fill up the jar with dry vermiculite to the top. This layer hinders airborne contaminants reaching the underlying substrate in case they manage to come in during the inoculation and incubation.



Take a 5in(12cm) wide stripe of aluminium foil and fold it in the middle.
Put the foil over the opening of the jar as shown in the pictures. If you're using jars with metal lids, you can poke 4 holes at the very edge of each lid with a small nail and hammer and screw the lid on. The holes should be slightly bigger than the diameter of the syringe needle.

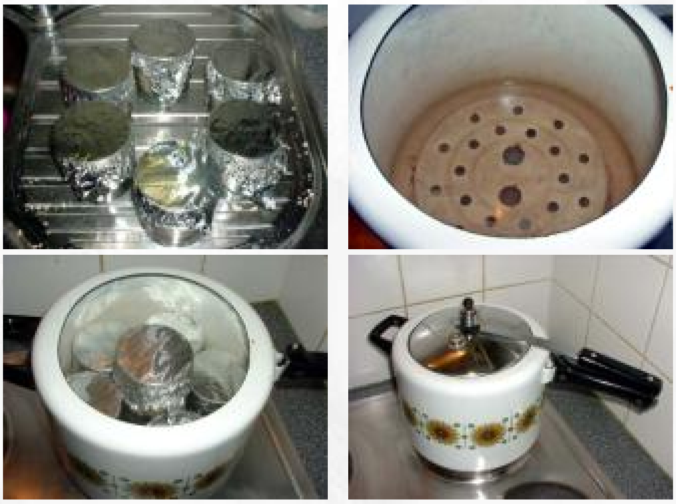


Fold the foil edges up and press them together so you get a nice aluminium foil lid.



Then take a piece of foil measuring 5in x 5in in and put it over the first two layers (respectively the metal lid if you're using lids) leaving the edges of the foil reaching down, since it has to be lifted again during the inoculation.
So now you have 3 layers of foil over the opening. The top layer is lifted during the inoculation.

Sterilization



Pour approximately 1in (2.5cm) of water into the pressure cooker, don't put in too much water otherwise it will come into the jars and alter their water content.
Then stack the jars into the pressure cooker. The use of a rack to keep the jars from directly touching the bottom of the cooker is strongly recommended.
Put the lid on and bring the cooker to the required pressure (15 psi = 1atm over atmospheric pressure) slowly over a period of 15 minutes on a medium flame.

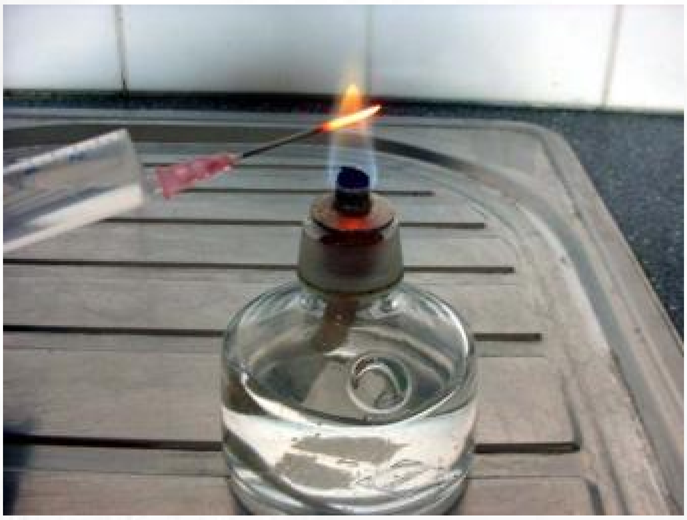
If you heat up the cooker too fast this can cause the jars to crack.
As soon as the steam begins to escape the rocker or the vent at the top of the pressure cooker turn the heat back so only a very small, steady steam flow persists from the vent. From this point on, pressure cook for 45 minutes.

Depending on the pressure cooker model the cooking procedure works a bit different so if you're not familiar with pressure cooking consult the instruction manual or someone who used pressure cookers before.
After 45 min take the cooker from the flame and let cool for at least 5 hours or even better over night.
If you never used a pressure cooker before check out this document about the correct pressure cooker use.

If you are unable to find or buy a pressure cooker, you can also sterilize the jars using a big pot with a lid.
In this case steam the jars for 1.5 hours in a pot lid on. Use only approximately 1 inch of water at the bottom.
You might have to add some water to the pot during steaming due to evaporation.

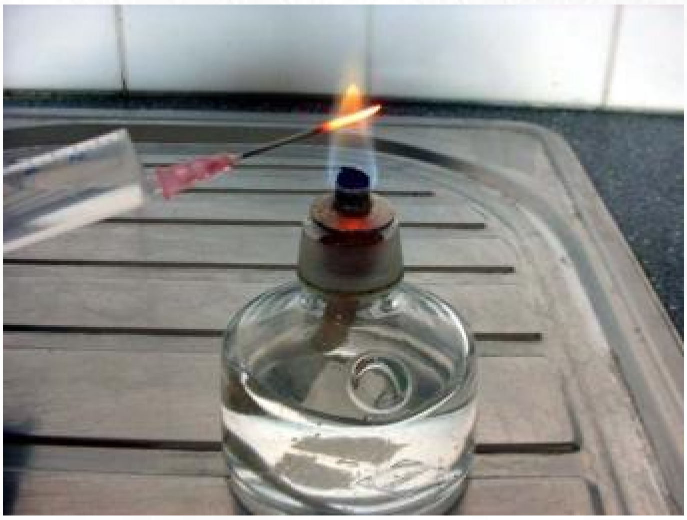
Inoculation

After the cooker is cold to the touch take the jars out and place them on a clean surface, have an alcohol lamp or a lighter and the spore syringe ready. Shake the spore syringe to break up the spore clumps.

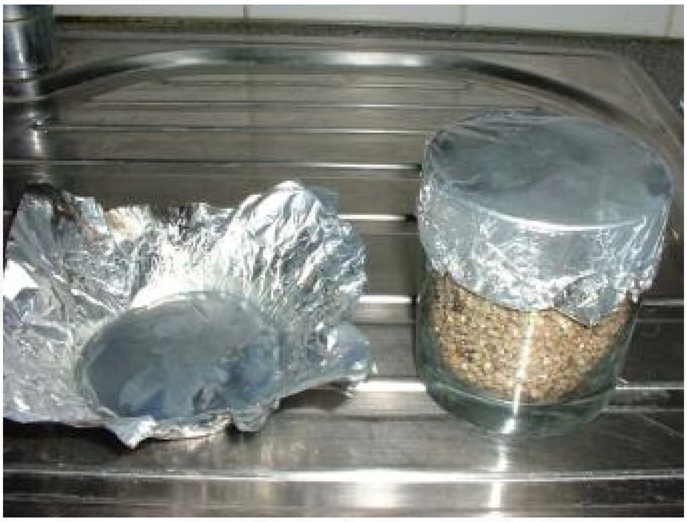


To be able to shake it it's necessary that there is a small bubble of air in the syringe. If this is not the case, then you can suck approximately 1cc of sterile air into the syringe by placing the tip of the needle into the flame and slowly pulling the plunger back.

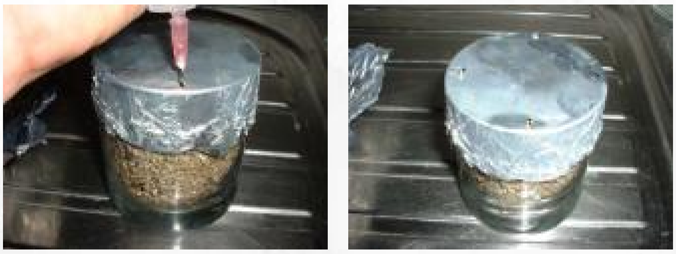
Loosen the foil from all of the jars so it can be lifted easily when you inoculate.



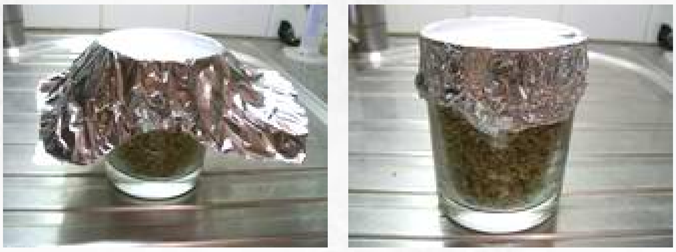
Take the cover from the needle and heat it over the flame until glowing red. Let cool for a few seconds.



Take the upper foil layer off and put aside upside down.



Pierce the foil at the edge of the jar with the needle app. 1 in (2.5cm) deep and inject the spore suspension towards the inner jar surface. You should see a small drop running down the inner surface of the jar towards the bottom. Each jar is inoculated on 4 equally spaced points. You should use 1 - 1.5 ml of the spore suspension per jar so one 10 ml syringe is sufficient for 6-10 jars.



Put the foil on again. Flame sterilize the needle again after inoculating 3 jars to prevent cross contamination just in case a jar wasn't properly sterilized.

When all of the jars are inoculated fold the foil edges up and press them firmly together so you get a nice aluminium foil lid. Write the inoculation date and the species/strain information on the foil with an all surface felt tip pen. If you touch something other with the needle during the inoculation procedure except the foil surface of the bottom foil layer immediately flame sterilize the tip again.

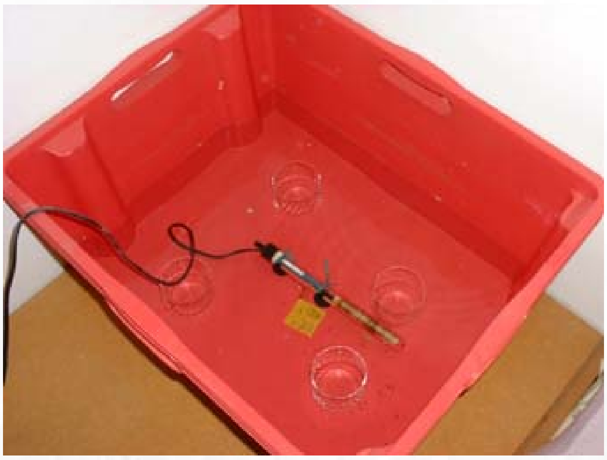
I made a video of the PF-Tek for Simple Minds substrate preparation and inoculation.

Incubation

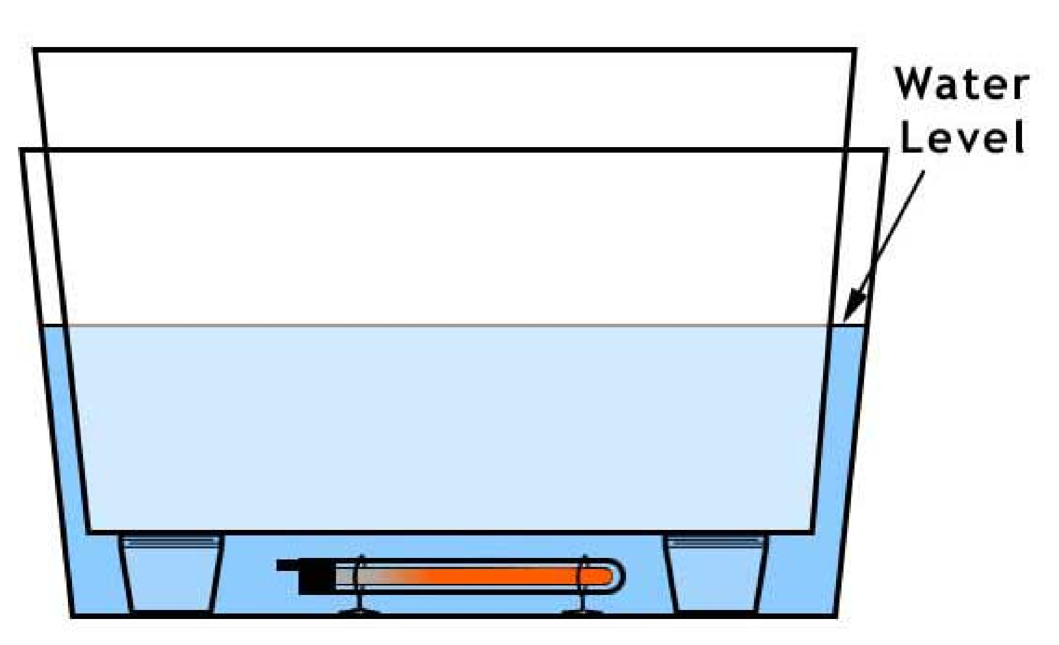
The jars should be stored at 21-27°C (70-81°F), the warmer the better, but not exceeding 27°C. If you don't have these temperatures at home you can build an incubator to accommodate the jars.

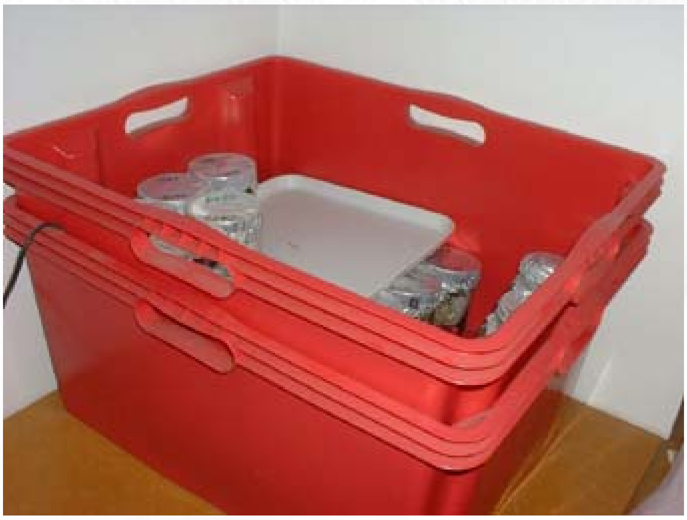
Incubator

The inoculated jars develop fastest if they are stored at a temperature of 27°C (80°F) (According to Stamets the best incubation temperature for *P. cubensis* would be 86°F, but since the jars themselves are a few degrees warmer than the surroundings (mycelium emits heat when growing) 80°F is a good and safe incubator temperature).

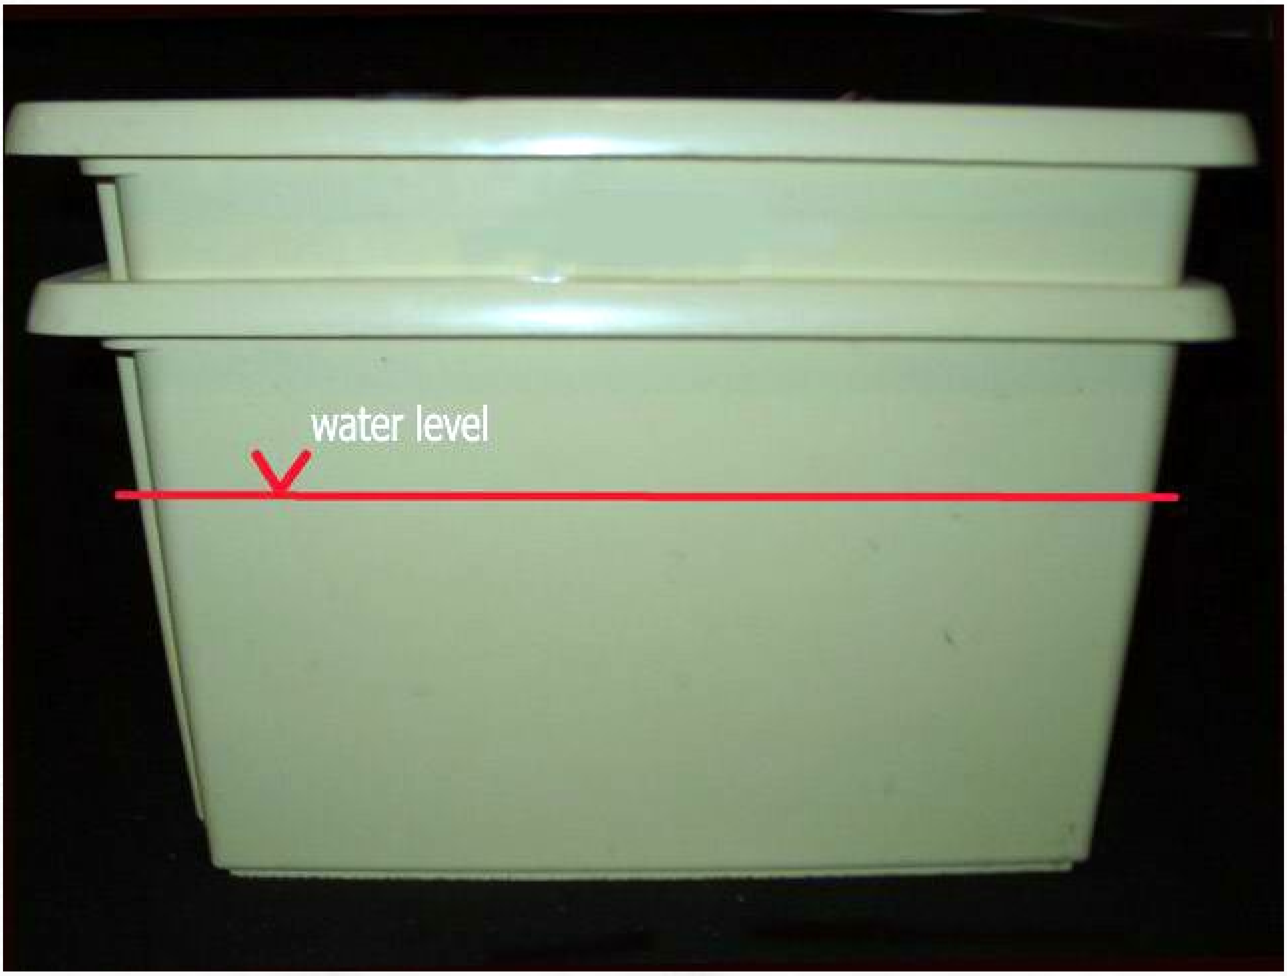


You can build an effective incubator by using two plastic boxes of the same size and an aquarium heater.
There are several types of aquarium heaters. When you're buying a heater, make sure that it is of the "fully submersible" type.
Attach the heater to the bottom of the first box and pour in as much 27°C warm water that the heater is completely submerged.
Adjust the heaters thermostat so that the heater just shuts itself off at 27°C.
Put some spacers on the bottom of the box, they carry the second box and prevent it from touching the heater.
In the above picture 4 jars are used. You could also use bricks, stones or something similar.

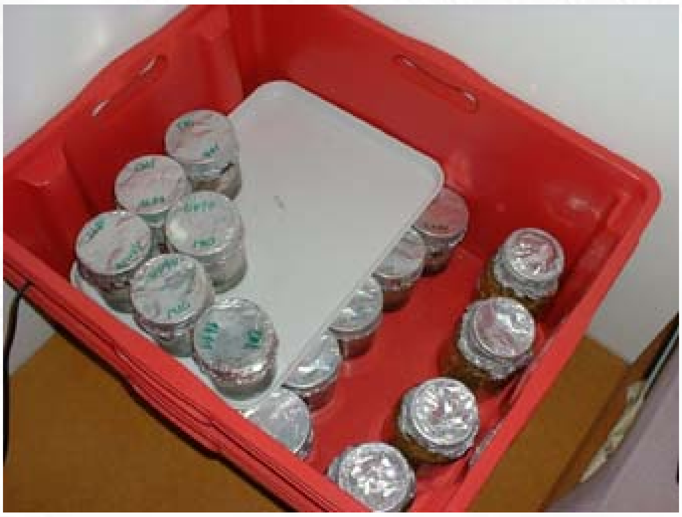




Put the second box in the one containing water.
After a few hours measure the temperature again and adjust the heater if necessary so the water temperature is 27°C.

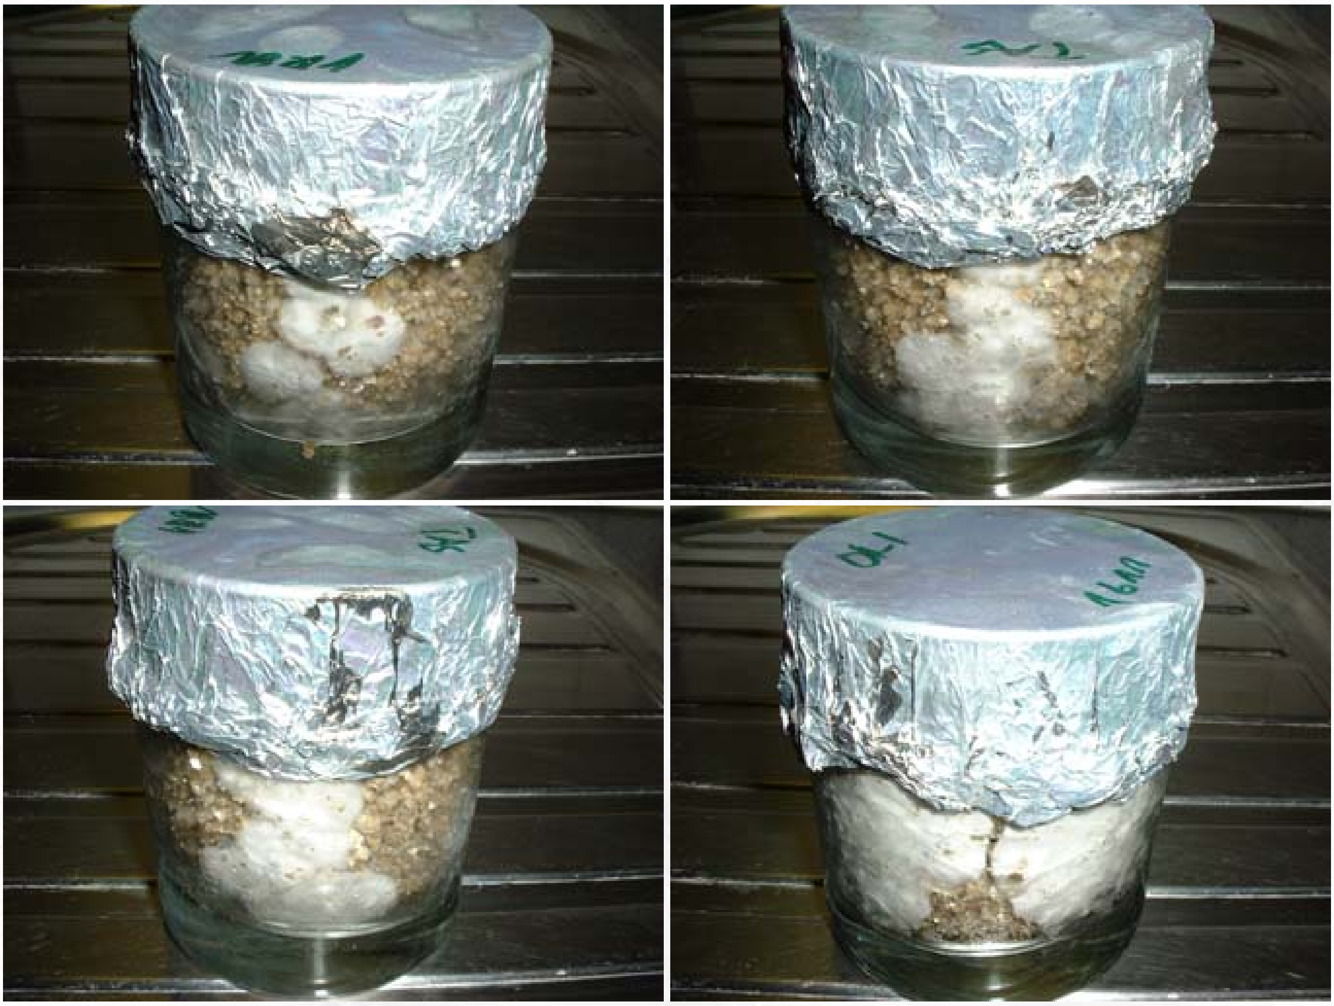


When the box is empty, it will float on the water.
The water level in the lower box should reach app. 2/3 the height of the box, supposing the upper box is in place loaded with jars and resting on the spacers.



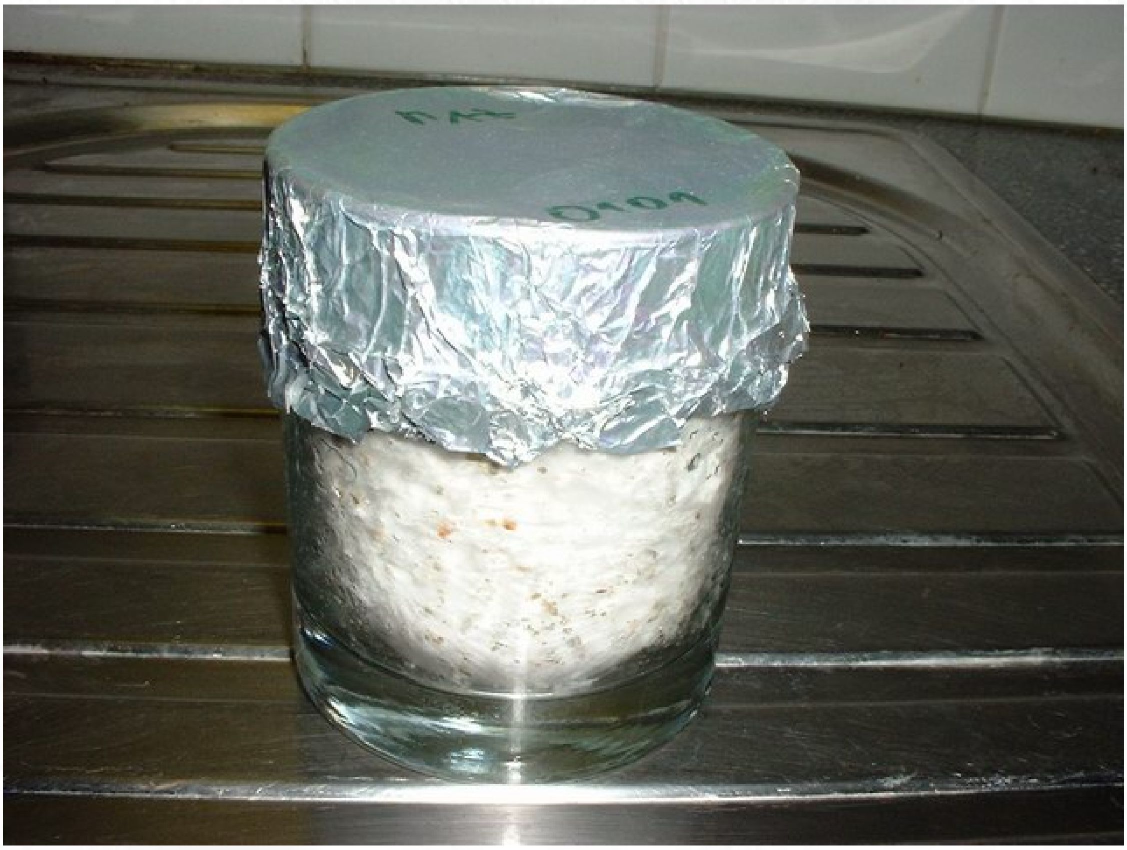
Now you can put the inoculated jars into the box.

Cover the jars with a blanket to keep the heat escaping and to keep the jars dark. Note: the water level drops in some weeks by evaporation. Therefore you have to fill some fresh water in from time to time to keep the water level high enough. Never let evaporate so much water that the heater isn't submerged in water anymore!

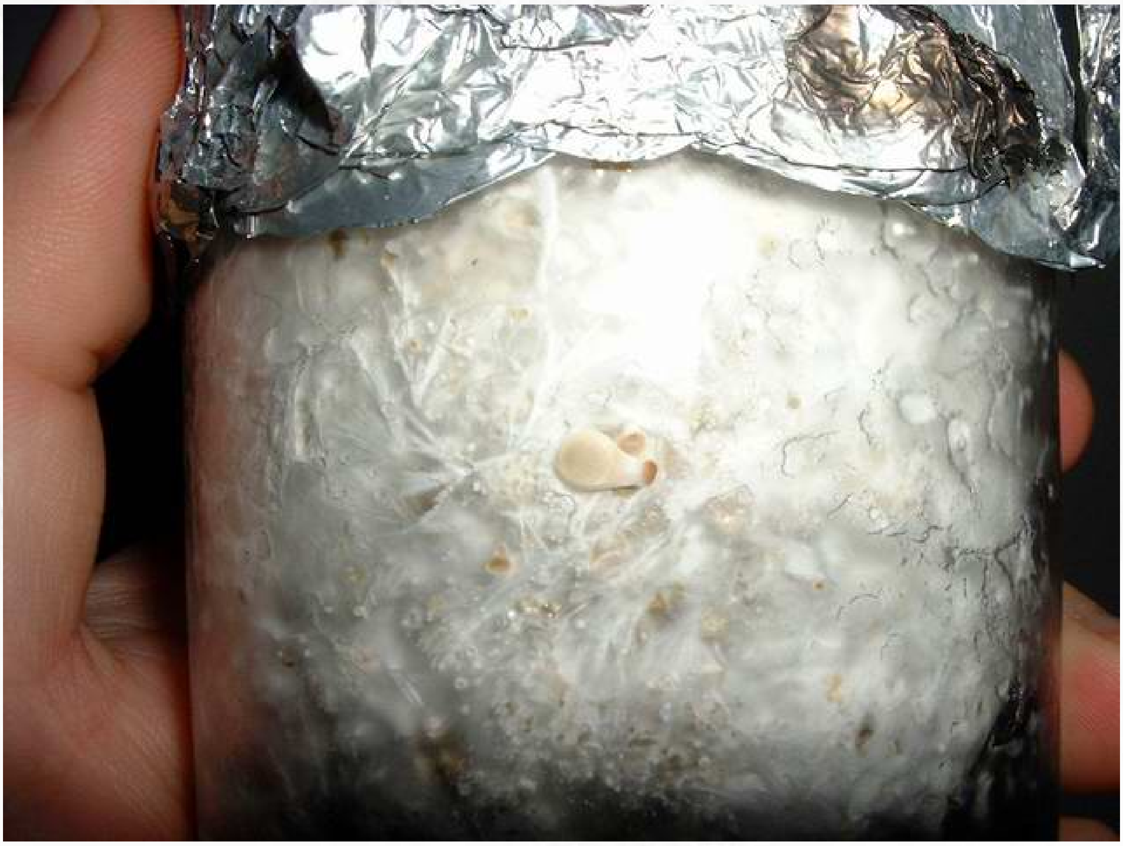


Providing the jars are kept warm you should see the first sign of germination after 3-5 days as bright white specks. This is mycelium. If anything grows that is not white, for instance green, black or pink, then the jars are contaminated and their content must be discarded and your clean procedures need some improvement. After the jars are emptied and the jar is washed with detergent and hot water it can be used again.

Check the Shroomery Contamination FAQ for more information on possible contamination in mushroom culture.



Depending on the temperature and the viability of the spore syringe it takes 14-28 days for the mycelium to colonize the whole jar. Once colonized store the jars at normal room temperature, about 21°C (70°F) to initiate pinning.
Don't expose the jars to direct sunlight. Indirect sunlight (= the natural light that lights up a room because at day time out) or a low wattage lamp (cool white fluorescent lamp is ideal, incandescent lamp is less suitable) for 4-12 hours a day is sufficient.



Within 5-10 days (with certain mushroom strains it can however take up to 30 days) pinhead-size accumulations of mycelium should form. These so called pins represent the beginning of mushroom growth. In the following days also small mushrooms with brown heads become visible. When this is the case it's time to birth the cake into the fruiting container where the mushrooms can develop to maturity.
Some strains don't easily develop pins. In this case put the colonized jar wrapped in a plastic bag in the fridge over night and then proceed to fruiting next day, even if the cake doesn't show pins yet. This cold shocking usually helps trigger pinning somewhat.

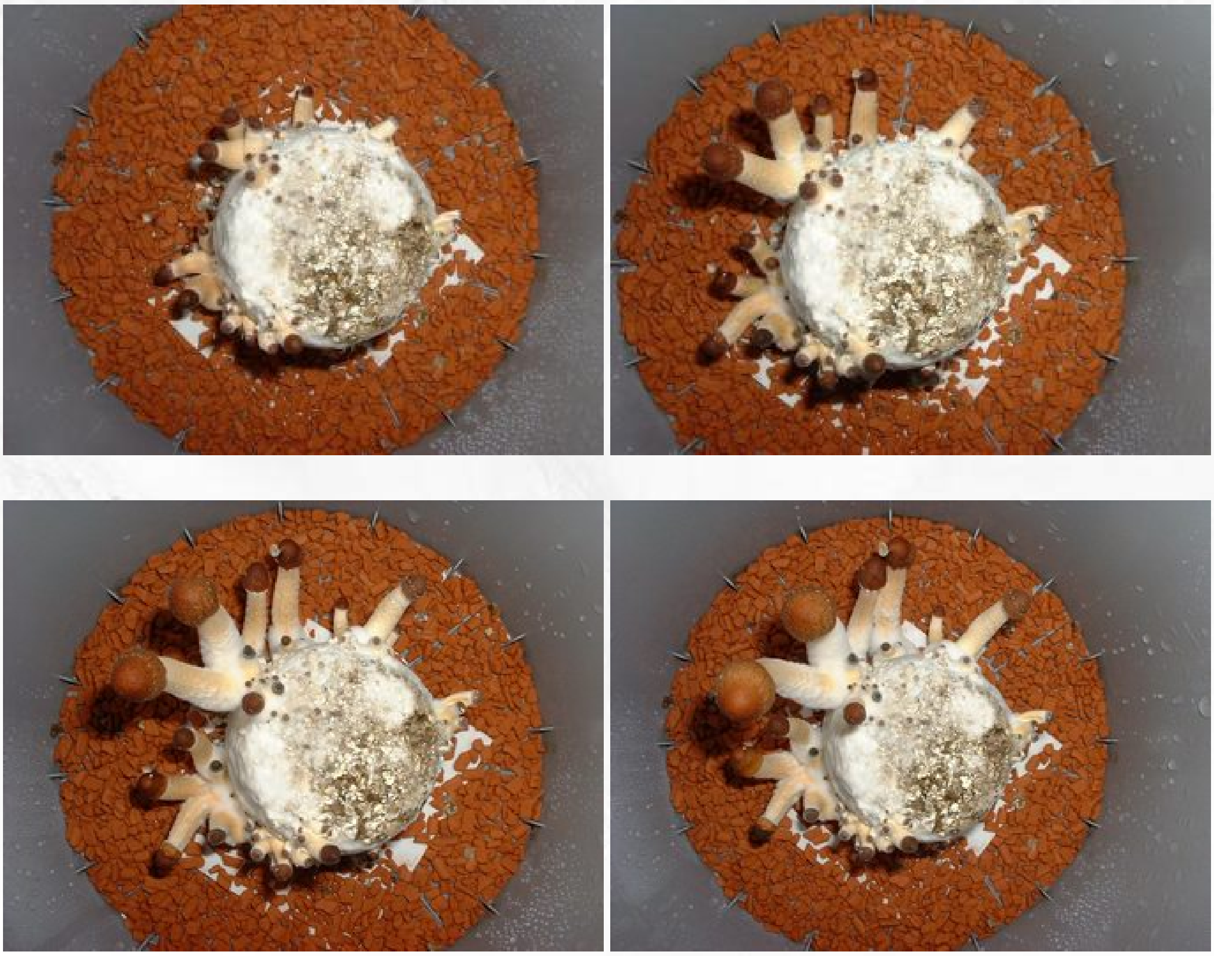
Fruiting

The fruiting of the cakes can be accomplished in any sort of container that can be loosely sealed and has at least one translucent side, preferably on the top. Suitable containers are a plastic bucket, Rubbermaid container, terrarium, aquarium...

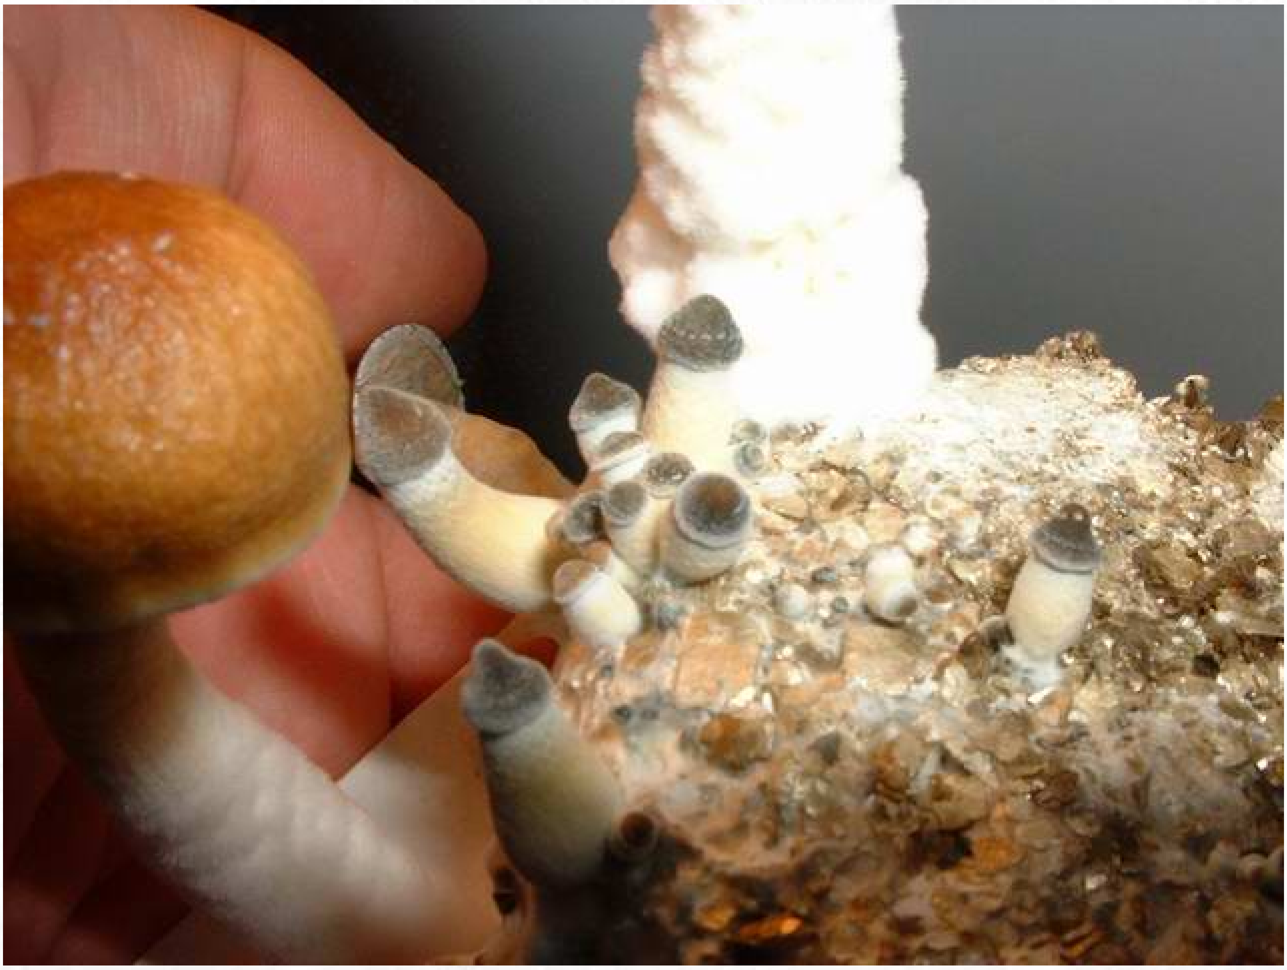
Put an 1/2 inch layer of moistened perlite or expanded clay pellets or even a wet paper towel at the bottom of the container and birth the cakes onto this layer by letting them slide from the jar upside down.

Alternatively one can first apply a casing layer.

Sometimes the cake doesn't slide out of the jar easily by itself.
You just need to turn the colonized jar upside down in your hand and slam the hand lightly against the palm of the other hand. This will make the cake slide against the lid and it can be birthed with ease.



If you have a bigger fruiting chamber (a bigger plastic container or a terrarium) you can of course put in more than one cake to fruit.
The distance between the cakes should be at least 2" (5cm) for the mushrooms have room to grow. Put a sheet of translucent plastic over the opening of the fruiting container. Take this sheet off once a day and fan the air out with a piece of cardboard. If the bottom layer begins to dry out, spray it with some water to keep it moist since this layer provides moisture for the air to stay very humid. Don't spray the cakes directly.
Handle the cakes as little as possible but when you do it always wash your hands thoroughly beforehand.
Over a course of the next 7-14 days the cakes will begin to pin (if they haven't began to pin in the jars yet) and the small mushrooms will grow big in a matter of 2-5 days and as soon the caps begin to open they can be harvested.
This simultaneous maturation of all mushrooms is called a flush.



After the mushrooms have grown big there are usually a few small, stunted mushrooms left over, they are called aborts. They can be recognized by their blackish heads and the fact that they stopped growing at some point. Still they are good to use unless they are rotten.

It's crucial that you harvest all mushrooms, also the aborts, after the flush. This is most easily accomplished if you harvest the mushrooms off by gently twisting and tearing them off the cake with clean hands. Optionally you can dunk the cakes after each flush, this can increase the flush size significantly.

After approximately one week small mushrooms begin to form again and mature during the next days.
This cycle can repeat itself up to 4 times sometimes even more. After that the cake is exhausted it produces no more mushrooms and can be discarded. They can be also used to start outdoor beds.

Sometimes green mold attacks the cakes even before they are completely exhausted. If this is the case remove and discard the contaminated cakes immediately to prevent the spreading of the contamination.

Casing PF-Cakes

original source: http://www.fungifun.org/English/Casing

This document describes a simple casing procedure involving the PF-Tek cakes.

You are going to need:

- colonized PF-Tek cakes
- peat or peat based potting soil (for instance Jiffy Mix)
- vermiculite
- limestone flour
- potable water

Limestone flour is chemically mostly Calcium carbonate ($CaCO_3$), so you can take also pure $CaCO_3$ or any other material that is in powder form and contains high amounts of $CaCO_3$.

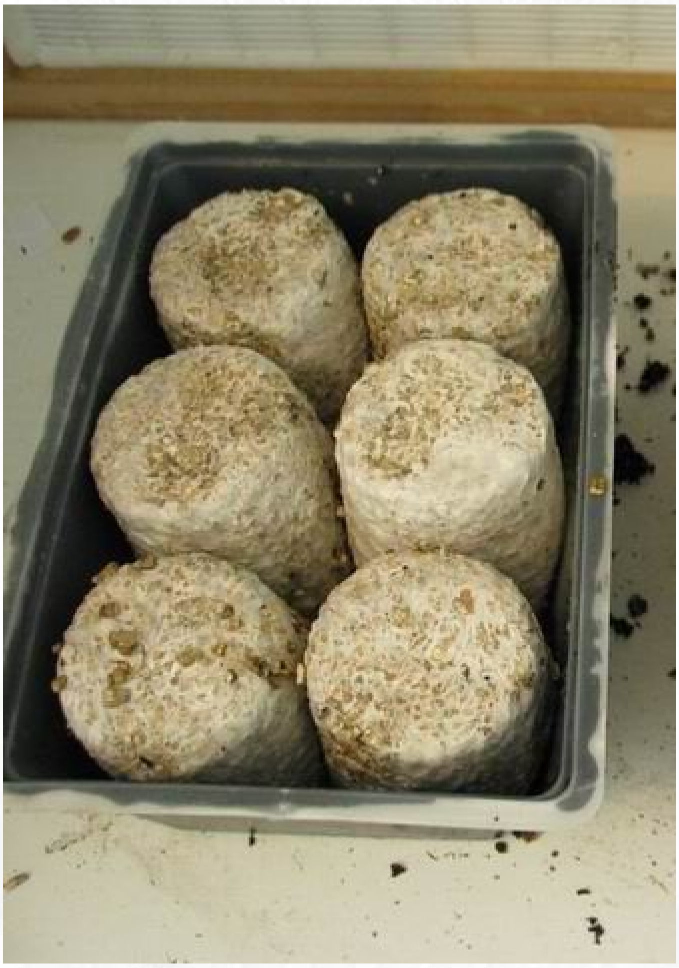
First we are going to prepare the casing mix.
Combine **60% peat, 30% vermiculite and 10% limestone flour by volume**, mix well, and under stirring add as much water to it, that when you take a handful of the casing material and *lightly* squeeze it in your hand some water begins to drop from it.

Then put this mix into a covered plastic bowl or a plastic bag, and put it into the microwave for 5-10 minutes, depending on the amount of the casing material. The goal is to get the casing boiling hot (~200°F), and when this is the case, take it out, stir the mixture in the bowl or shake the bag to redistribute the hotter parts and let it cool completely (several hours) in a clean place.

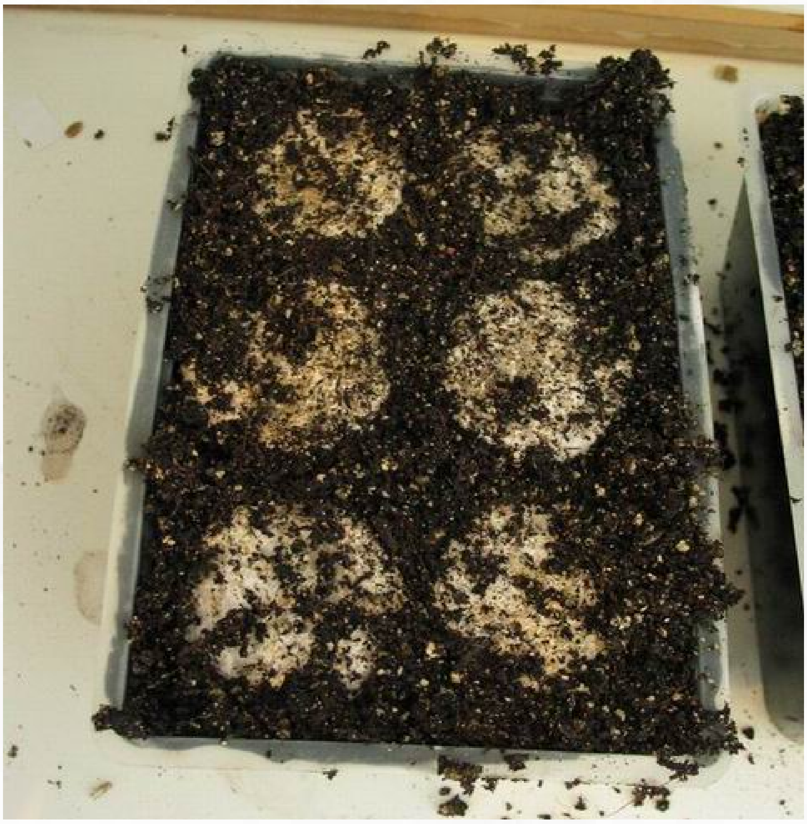
After the casing mixture is **completely** cool we can go to the next step, casing the cakes.
Prepare a dish that will accommodate your casing. This can be from any material: plastic, any metal, ceramics...
Ideally it should be opaque, if it is translucent, you will get pins inside the casing itself, which can lead to problems. If the container is not opaque, apply some aluminum foil and cover all the outer walls with it to keep the light out. Alternatively cover the inside of the container with the foil.

How big of a container you are going to use depends on how many cakes you are going to case.
In this example, I use 6 cakes, which perfectly fit into the pictured plastic container. I painted the walls of the container black to keep out the light (in order for the paint to stick on plastics, you will need to apply a primer first, otherwise paint won't stick...)

The depth of the container should be $^1/_2$ to 1 inch larger than the cakes are tall. If you only have a lower container, you can cut the cakes in half, or even put them into a clean plastic bag and crumble them from the outside, so you end up with pieces the size of a marble. I prefer the taller containers because it is simply less work.



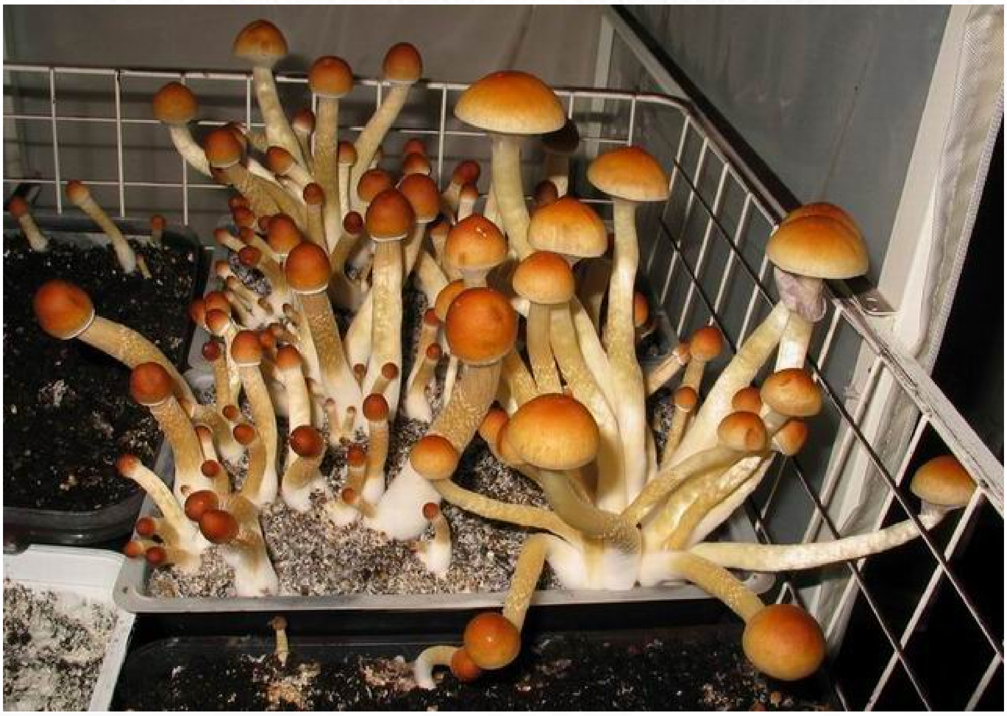
Once you have the containers, loosen the fully colonized cakes by bumping them slightly top down on the palm of your hand, or directly into the container. Arrange the cakes in the container.



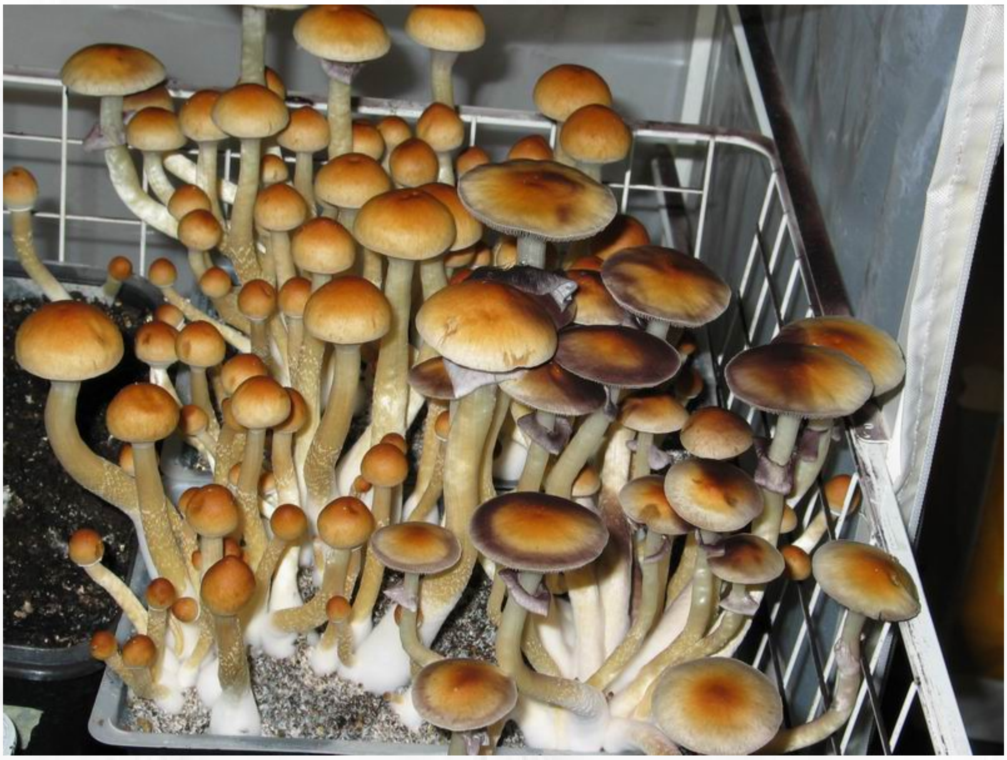
Apply some casing material between the cakes.

Loosely apply around 1/2 inch on the top of the cakes. Don't press the casing material down, it should stay lose and the surface should have hills and valleys.
Give the casing layer a good spray with clean water and cover with a piece of aluminium foil. Put in the incubator or leave at room temperature for 3-7 days. After the day 4 check on the progress by lifting the foil a bit and peeking underneath. Alternatively use polypropylene wrap instead of aluminium foil.

As soon you see first strands of mycelium starting poking through the casing layer take off the aluminium foil, give it a good spray with water and put into your fruiting chamber.
The humidity should be kept at 95-100°RH at this phase, and temperature maintained at around 70-75°F.
After 5-10 days the pins should appear.



After the pins are visible, lower the humidity to around 90°RH.
If the casing layer seems dry, lightly mist the casing layer with water. The casing should remain moist at all times but not soaking wet.



The pins will grow into fully grown mushrooms over the next couple of days.

The same casing procedure can also be done with colonized grain.

PF Block Tek

original source: http://www.shroomery.org/11388/PF-Block-Tek

My goal was to find or create a method that has the simplicity of PF TEK while adding the benefits of more complicated bulk methods while being extremely contaminate resistant.

Supplies needed:

- Large Spawn bags with filter patch.
- 100% pure silicone
- 8" or larger impulse sealer.
- Large Pressure Cooker.
- Vermiculite (my recipe is based on COARSE vermiculite)
- Grain Flour (any type will do, I recommend blends)
- Gypsum
- Spend Coffee Grounds
- Alcohol wipes (or alcohol + paper towels)

Supplies recommended by not required:

- Large amount of liquid culture. (I recommend 10-30cc per bag)
- Alcohol Lamp (just makes things easier)

Step 1: The Injection Port
Apply a quarter sized blob of silicone and smear it around for a moment. If you just leave the blob as is it will often dislodge very easily.

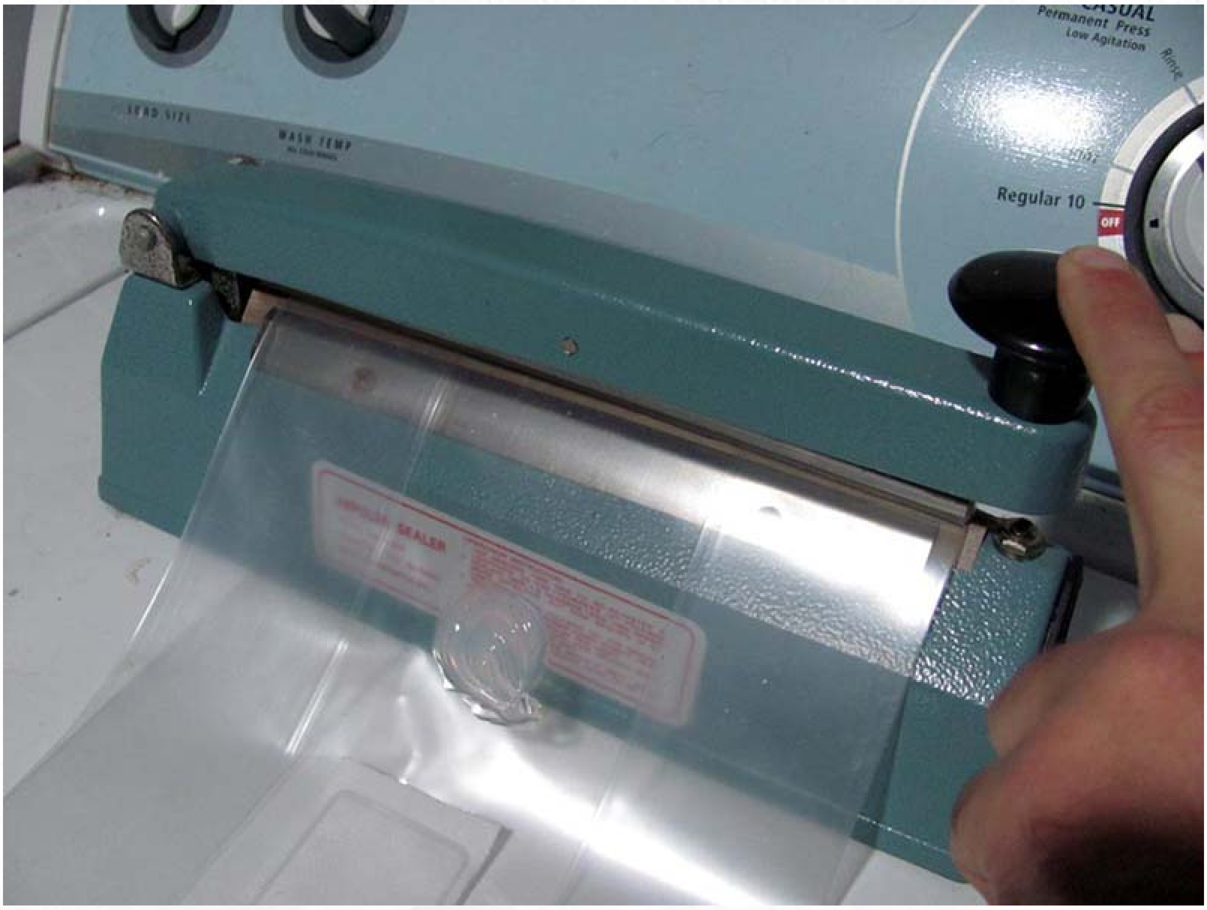
I recommend placing the port just below the filter patch for easiest access.

Wrong Way.

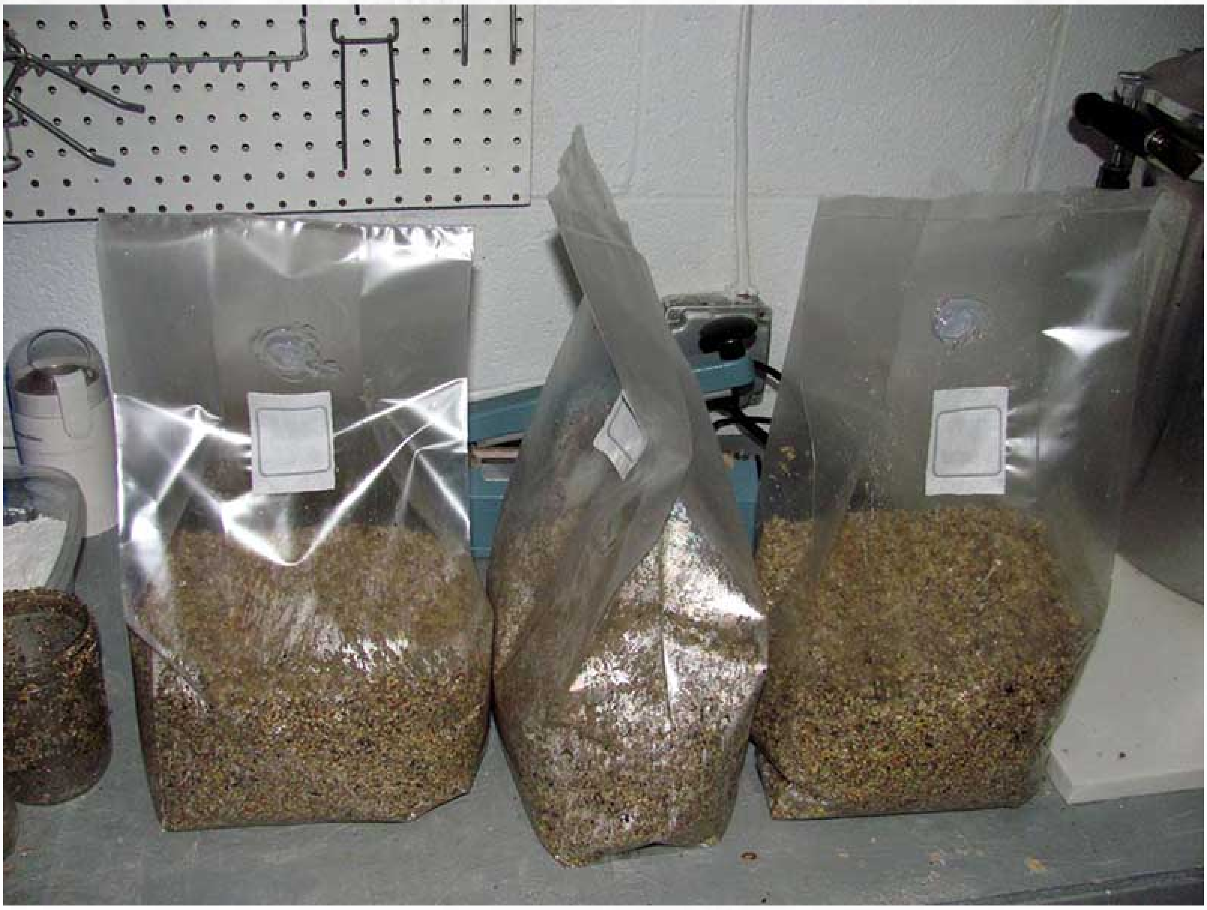
Right Way.

Allow the silicone time to set. Several hours at minimum.

Step 2: The modified PF Mix (SpongiMix?!)
3 Quarts Coarse Vermicute
1 Quart Water (add 1 half cup gypsum and 1-3 tablespoons of spent coffee grounds to the water and mix WELL first!)
Mix this together and let sit for 1 minute then mix again before adding dry ingredients.
1.5 Quarts Grain Flour (Any grain will do, I recommend mixtures of multiple grains).
Mix well then dump into bag. Try not to get any on the filters.
This recipe creates about 5 quarts by volume and a bit on the dry side.
Seal the bag using your awesome handy dandy impulse sealer.



Should look about like this when you're done.

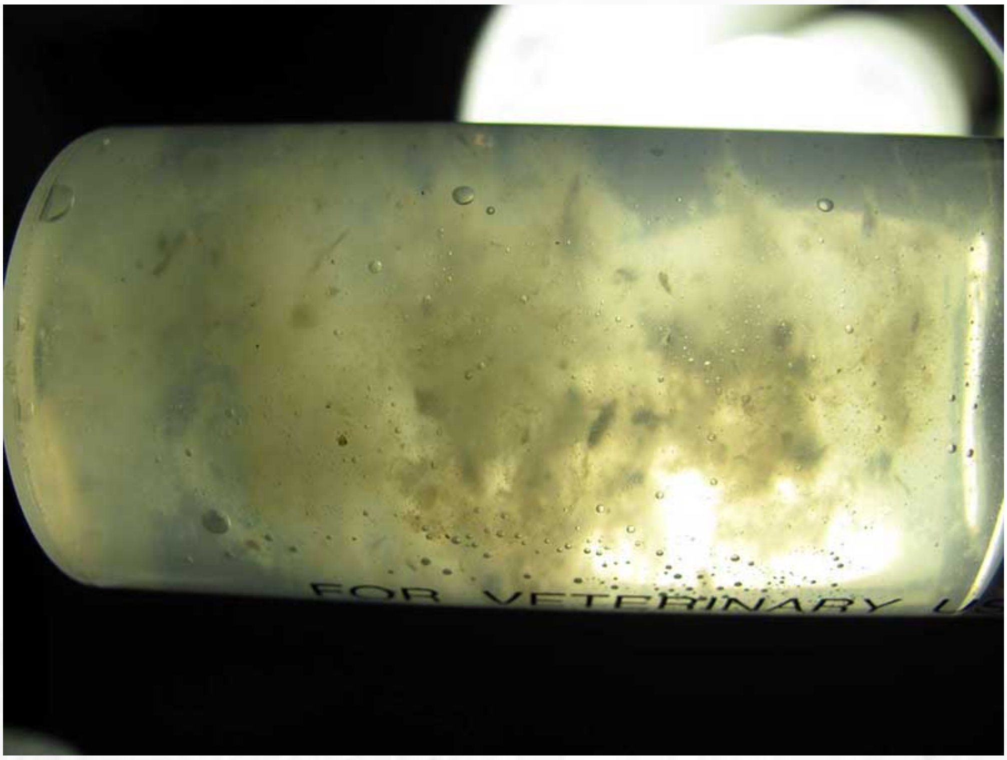


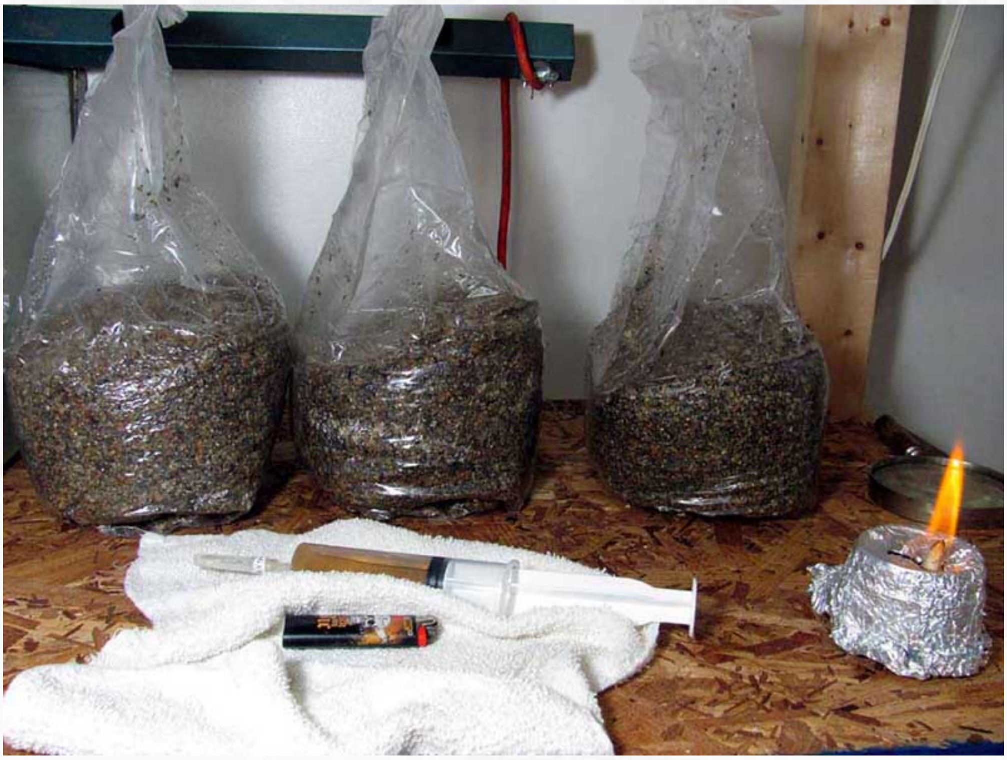
Step 3: Sterilization

My AA 75x sterilizer handles up to 41.5 liquid quarts and can hold 6 bags of this size. Your mileage may vary. Fold the tops down leaving room for the filter to breath as you don't want your bags assploding in the cooker. Pressure cook @19-21 PSI for 90 minutes or @15 PSI for 120 minutes.

Step 4: The Inoculation

Grab your LC syringe and get to work. Inoculate with 10-30cc's of nice thick mycelium laden liquid culture.

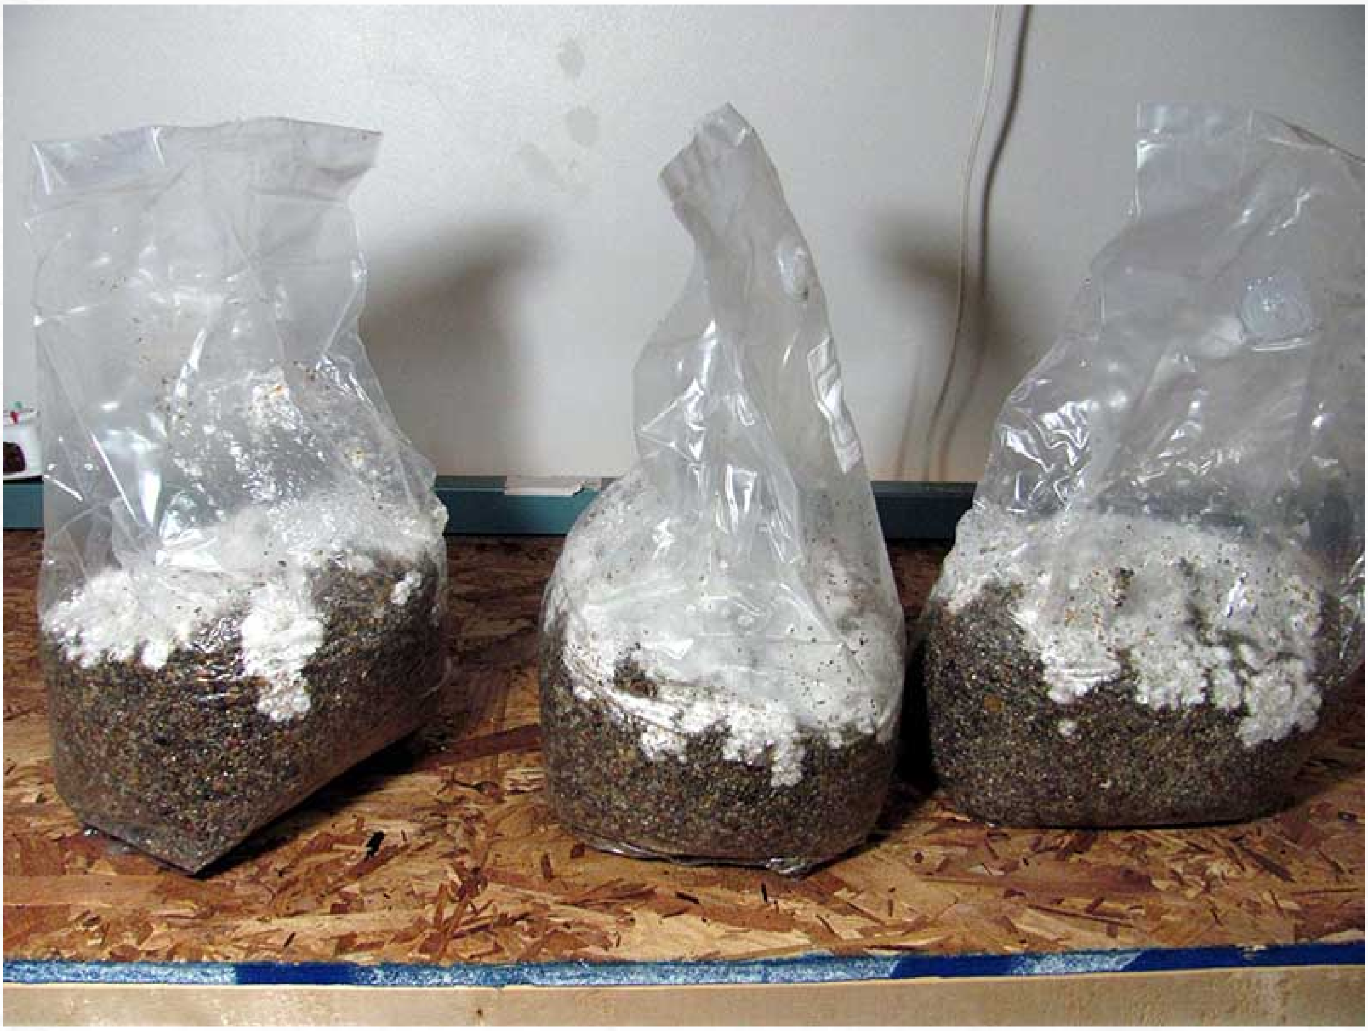




I recommend spraying as much of the surface area as you can reach.

Step 5: The Incubation

Incubate on an open shelf in normal lighting at 70-75F for 7-14 days until you have a good thick fuzzy covering of mycelium similar to this:



Step 6: Break, Shake & Roll

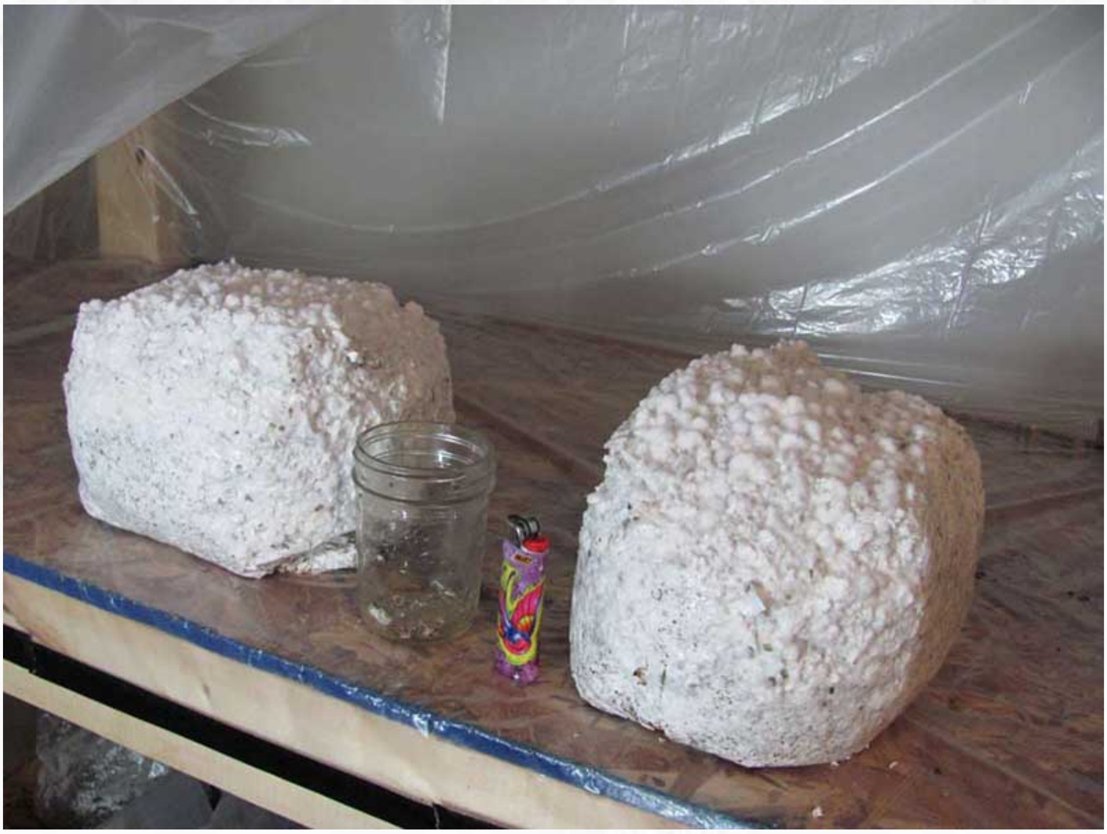
Using your hands break up every single chunk in the bag. Continually roll the bag to expose new chunks until you can find none. This will take up to 5 minutes per bag.
Once you've got all the chunks shake and roll the bag for at least 2 minutes.
Set back on the same shelf and allow to continue colonization.

IMPORTANT: At this stage I recommend dropping the temperatures to about 70F. Growth will explode at this point creating a large amount of internal heat. I've recorded up to 12.5F over ambient temps externally. So if you're incubating at 80F you're bags may stall, not properly colonize the center and increased risk of contamination (contams like high temps, cubes don't).
Once the bags appear to be fully colonized allow 1 week to consolidate unless you intend to spawn to bulk, in which case go ahead and do it.

Step 7: Fruiting

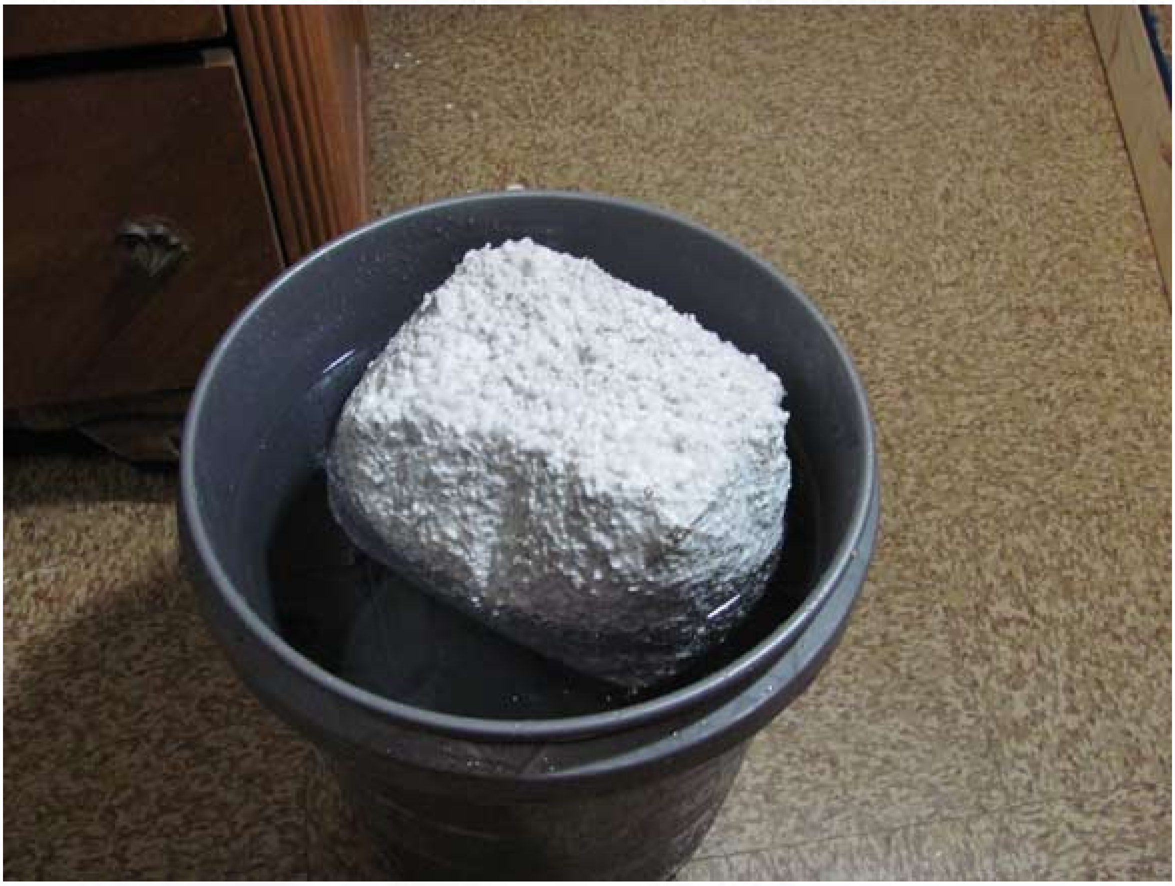
Carefully cut away the bag using something sharp. Often little bits will get torn off from the bottom, do not worry about them.

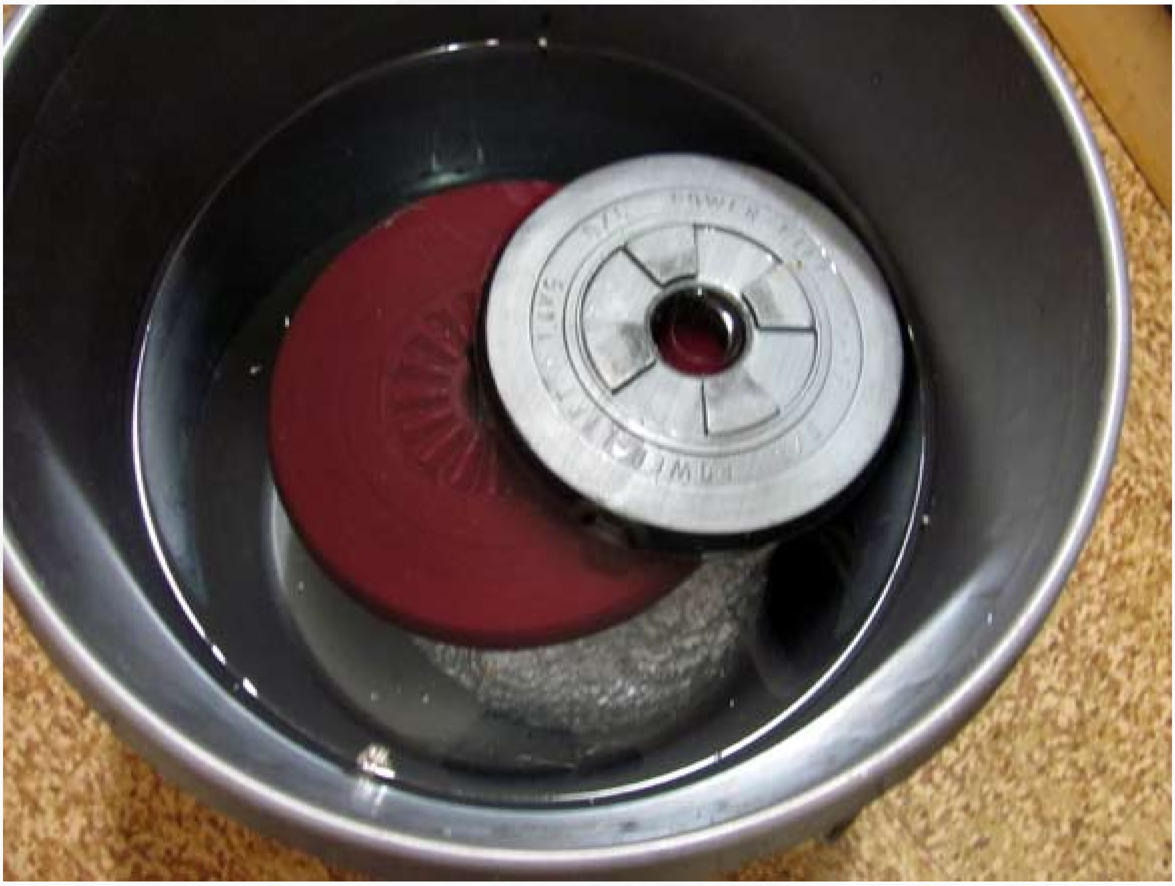
You should end up with something like this:



(note the sad little half pint jar there, dwarfed by these awesome blocks)

Dunk for 18-24 hours in cool water.





Takes about 7.5 lbs to hold these down, in case you were wondering.
I've tried with and without rolling these and the results were similar therefore I recommend the simplicity of not rolling since it doesn't seem to serve a good purpose.
Pop these into a standard shotgun style fruiting chamber - you can fit 4 cakes in a 66 quart fc or 6 in a 108 quart fc.

You can also fan and mist manually or use my automated shotgun technique for equally awesome results.
I recommend 2 flushes then toss them as the risk of contaminates is very high after the 2nd flush and not worth the trouble of having to de-con your FC's / Fruiting Rooms.
Yields will average between 2.5 oz and 6 oz dry weight PER block.
Provided you use proper conditions you can expect about 1 flush per week.
Here's a few pictures of Albino Penis Envy grown using this technique.

Enjoy!

Scotsman's Beginner's Cake Tips

by scotsman1

original source: http://www.shroomery.org/8413/Scotsmans-Beginners-Cake-Tips

Some useful tips for a successful cake grow.

I always always seem to get good flushes on my cakes and for the life of me I don't know what I do that's different from anyone else, or do I? Well here in a few simple tips and I will give all my little secrets, well they ain't exactly secrets, more must do items, items that if you follow you will also end up with bigger flushes, maybe.

I always stick to what I know best and what gives me the best results, and that's straight Brown Rice Flour cakes done the old-fashioned way, PF style cakes.

These tips may help, they may not but if one person shows an improvement in Flush sizes we have a winner, so here's my simple tips.

Quarter cup of BRF. As I said already Organic Brown Rice ground to a fine flour in the coffee grinder.

Vermiculite I use half a cup. Arthur Bowers Silverperl Vermiculite Horticultural Grade. It's not the fine vermiculite because we only get the one type here. I don't think the fine vermiculite would be as good because when this gets to the bottom of the bag its all smaller pieces which to me don't give as good a cake mix.

Quarter cup of water, this is one of the few times I just use tap water. I don't know how your tap water is but ours is not to bad.

When mixing the cakes I like to do my cakes 1 or 2 at a time it gets the mix better more even, so your waters right through the whole mix.

First Flush

Second Flush

Third Flush

The cups you measure the vermiculite etc with, well when you fill them make sure you don't go over the line; you don't want the cup full to the brim that way the rest of the mix will be off resulting in to dry a mix, I admit I fell for this one when I started.

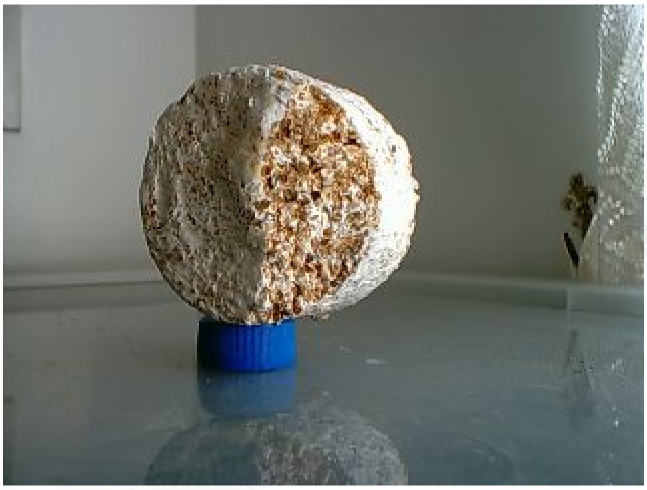
Brown Rice. Well I go for organic brown rice for the simple reason the shop nearest me sells it and if I changed maybe I would get lower yields, maybe I would get higher? I've never seen brown rice flour in Scotland so I settled for the rice ground in a coffee grinder and make sure its ground to a fine flour. Now i clean them and scrape with a fork and both are under water in the fridge for 18 hours.

1st the strain in the pics is Ecuadorian why? because they give great flushes and are no problem to print from and are easy to maintain. My grow tank is the standard Rubbermaid type, bought cheaply from the local diy store. 1.5 inch perlite pre soaked and spread evenly over the bottom. Fanning differs because it just depends if I am in or my wife is in. If I am in they get fanned up to 6 times a day, but if both of us are out they can go 8 hours without being fanned. Normally they can get by with 3 or 4 air exchanges a day but I like to give them more. If i am growing in winter i use a fish tank heater but its OK here at the moment so i am not using one right at this moment. They get misted every time the sides of the tank seem to be drying. Light, the tank has I clear lid and is at a window so they get natural sunlight. Even though I only spray when it looks dry I still water and spray the casing every day.

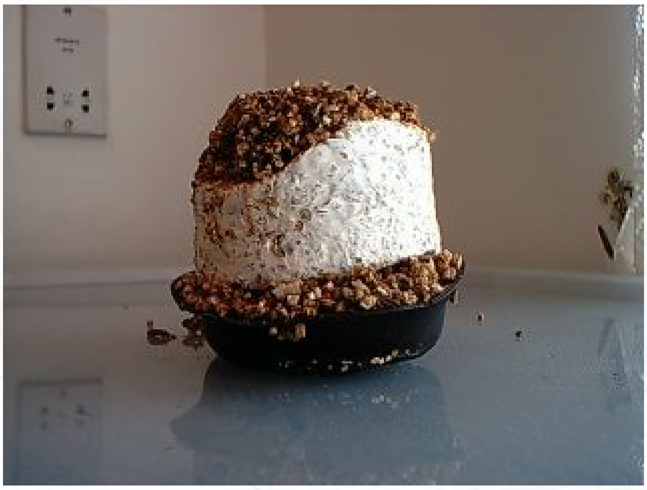
My Grow Tanks.

DBL end case after every flush.
Saving a Partially Colonized Cake.
Some of my cakes start OK then slows down to almost stopping. When this happens you don't have to throw the cake out, a small operation can save the cake and even though the flush will be reduced you still get a gram or two.
The Procedure.
First pic shows a cake I cut, notice how full the cut is, you should use as sharp a knife as you can. Prepare an area for working by washing with bleach and spraying Lysol on the surface and wear gloves. The idea is to cut

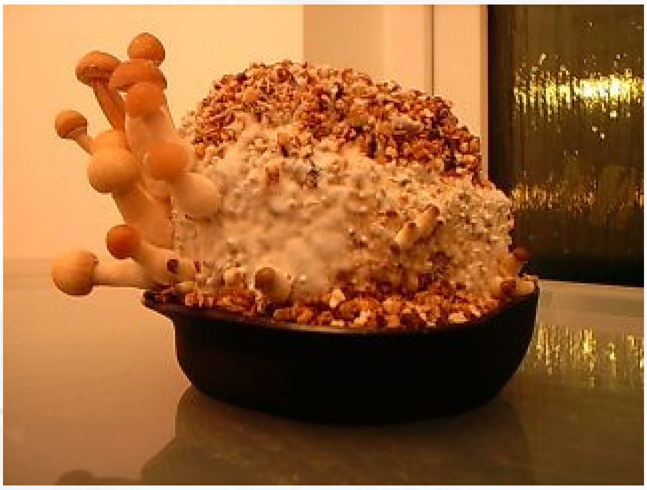
the uncolonized part of the cake off, leaving you with a cake with 1 small part removed.



Remove the cake from the jar and wash under running water. Get a sharp knife and plan where to cut the uncolonized part of the cake off, cut the part off with 1 cut no sawing or gouging, 1 cut. Next dunk for 18 hours.



Dbl end case your cake and make sure you pile plenty over the cut part of the cake this helps prevent contaminations.



A small flush but better than nothing and if you have a few cakes that go in this direction then a few grams is better than total failure.

Happy Shrooming and good luck.

PF-Tek - Dunk and Roll

original source: http://www.shroomery.org/10253/PF-TEK-Update-Dunk-and-Roll

Explaining the method of dunking your cakes in water and then rolling them in vermiculite to improve your flushes

Why Dunk and Roll?

Mushrooms are basically 90% water. Dunking and rolling will increase your yields dramatically with hardly any work. You are essentially replacing the water lost by the cakes and allowing them to produce more fruits. Normally the water runs out way before the nutrients in the cake do, so as long as you are replenishing the water the substrate will keep on producing fruits for at least a few more flushes.

When Should I Dunk and Roll?

- Immediately after birthing a cake and before placing it in the fruiting chamber you should always dunk and roll. A lot of water has been lost during the weeks the substrate has been colonizing.
- Between flushes. Once you have picked all the fruits off the cake or none have been growing for a few days you know your flush is over. Now is the time to dunk again, preparing the substrate for the next flush.

The procedure is divided in two parts:

The Dunk

In this step you will be replacing the water lost by the substrate.

1. Rinse off your cakes under the tap, rubbing them softly do dislodge any loose material or bits of mushroom material left over from picking the fruits. Be careful not to break off any pins (little immature mushrooms) as they will be your next crop. Pins will survive the dunk and roll no problem, so no need to take them off. Just be delicate with them.
2. Submerge the cakes under cold tap water for 12-24h inside a clean container. Try and avoid dunking for much longer than 24h but the closer you get the better as cakes are very dense and need a long time to absorb all the water . You can use the pan you sterilized you cakes in, a clean tupperware container a bucket, whatever is available. You will notice that the cakes actually bob about like corks so you will need to put something heavy ontop to keep them fully submerged. This is important as it seems that the extra bit of water pressure that comes from being totally submerged aids the rehydration process.
3. There is no need to dunk inside a fridge. As long as your water stays cool (below 40°F) you will be fine. The cool temperatures of the fridge prevent bacterial bloom while you are dunking (it has nothing to do with cold shocking the mycelium, as this procedure is not required for Psilocybe Cubensis) but unless you are pretty clean your fridge probably harbors a lot of contaminants, so it can be counterproductive. Use ice, running water (can be costly) or the fridge to keep your water below 40°F.
4. Once your dunk has finished, re-rinse your cakes under the tap and proceed to...

The Roll

Rolling your cakes increases the water holding capabilities of the cake. It essentially acts as a mini casing layer.

1. Roll your cakes in dry vermiculite so they are evenly coated with it. You can optionally bake your vermiculite in the oven for an hour at 350°F if you think it might not be clean (the bag has been opened for a long time for example) but it is not necessary if the vermiculite is out of a new bag.
2. Place the cakes inside your fruiting chamber (not in direct contact with the perlite, use a circle of foil or an old jar lid as a coaster) and wait for an hour or so.
3. Mist your cakes thorougly making sure you wet all the vermiculite.
4. Maintain fruiting conditions as usual.

Extra Tips

- While dunking between flushes is a must, re-rolling between flushes is optional. You will see that the mycelium colonizes the vermiculite slightly so it does not all come off during the succesive dunkings. There is no need to get it all off. Either do not re-roll, just patch up the bald areas or roll again. Whatever looks best to you.
- Letting the cake dry out between flushes. By not misting for a few days after the flush has finished and then dunking you are imitating the natural cycle of drying out followed by sudden rehydration. In nature this rehydration will stimulate rapid fruit formation. Also, the drying out protects your cakes from molds during the waiting period as the drier surface is not as prone to contamination.
- Extra vermiculite reservoir: Put a spoonful of vermiculite on the top of the cake when you place it in the fruiting chamber. Once wetted when you mist, it will act as an extra water reservoir.
- Try and create a good microclimate. By dunking and rolling all your cakes and packing them close together you will be creating a microclimate among your cakes where humidity is at its max. This is an invaluable aid for good flushes. These pictures show how well dunked and rolled cakes can perform.

Hippie3's Dunk Tek

by Hippie3

original source: http://www.shroomery.org/5185/What-is-the-dunk-tek

The cake is dunked in water overnight to rehydrate and enable bigger and more flushes.

Hippie's Dunk tek is a simple yet effective way to extend the useful lifespan of cubensis cultures such as PF cakes.

This tek should be used whenever the cakes/casings dry out. Also it can be given after full colonization to replace water lost so far.

The tek itself is quite simple. It essentially consists of submersion of the cake/casing underwater for 12 to 24 hours. Don't worry, that will not harm your cakes/casings.

One can even dunk cakes/casing that already have small pins safely. Just don't overdo it, by 48 hours underwater they will be dead.

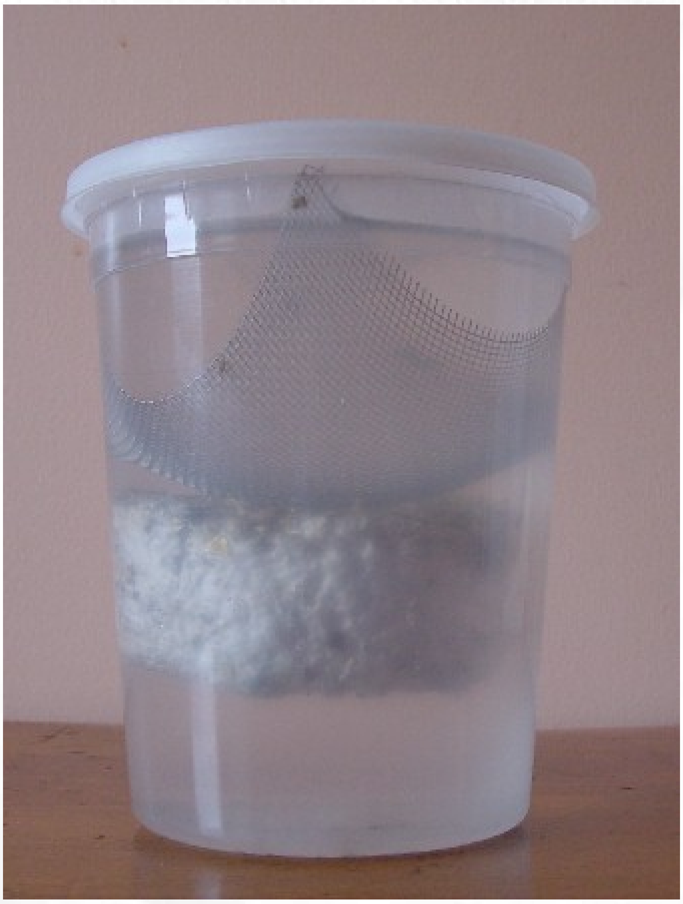
As for what kind of water to use, natural spring water is best but you can even use it straight from your faucet if need be.

Temperature during the dunking should be be cool but not cold, refrigeration is not recommended.

Time spent dunking should be not less than 6 hours for minimal benefits. 12 hours is about right for dunking in between flushes and at birth but 24 hours is the maximum for full rehydration of nearly spent cakes.

There are at least 2 options for how to dunk. My prefered method is to dunk each cake individually by placing it in a jar, filling with water, then screw on the lid to keep the cake submerged. This way is good for small batches, and has the advantage of keeping each cake isolated so no contaminants are spread from cake to cake.

For larger batches, you can simply place several cakes in a large pan or bucket, cover with water and weigh down the cakes by placing a weighted down lid, plate, etc. on top of the cakes.



After dunking, drain well, gently pat dry with paper towels, etc. and return it to the fruiting environment.

Photo of dunked cake pinning.

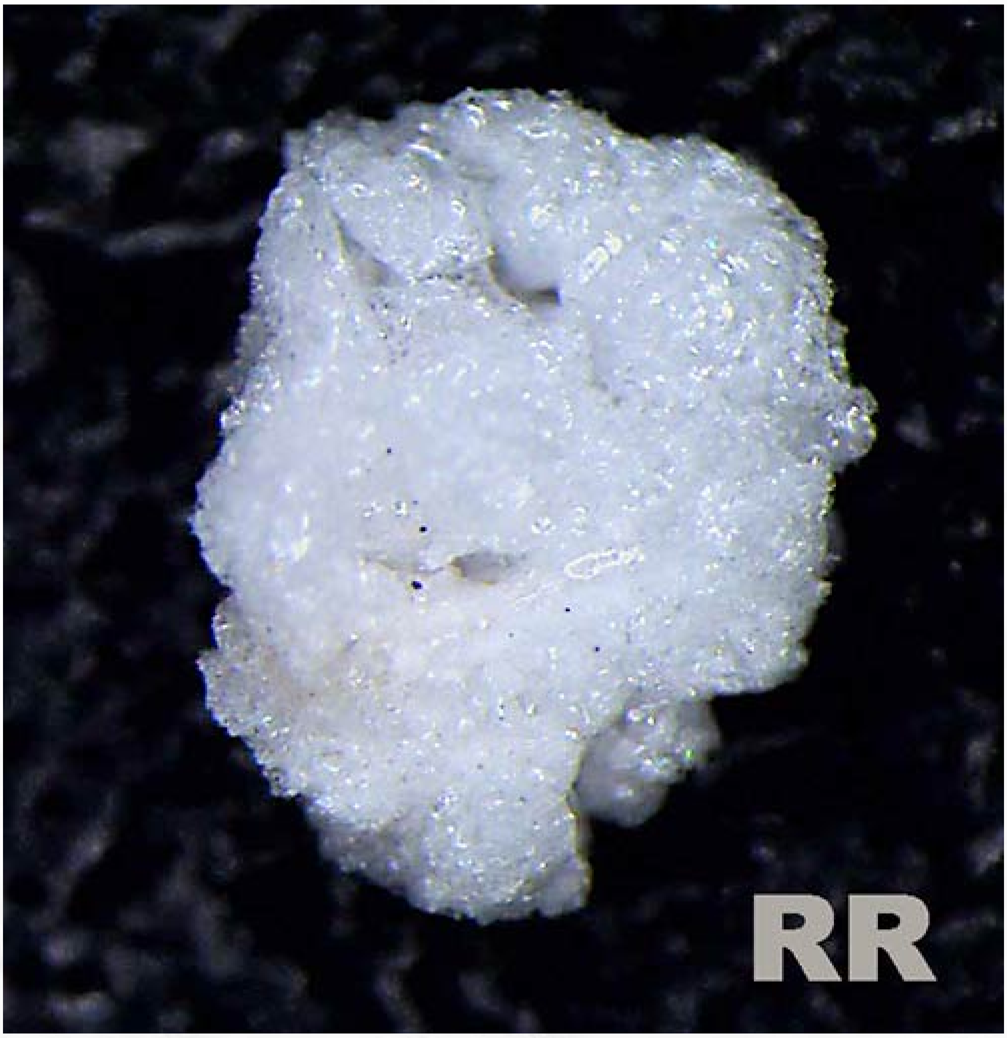
Shotgun Terrarium

How to build a simple, low maintenance, fruiting chamber.

The Shotgun Terrarium is an easy to make and easy to maintain fruiting chamber. It has no moving parts, needs no electricity and does away with shields and other complications.

How does it work?

The principle behind the shotgun terrarium is that of using perlite to increase air humidity. This is by no means an innovation as before the shotgun terrarium was developed it was already used. Here is a closeup picture of a piece of perlite. Notice how perlite is covered with ridges and bumps. Once you wet your perlite, this increases the surface area of water exposed to the air thus dramatically increasing evaporation rates over the same volume of water on its own. More evaporation means higher humidity.



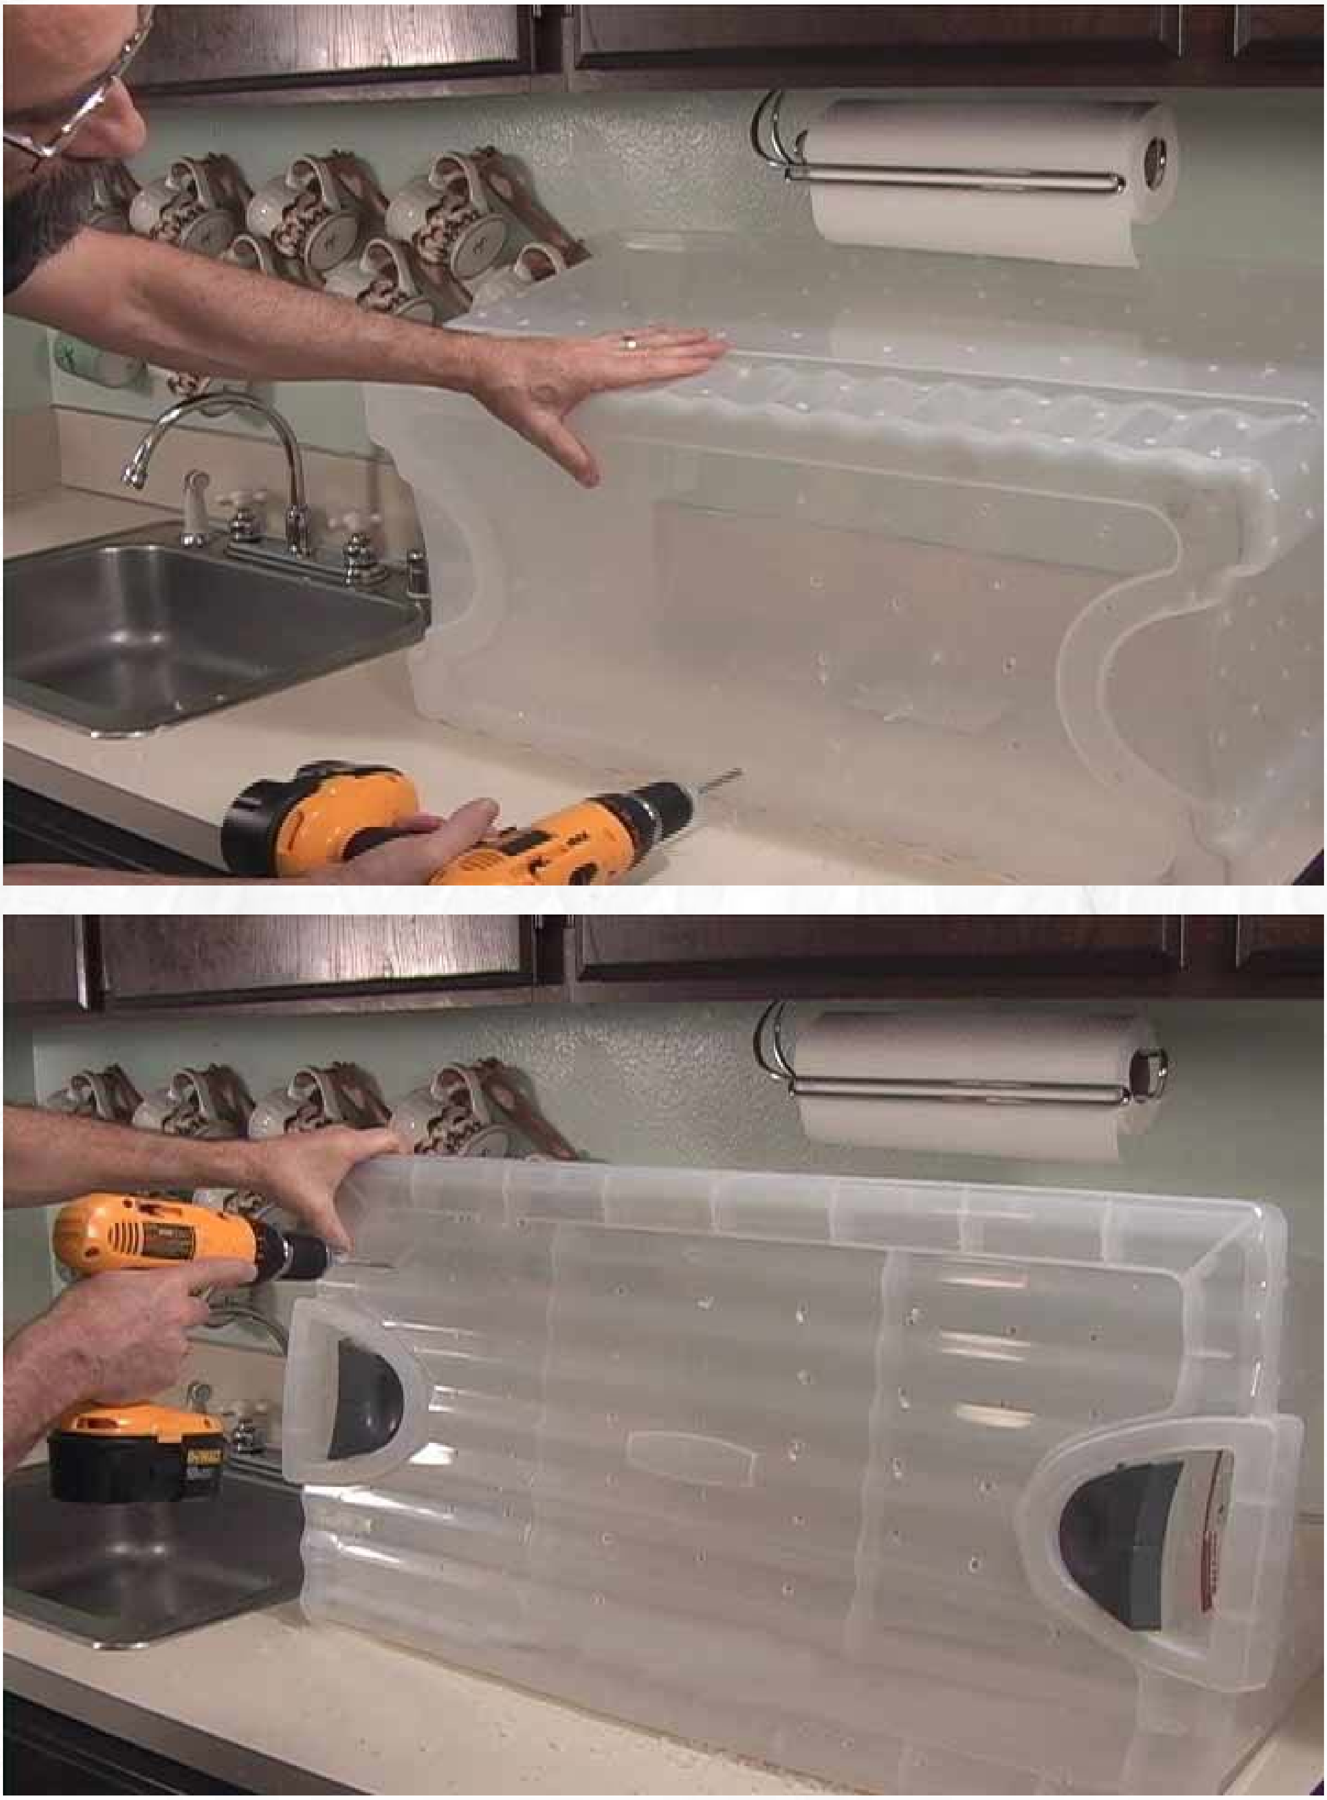
Building a Shotgun Terrarium

You will need:

- A transparent/translucent plastic storage container. The lid does not have to be transparent but if you have the choice, go with the transparent top. Mushrooms grow towards the light and if they get no light at the top they will grow sideways.
- Electric drill with a 1/4 inch drill bit
- Perlite. Enough to fill 3-5 inches of the bottom of the container.
- Pasta strainer or similar.

Step 1 - Drill the holes

Drill holes in all six sides of the container. Space them out evenly, with about two inches between holes. Now you know why it is called a shotgun terrarium :D



Drill holes in all six sides.

Step 2 - Prepare your perlite

Fill your strainer with perlite and wash it thoroughly under the tap. This both cleans the perlite of any dust and covers all the surfaces with water. Drain the perlite well.

VOLCANIC PERLITE
NATURAL

Allow perlite to drain well.

Step 3 - Place perlite in the fruiting chamber

Fill up your terrarium with the moist perlite. It should fill 3 to 5 inches of the bottom of the container. Spread it out evenly, keeping it as light and fluffy as possible. Your fruiting chamber is now ready.

Rubbermaid
Max Latch
XL

Use 3 to 5 inches of damp perlite (7cm - 12cm)

Step 4 - Put your cakes into the fruiting chamber

It is now time to put your fully colonized cakes into the terrarium and put the lid on. Do not place them directly on the perlite. Use old jar lids or pieces of tin foil as coasters to avoid direct contact.

Now, all you have to do is open up the lid twice a day and fan some fresh air into the fruiting chamber. You can use the actual lid of the terrarium as long as you keep it clean. We do this to introduce extra fresh air into the chamber.

While a lot of fresh air gets in through the holes you can never really have enough fresh air (as long as the humidity stays in the high 90%s) as it is a very important pinning trigger and also hinders the growth of contaminant molds. Before fanning (30 seconds is enough) give the cakes a good thorough mist with your water mister to keep them nice and hydrated.

Rubbermaid
Max Latch
XL

Extra Tips & Tricks

- Use a hygrometer to measure the humidity inside your fruiting chamber. It should be as close to 100% as possible. If on its own this terrarium does not achieve over 95% relative humidity, tape up some of the holes to slow down air exchange and that should increase your humidity levels.
- Expose your terrarium to light for at least a few hours each day. Light shows the mushrooms which way to grow and ensures even and prolific pinning (if all other conditions are correct). Indirect sunlight is good (avoid direct sunlight) or if you can't have it, use a compact fluorescent (energy saving bulb) or standard fluorescent bulb that gives off light in the daylight range. The packaging will say something like daylight or white light or 6000K (somewhere around that number). Good results have been obtained with a 12 hour on 12 hour off cycle. Stay away from incandescent (regular) lightbulbs as they do not emmit the right kind of light and produce a lot of heat
- Keep your terrarium slightly elevated. Use a couple of bricks or something to elevate the terrarium off the floor. This keeps it away from the dust and muck on the floor and more importantly lets air go through the holes you have drilled on the bottom.
- Here is a video describing the process and also another document (see below) describing the science behind the shotgun terrarium in greater depth. This site has also got some great videos explaining many other procedures, including the PF Tek.

Nibin 2009. Special thanks to RogerRabbit for letting me use his pictures and video.

Constructing Your Terrarium/Fruiting Chamber

This page explains the construction of a simple terrarium, also known as a fruiting chamber, for growing mushrooms. The function of a mushroom fruiting chamber, or terrarium as they're sometimes referred to, is to provide an environment with near saturation humidity, while allowing plenty of fresh air to enter and circulate. My terrarium design has become widely referred to as the *shotgun terrarium* due to the abundance of holes on all six sides. The ideal mushroom fruiting chamber will be constructed in such a way that stale CO2 laden air can exit, or be forced out, while a constant supply of fresh moving air is allowed to enter. While the terrarium needs to provide this supply of fresh air, it also needs to maintain a humidity level at or above 95% to promote mushroom formation and growth.

Over the years, I've seen many mushroom fruiting chamber designs come and go. Those that hold a high humidity often get saturated with stale air, and the mushrooms develop fat, tough stipes (stems) and tiny caps. Since with many species of mushrooms, it's the cap that we eat, the entry of fresh air is vitally important. Other terrarium designs use complicated systems of humidifiers and fans, and while these often provide the fresh air that's required, they sometimes fail to keep the humidity levels high enough, resulting in dry substrates and poor mushroom fruitbody formation. In addition, the use of mechanical or electrical devices introduces the possibility of failure, either by over saturation or drying out, due to equipment malfunction. That's why I advise to keep it simple. The terrarium I present here can be left unattended while you're at work all day, and you won't have to worry about losing your mushrooms.

The terrarium system that I designed and demonstrate here is what I consider to be the best combination of easy construction, excellent function, and low maintenance. To watch a video of the terrarium under construction, see part 3 of the BRF/PF tek video. It's been dubbed the *shotgun terrarium*, and the name seems to have stuck. The name comes from the appearance of up to a few hundred holes that are drilled into the plastic storage bin.

Shotgun Terrarium Theory of Operation

The theory of operation for the shotgun mushroom fruiting chamber is that natural air currents travel from areas of high pressure to areas of low pressure. Cool air has the molecules closer together than warm air, thus cool air is at a slightly higher pressure than warm air. When we put several inches of damp perlite in the bottom of our terrarium, we create an area with a slightly cooler temperature than the air above, which is exposed to lights that create heat, and our mushroom substrates, which are often at up to a few degrees warmer than the surrounding air due to thermogenesis.

This temperature differential, however slight, results in enough of a pressure gradient that it causes air to flow up through the perlite, absorbing moisture as it travels, and into the relatively lower pressure air within the fruiting portion of our fruiting chamber.

This air then exits through the holes in the upper section of the terrarium, carrying the excessive CO2 produced by our mycelium out with it. With this design, no electrical or mechanical equipment is required. Regular misting helps to keep our brf cakes or other substrates moist, and also serves to replace the moisture that evaporates from the perlite.

When using this system, drill holes as shown in the pictures and video clip on all six sides. I use a 1/4" (6mm) drill bit. Use of a larger drill bit is not recommended. It must be remembered that a 1/2" hole has four times the area of a 1/4" hole. (A 12 mm hole has four times the area of a 6 mm hole) If the holes are too large, your terrarium will not be able to maintain the high humidity necessary for growing mushrooms.

This system also requires an ambient humidity in your house of 30% or above, which incidentally will ensure your own comfort as well. In desert climates, and especially in cold climates during the winter months, indoor humidity is often very low. If you get shocked from touching another person, or a light switch, etc., after walking across the carpet in your home, it means your humidity is too low. The answer is to run a cool mist humidifier 24/7 in your home. Moist air holds heat much better than dry air, so you'll actually lower your utility bills by doing so. If you'll ensure that the humidity in your growing room is at least 30%, this design terrarium will easily maintain 95% humidity on the inside where your mushrooms need it.

Of course, it should go without saying that for this system to work properly, the terrarium must be elevated at least 1" above the table it's sitting on. Use blocks of wood, shot glasses, or whatever you have around the house to raise the terrarium off the table so air can circulate under it. It should also be noted that 90% of all airborne contaminants in a room are located near the floor, so make sure your terrarium has a home on a table or shelf.

Lighting Requirements of Mushrooms

Some mushrooms, such as the *Agaricus* species commonly found in grocery stores require no light at all. However, those commonly grown by hobbyists, such as *Pleurotus ostreatus* (Oyster Mushrooms), *Lentinus enodes* (Shiitake), *Psilocybe cubensis*, a hallucinogenic mushroom, and *Hericium erinaceus* (Lion's Mane) all require light to produce abundant, normal sized fruits. Experience has taught us that the light best suited for primordia formation and the development of fruitbodies is bright light with a color temperature of 5,000 Kelvin to 7,000 Kelvin. Fortunately, this type of light is easily obtainable at your local home improvement center in the form of fluorescent fixtures. For a small terrarium as described in this chapter, a single CFL (compact fluorescent) that screws into a standard light bulb socket will work very well. These can often be found in grocery and drug stores in every neighborhood. 15 watt CFLs will do the job well, but the package will probably have a large 60 stamped on it, indicating they produce light "equivalent" to a 60 watt incandescent light bulb. They're referring to lumens of output, not the frequency. Incandescent light bulbs are the worst possible choice for growing mushrooms, since they emit a 'red' light in the 3,000 Kelvin color temperature range.

The higher the color temperature, expressed in Kelvin, the closer to the 'blue' end of the spectrum the emitted light is. The lower the color temperature the 'redder' the light is. If you have a choice of fluorescent lamps, purchase those labeled 'daylight' since these have a somewhat higher color temperature than cool white. Daylight, sometimes called 'natural daylight' fluorescent tubes generally emit light in the 6,500 Kelvin range, while cool white fluorescent emits light at around 5,000 Kelvin.

If you have several terrariums stacked or otherwise near each other, you can use larger 2 to 4 tube fluorescent fixtures. These come in 48" and 96" lengths. Place the fluorescent lamps as close as you can get them to your terrariums without causing excessive heating. Species such as Shiitake and Oyster mushrooms prefer to fruit at temperatures in the upper 50's to mid 60's Fahrenheit (15C to 20C), while *Psilocybe cubensis* prefers to fruit at a temperature in the mid 70s to about 80 Fahrenheit (23C to 27C). Most mushroom species don't mind a slightly warmer temperature during daytime than at night, so if your grow room is a bit colder than the temperature ranges given above, a little warming from your lights during the daytime won't hurt at all, provided you don't let the air in your terrarium get too dry. For cakes, try to keep the humidity above 95%.

Cased substrates are a bit more forgiving, but still try to keep your humidity above 90%. 12 hours on, 12 hours off has proved to be a great combination over a wide range of species. Of course, if you have a bright window near your terrarium, that will suffice, but direct sunlight for more than a few minutes per day should be avoided.

Disregard outdated advice in old books which is constantly repeated on the internet to colonize mushroom substrates in total darkness. Experience and rigorous peer reviewed studies have proved that exposure to low level ambient indoor lighting during spawn run and substrate colonizing will speed up the process, leading to full colonization up to a few days earlier than the same substrate would if colonized in darkness. In addition, mushroom mycelium develops a day/night circadian rhythm, so exposure to light from day of inoculation sets this process in motion, leading to earlier fruiting and harvest.

Pf tek done right TEK

by Shea25

original source: http://www.shroomery.org/forums/showflat.php/Number/11585613

PF tek
Things needed

- 1/2 pint wide mouth canning jars
- Pot/Pressure cooker
- Vermiculite
- Perlite
- Brown rice/Brow Rice Flour
- Tin foil
- 70% Iso alcohol
- Plastic Tote
- 6500K fluorescent bulb
- 1/4 inch drill bit/Drill
- Hammer/Nail
- Mixing bowl and spoon
- Gypsum
- Spore syringe
- Latex gloves
- Dust mask
- Lighter

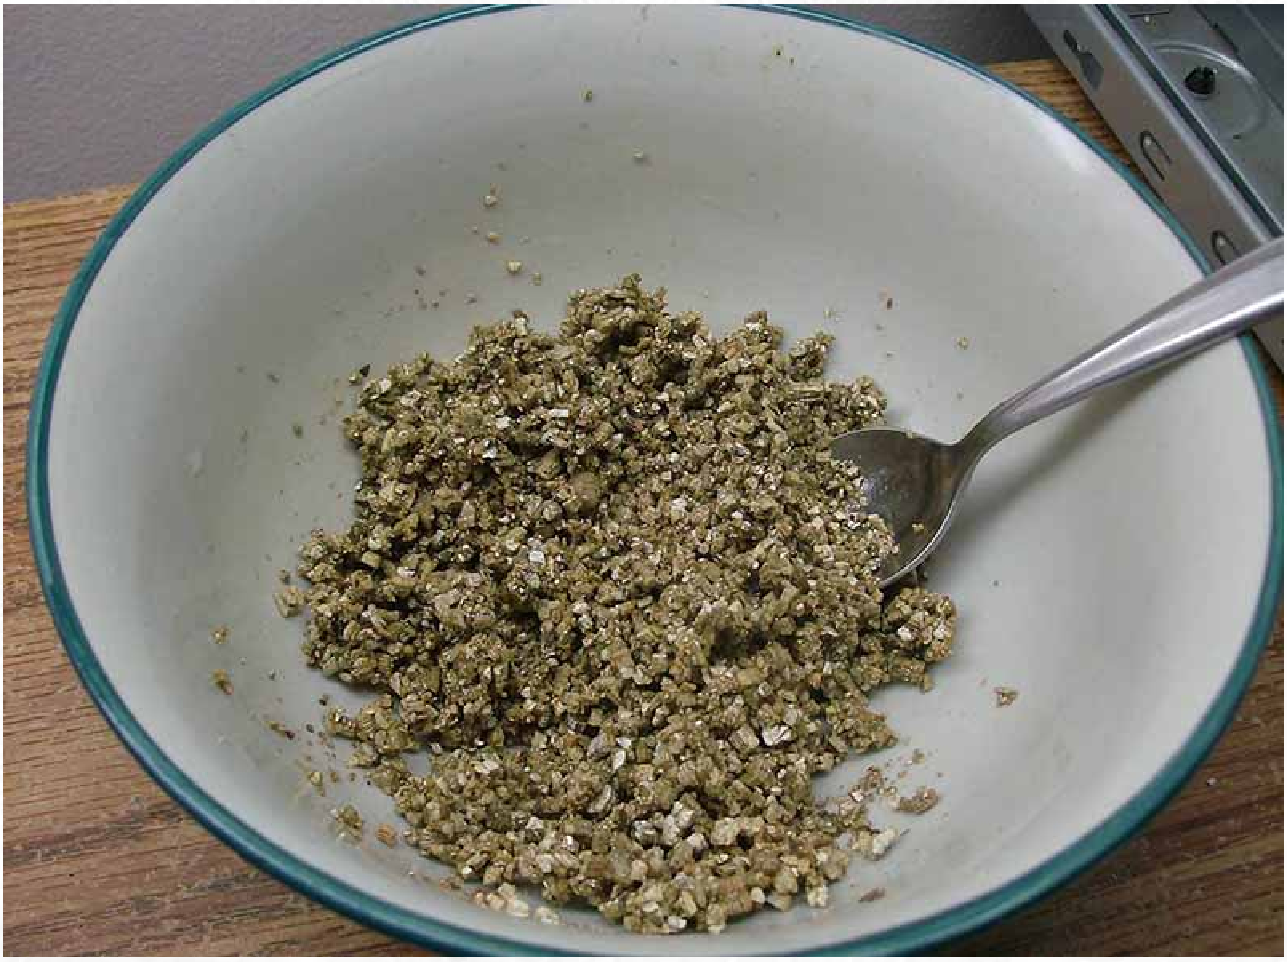
Preparing the jar

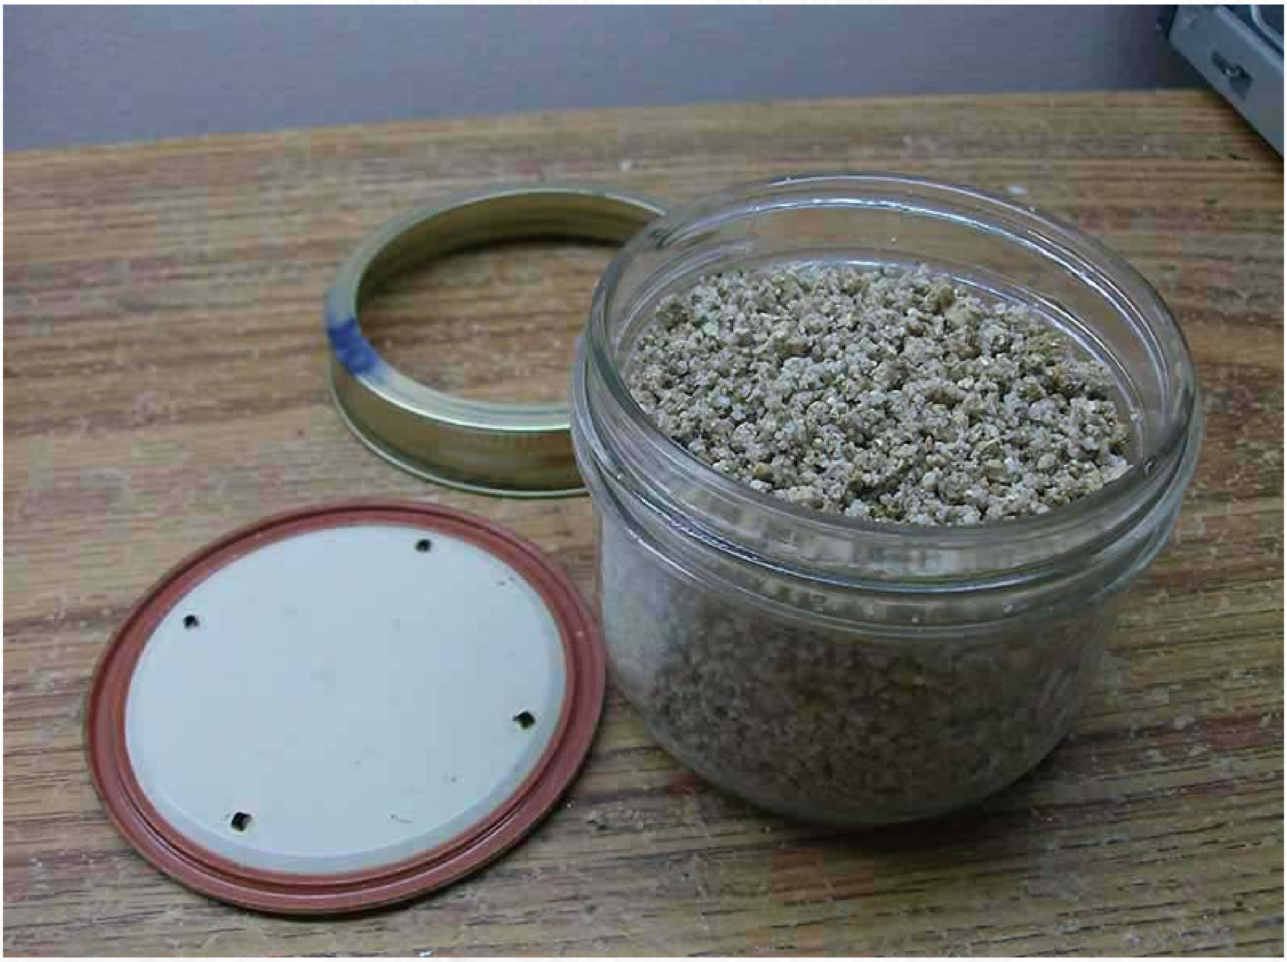
Take the lids and using a nail and hammer or a 1/8 drill bit, drill 4 holes near the rim of the lids nicely spaced out. Depending what way you use you lids i use mine rubber side down just punch the holes so they don't leave burrs pointing towards you.

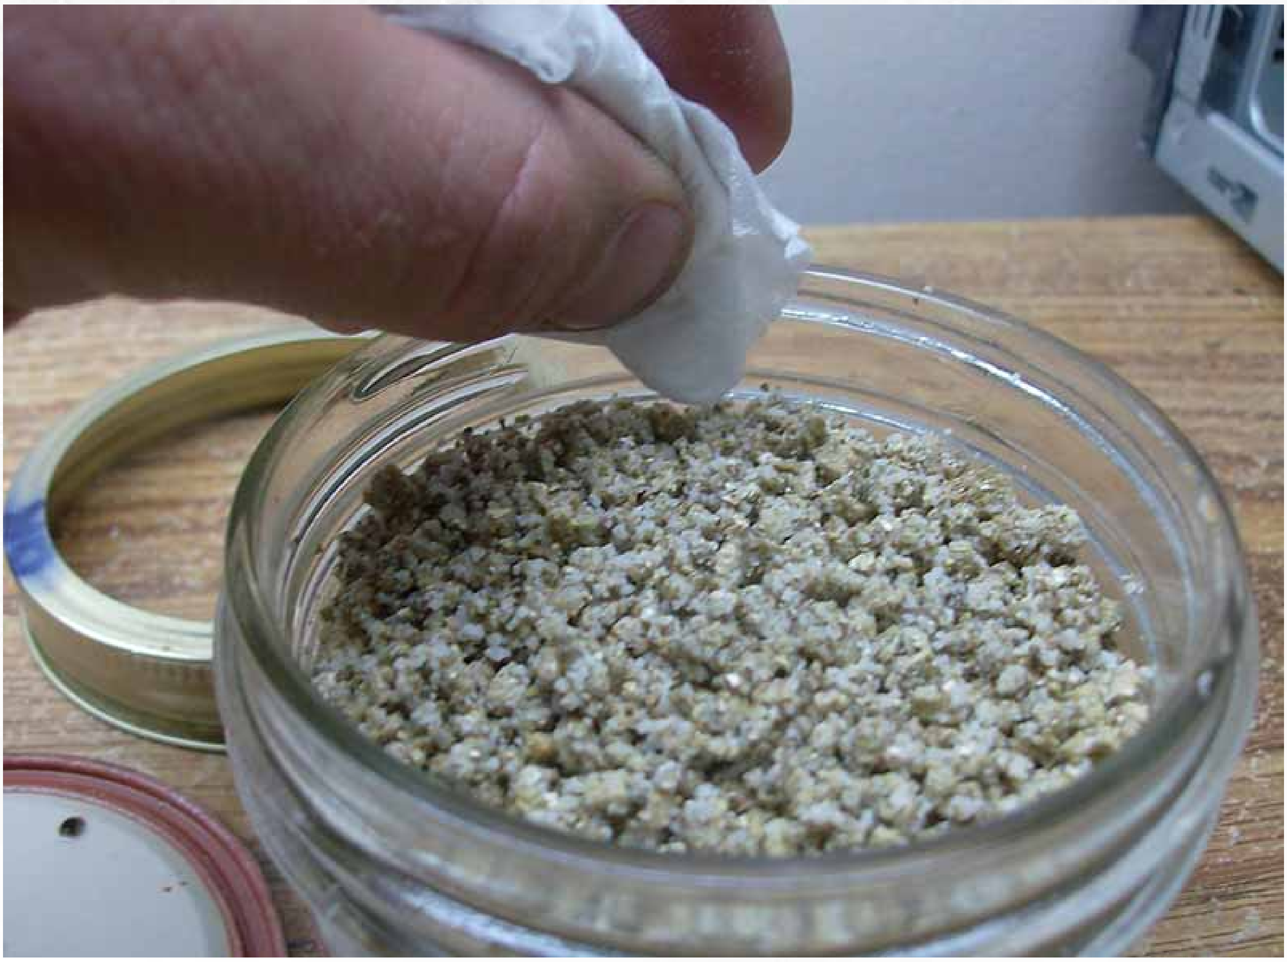
The basic recipe for 5 PF jars is this 2 parts vermiculite 1 part water and 1 part BRF (additionally you can add 1 tablespoon of gypsum for 5 jars)

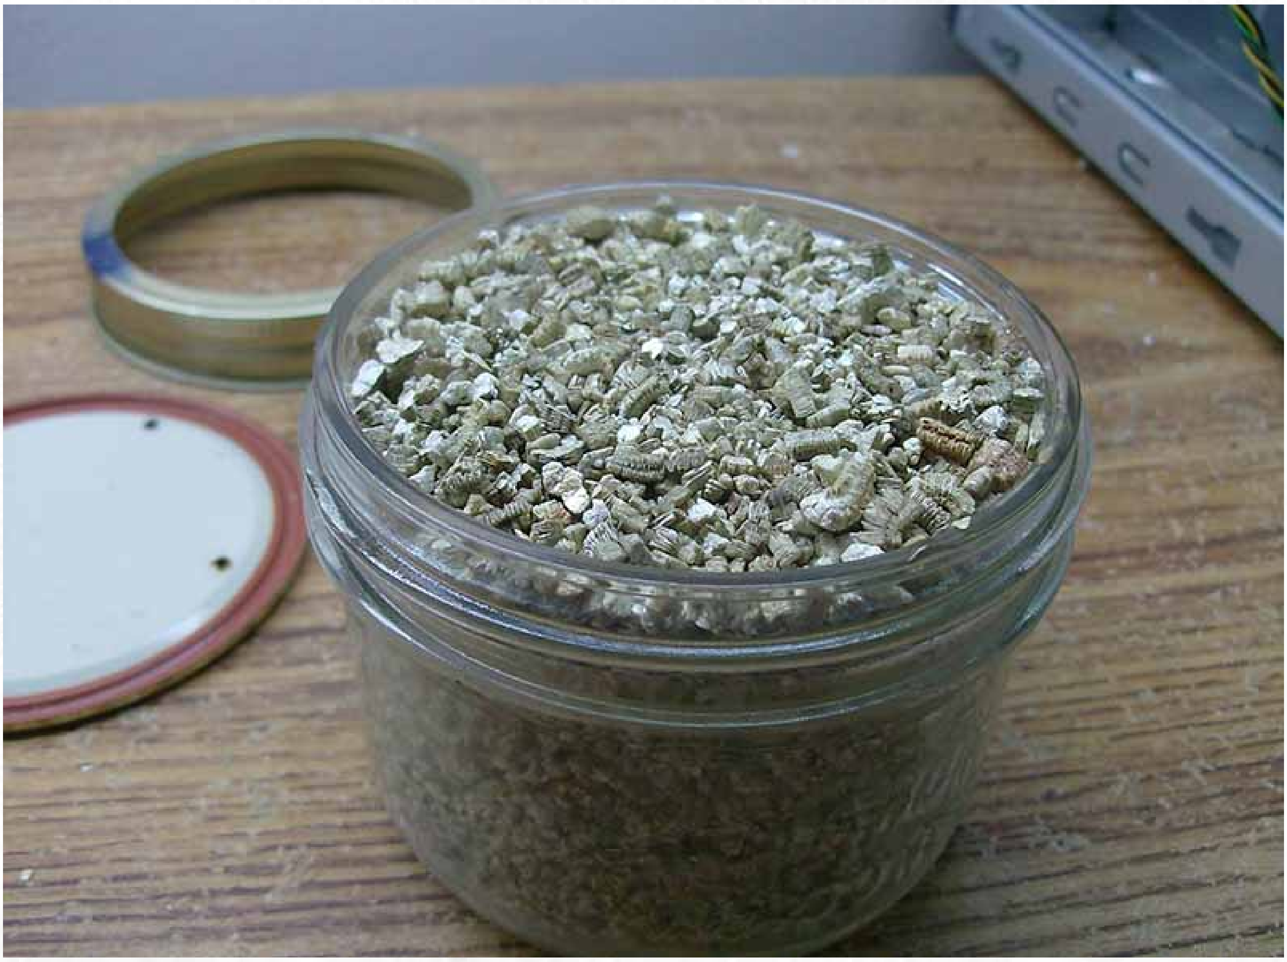
In a bowl add the 2 cups of vermiculite (and gypsum if you use it) now add the 1 cup of water, mix really well. Now add the 1 cup of Brown rice flour (you can make your own by grinding brow rice in a coffee grinder). Mix this really really well. Now load this into the 5 canning jar equally, making sure not to compress the mixture in the jars you want it nice and airy. You will be leaving a 1/2 inch space at the tops of the jars for the dry vermiculite layer.

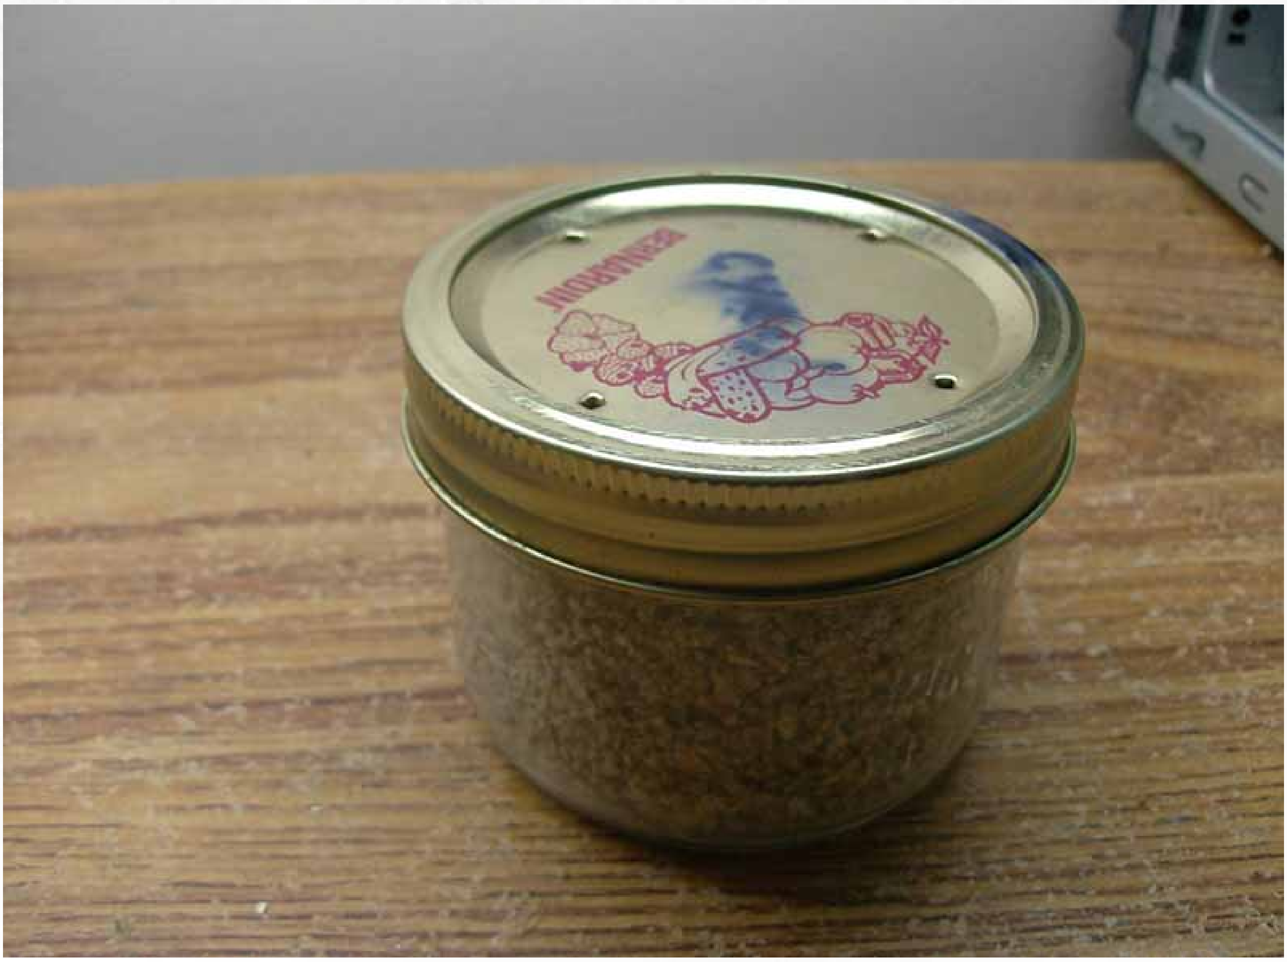
Take a paper towel and wipe the 1/2inch space you left at the tops of the jars making sure to wipe away any BRF mixture or moisture away. Now top off the jars with dry vermiculite, screw on the lids and cover the tops the lids with tin foil. The tin foil is there to keep any moisture from entering the jars while there sterilizing.





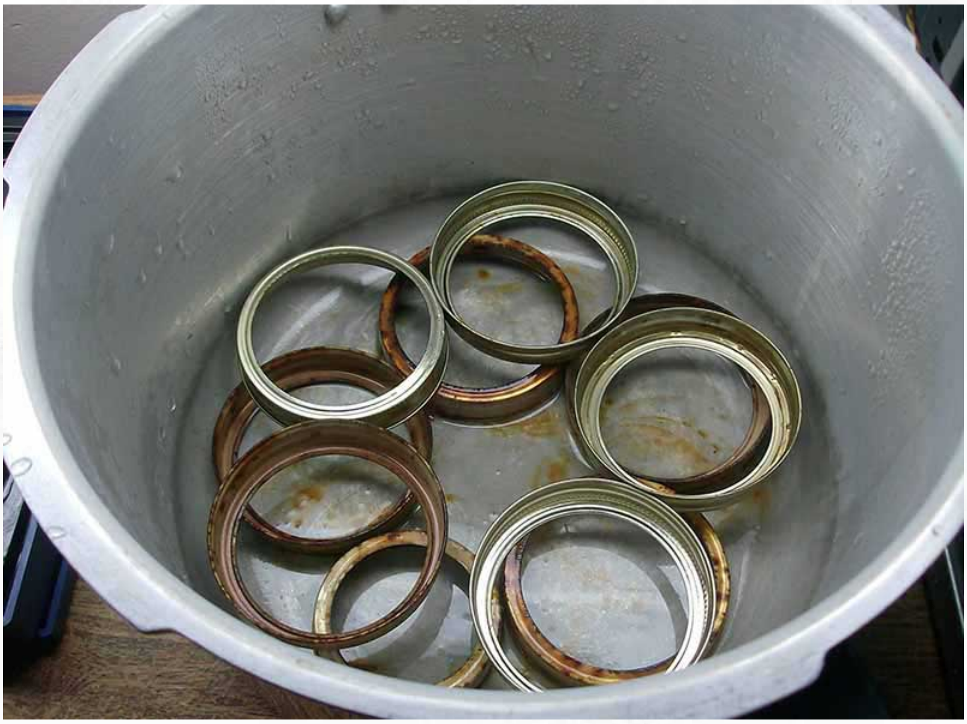


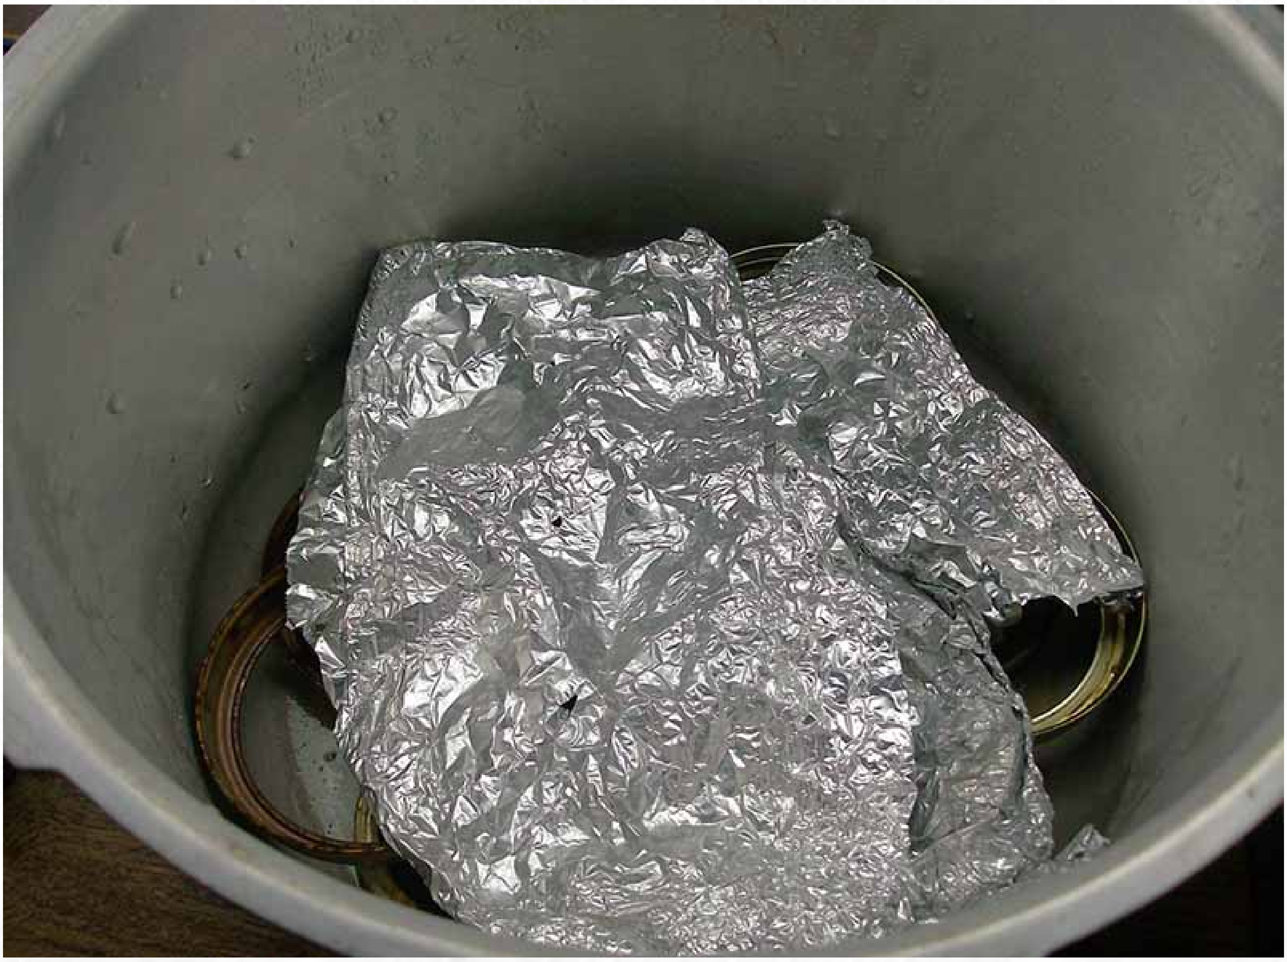




Sterilizing

Now you want to take you PC (or pot with a tight fitting lid) and fill the bottom of it with jar lid rings and tin foil this is to keep the bottom of your jars off the bottom of the PC/Pot so they don't burn. Some PC's come with trays to keep the jar already off the bottom use that if you can. Once that is done put the jars into the PC/pot and fill it with cold water just almost to the bottom of the jars. Now put on the lid of the PC/Pot and put the heat on High. Once the rocker on top of the PC starts to rock turn the heat right down to just keep it to a slight rock and start your 60 minute count down. If you're using a pot once it come to a boil turn it down to a slight simmer and start your 90 minute count down. After the 60(PC) or 90(Pot) minutes are up turn off the heat and walk away let them cool down over night or for 8 hours.

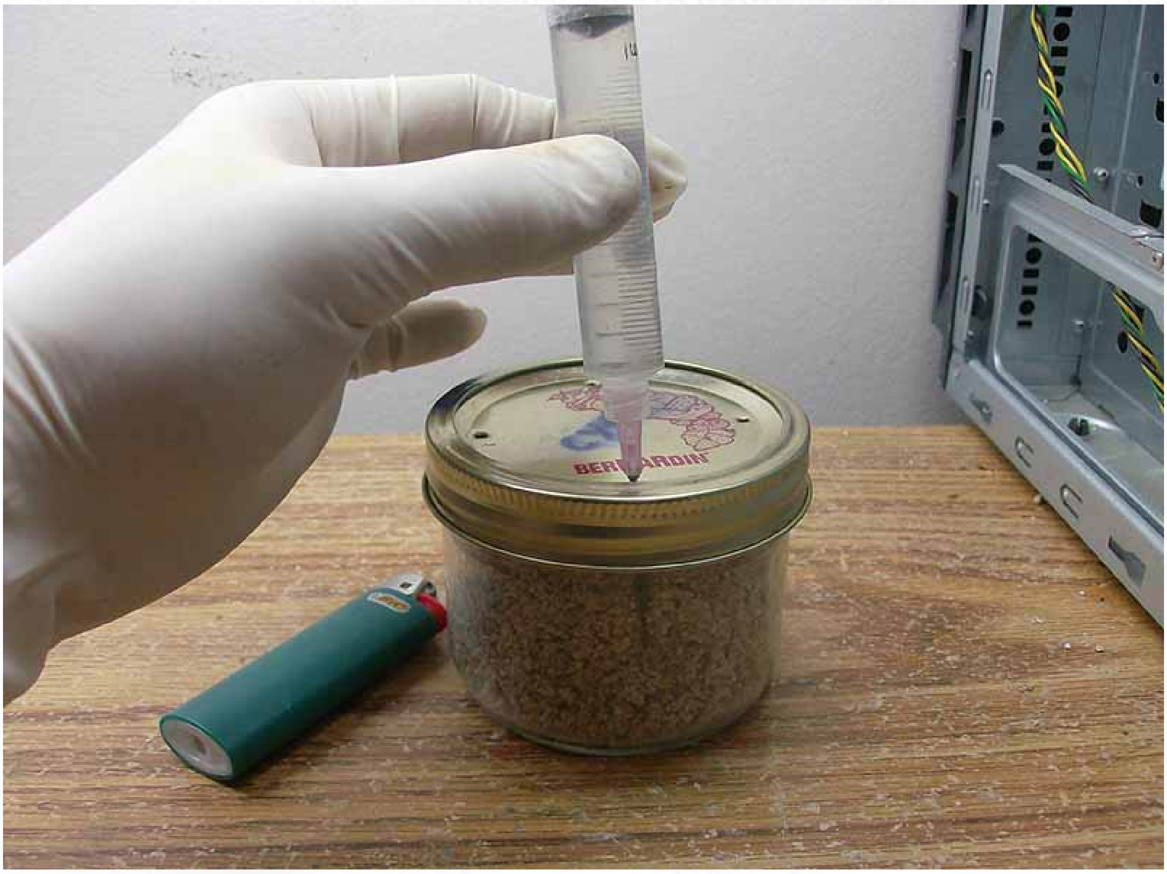




Inoculation done right

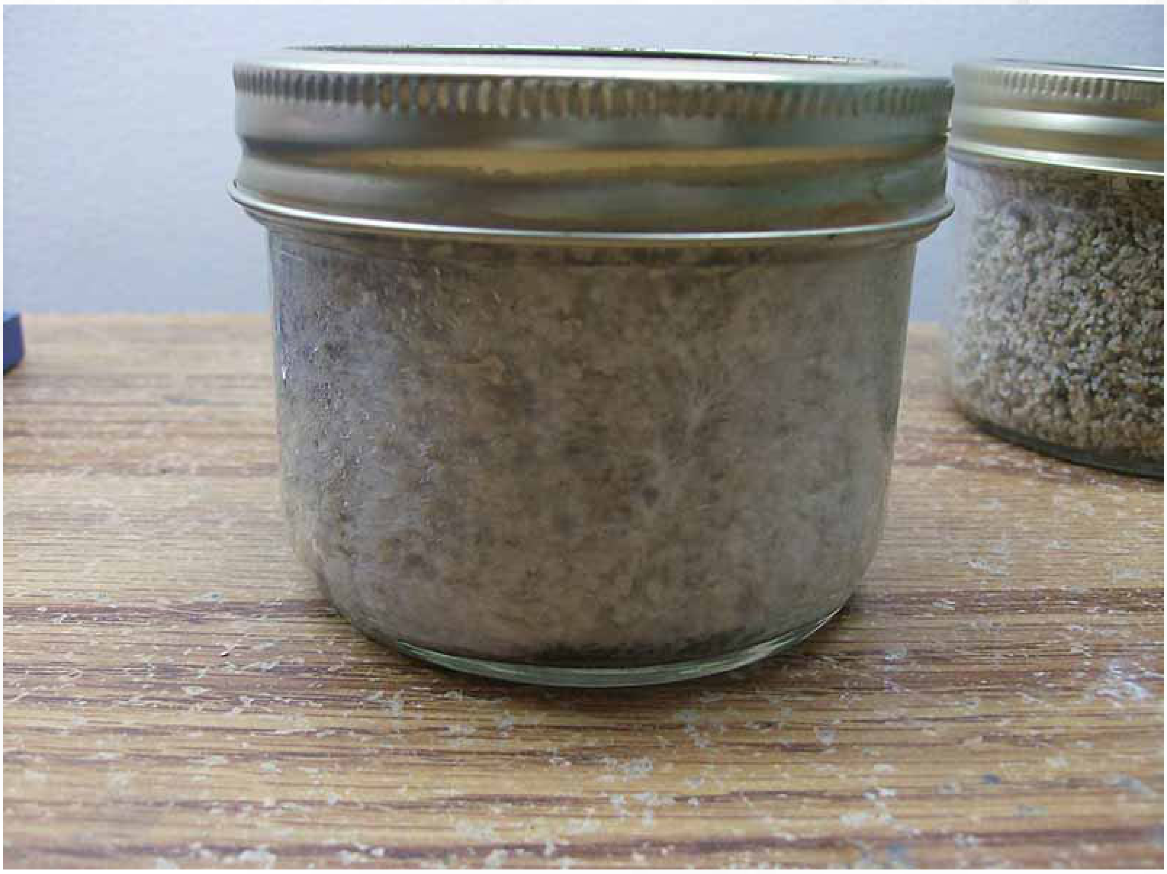
Once the jars are cooled down put them in a draft free room along with the 70% Iso, Lighter, spore syringe. Make sure the rooms windows are shut and AC or heater turned off. Wash your hands and arms really good. Now put of the gloves and mask. Take the foil lids off the jars you won't need them anymore. Now rub your hand down with the 70% ISO wait a few seconds for it to evaporate. Now shake the syringe really well, using the lighter heat the needle of the syringe till its red hot now proceed to inoculate the jars using a 1/4 cc of solution per hole inoculating towards the glass. That's 1 cc per jar. After every jar heat the needle back till its red hot and repeat.

BERNARDIN
CYA
TC



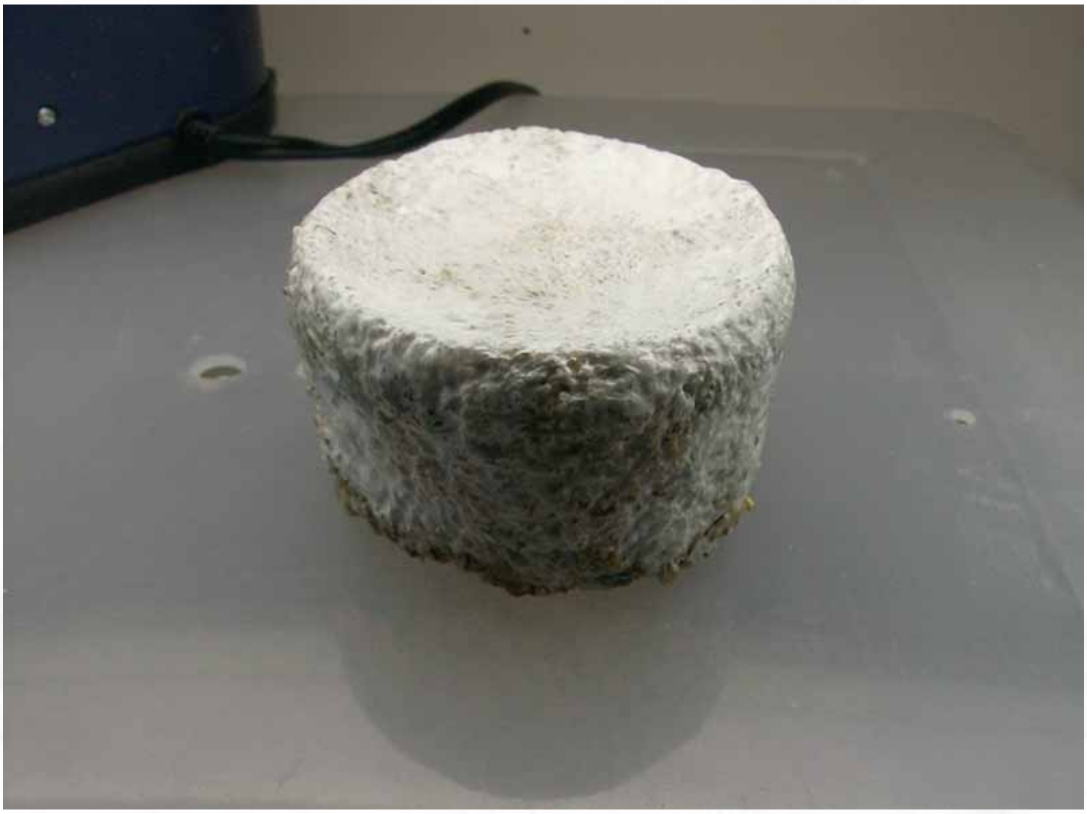
Incubation done right

Now put the jars away in a closet of shelf at room temp they will start to colonize in a few days. Keep an eye on them every 4 days or so. Once they appear to be 100% colonized let them sit for another week to consolidate.



Birthing and dunk

Once the cakes are finished their 1 week consolidation it's ready to get them out of the jars. Open the jars get rid of the dry vermiculite layer now slap the jars (upside down) onto a wood cutting board or counter top, trying to coax the cakes out of the jars. Once out rinse them off and submerge in cool water for 24 hours making sure they stay submerged. After 24 hours rinse them again and now roll the cake in dry vermiculite making sure to cover the cake well tops and bottoms.
I find busting up some of the verm for the dry roll up alittle finer helps.



Fruiting done right

Build one of these Shotgun terrarium.

I personally use a PMP.

Mist your cakes 3-4 times a day and fan right after, fan 5-6 times a day. Water evaporating off your cakes is a major pinning trigger. Give them a 12/12 light schedule using a 6500K Florescent bulb (daylight or cool blue). Once they have pinned and grown and all picked, dunk them for 24 hours again this time no dry roll in vermiculite and put back in the Shotgun Fruiting Chamber.

Good Luck

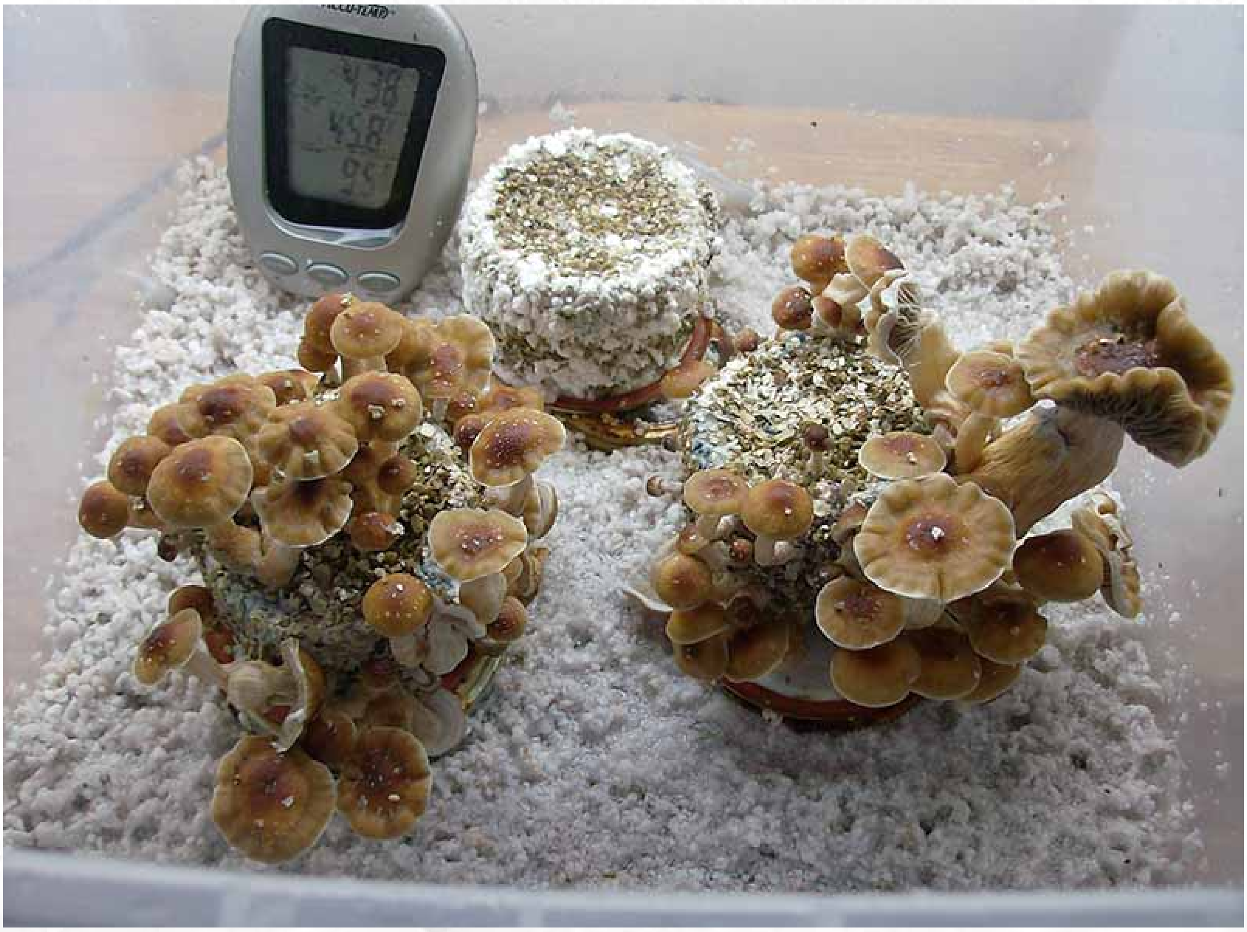
Tips

Gypsum really helps the development of the fruit bodies I recommend using it.
Room temp 70-75 is perfect for incubation and fruiting.
There's no need to keep the dunking cakes in the fridge.
Mist and Fan Mist and Fan.
Use short wide mouth 1/2 pint jars.
Dont cover the lids after inoculation with anything example, foil/tape.
Give them love.

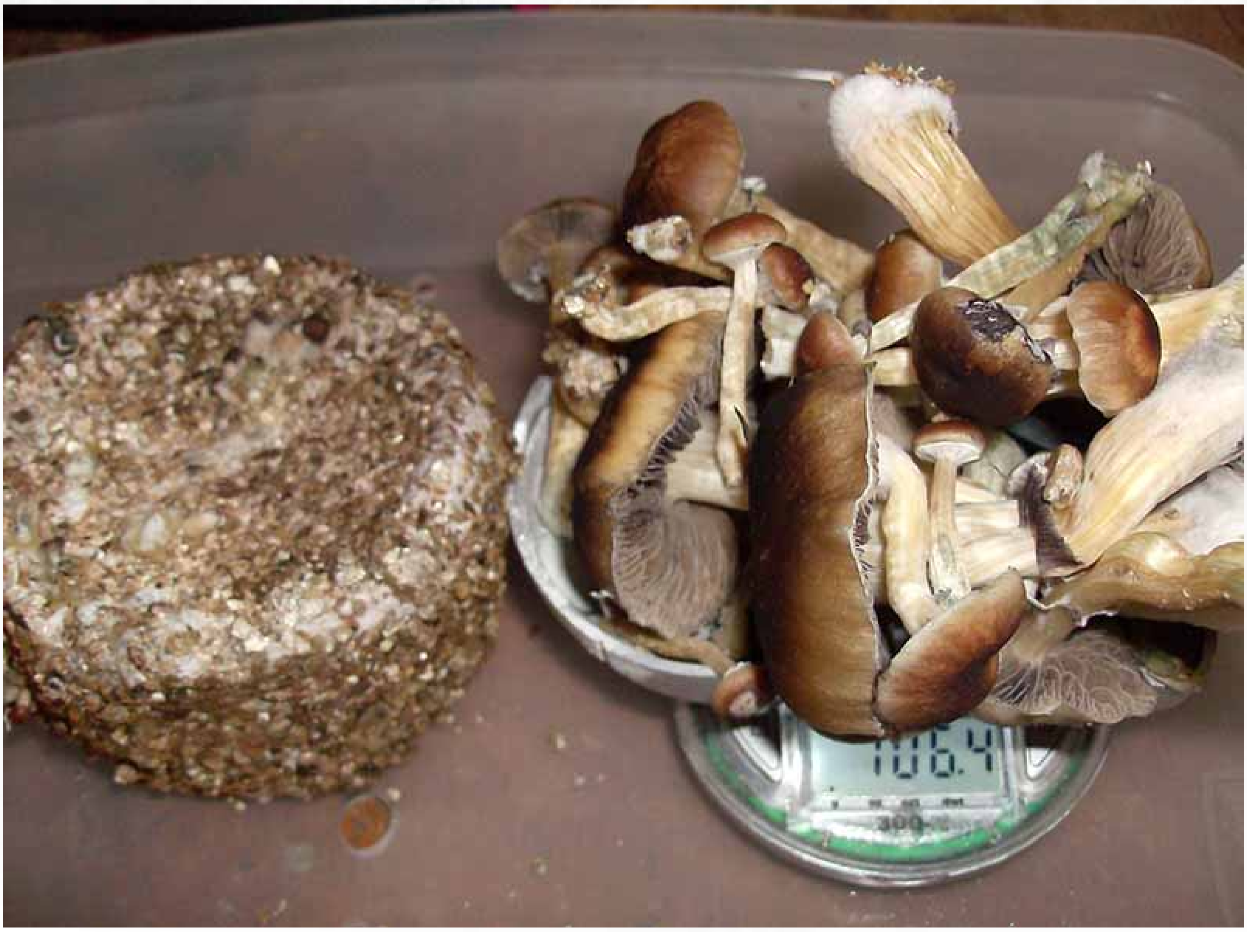
Results in this Golden Teacher.

Capacity 300g x 0.1g
72.6
300

This was 2 cakes first flush, came just under 19 grams dry. Oak Ridge.



Heres another set of cakes.



Results may vary.

Sterilizing a syringe

Here is a How to on sterilizing a syringe to make up a spore syringe.

How to sterilize a syringe with just a pot water and syringe.

Thing needed.

- A pot
- Empty Syringe
- Water (tap can work)

Fill the pot with cold water. Turn the burner on High and wait for the water to come to a full boil. Now start a 10 minute countdown and keep the water at a full boil.

After 10 minutes take the empty syringe and suck back the boiling water and let it sit in the syringe for 1 minute then expel the water in a sink (not back in the pot).

Repeat 4 more times on the last time keep the water in the syringe cap it and let it cool down.

Hope this helps.

PF-Tek F.A.Q (Shroomery)

Recipes through Inoculation

original source: http://www.shroomery.org/8515/Recipes-through-Inoculation

What is a PF cake?

A "PF cake" is named after its "creator", psylocybe fanaticus.
It is a mushroom growing substrate prepared of brown rice flour (BRF), vermiculite, and water, spooned loosely into a glass 1/2 pint jar, and inoculated with a spore syringe.
It is often referred to as the "PF style," "PF method," etc. Generally these terms refer to the substrate recipe and the style of inoculation (the creation of the colonized/colonizing substrate).
Please refer to the Basic Cultivation Guides for detailed overviews of the "PF" method, including substrate recipes, inoculation methods, colonization parameters, and the like.

What is the point of each step in the recipe?

PLEASE read the getting started Q&A before reading this overview, otherwise it won't make sense!

Using 1/2 pint mason jars.
1/2 pint jars are ideal for the PF-tek for various reasons. First and simply, they have been "tried and true" for quite a long while now. But, there are better answers than that, of course. Glass jars have been used for the (edible) mushroom cultivation for quite a while, for spawn production as well as fruiting. Glass jars are easily sterilized, as they can be safely autoclaved/pressure cooked/boiled without damage to the jar, and while maintaining internal water content of the jars. The 1/2 pint size is ideal as well, since jars can "finish" colonizing within 3-4 weeks. The reason why this is ideal is because you want the substrate to colonize as quickly as possible - so it can ward off any potential contaminants that may settle in the substrate through a vector you have not discovered, through inadequate sterilization of the substrate, etc.
Using 1 pint jars or larger with the PF-tek means the time to colonize is increased to a point where it is no longer worth it when weighing in the added colonization time as well as the additional risk of potential contamination (in its slower colonization times). It is more generally regarded as "the law of diminishing returns." There have been reports of successful PF-tek recipes used in 1 pint jars, but this is the exception and not the norm. Glass also serves a utilitarian purpose - you are able to see the progression of the mycelial growth (and any possible contaminants as well). Glass cups can also be used, but are not as "plug and play" as mason jars are. They also don't seal as well. But, mason jars can be hard to find in some areas, and their substitution can be necessary for the PF-tek.

Using 1/4 cup BRF, 1/2 cup vermiculite, and 60ml water.
To adequately colonize, mycelia needs food, water, air, and proper temperatures. The brown rice flour is the "food", and the vermiculite makes the entire mixture airy enough for air to reach throughout the substrate (and hence, all the mycelia forming in the middle of the cake that you can't see). So why not up the food, and make colonization quicker? Because, too much food can be a bad thing. The "food" which mycelia loves so much also attracts contaminates, and more food means more of a possibility of contamination. And if mycelia likes air, why not increase the amount of vermiculite in the mix, making it more airy? Once you mix a batch, you will see that the recipe as provided is about as "airy" as vermiculite will get in the mixture. Also, the addition of one element will mean less of another. Water content should also be kept as close to the ratio provided as well. Too much water and too little water both can slow the colonization of substrate to a halt. Plus, too much water will make the mix pasty and muddy - so that the mycelia will have a hard time colonizing through it.

Using a dry vermiculite "seal" on top of the substrate.
The vermiculite seal has 2 purposes.

- It stops airborne contaminants from settling on non colonized substrate.
- It also acts to provide some air exchange to the jar.

Air exchange can boost the rate at which mycelia grows, so it is important to have some measure of fresh air passively able to reach the substrate. Also, mycelia and mushrooms create CO_2, while using a small amount of O_2. Allowing for some gas exchange can help speed colonization. Many people whose PF jars have slowed "flip" their jars, so that the lid is on the bottom - which allows for more air to circulate to the non colonized bottom of the PF cake (the top part generally colonizes more quickly than the bottom).

Lift the jars up from the bottom of the pot.
The heat from the burners on the stovetop transfers directly to the bottom of the pot, which transfers the concentrated heat to whatever is sitting at the bottom of that pot (your jars). Lifting the jars by placing them on the cooking rack that comes with the pressure cooker, or placing a washcloth on the bottom of the pot, will create a more even disbursement of heat. This means the bottom of your jars won't be "cooked" by the heat emanating from the burner. Remember, you're sterilizing by steaming the jars, not by cooking them. A jar whose bottom has been cooked will oftentimes not colonize on the bottom, as the resulting overcooked cake becomes hard and impenetrable for mycelia. Overcooking can also occur if your water level runs too low, so be sure to maintain water in the pot for the entire sterilization time. AND DO NOT ADD COLD WATER TO THE BOILING JARS, otherwise they will crack and be unusable.

What is the difference between brown and white rice?

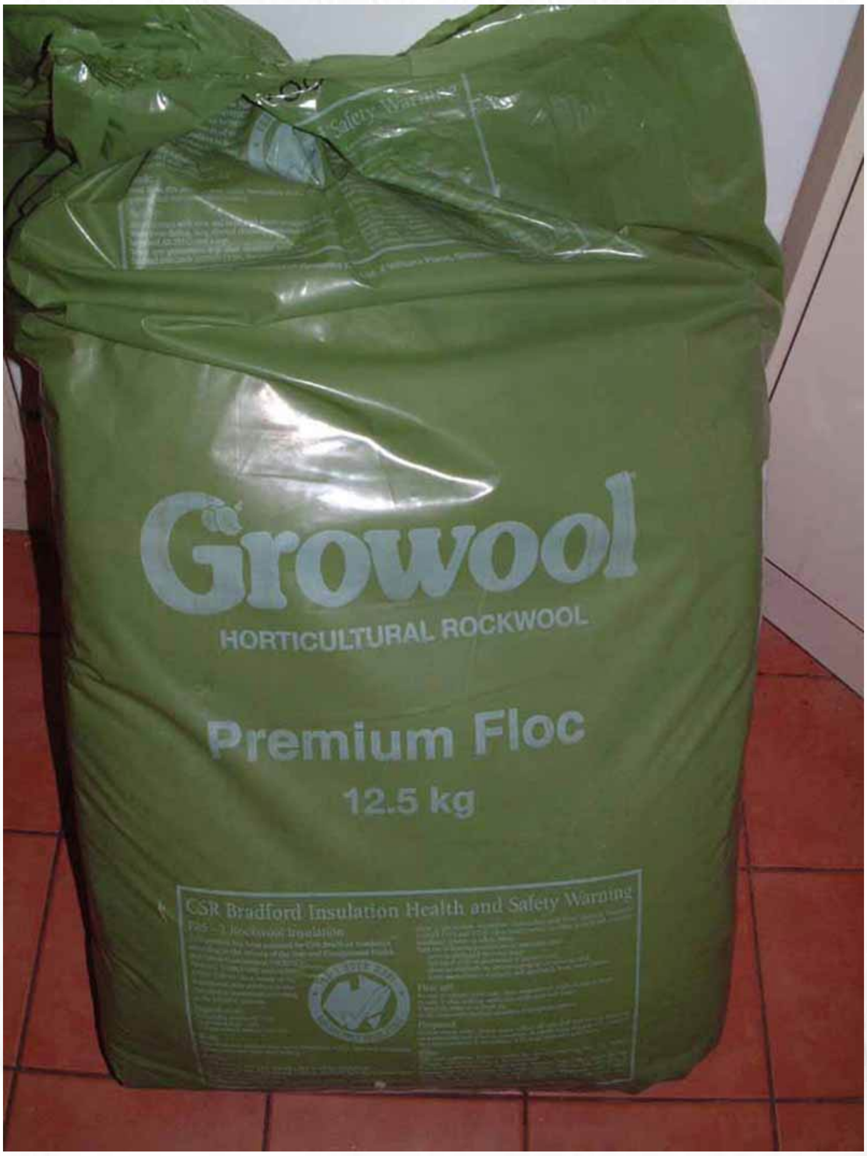
The difference between brown rice and white rice is not just color. A whole grain of rice has several layers. Only the outermost layer, the hull, is removed to produce what we call brown rice. This process is the least damaging to the nutritional value of the rice and avoids the unnecessary loss of nutrients that occurs with further processing. If brown rice is further milled to remove the bran and most of the germ layer, the result is a whiter rice, but also a rice that has lost many more nutrients. At this point, however, the rice is still unpolished, and it takes polishing to produce the white rice we are used to seeing. Polishing removes the aleurone layer of the grain - a layer filled with health-supportive, essential fats. Because these fats, once exposed to air by the refining process, are highly susceptible to oxidation, this layer is removed to extend the shelf life of the product. The resulting white rice is simply a refined starch that is largely bereft of its original nutrients.

Why do we boil the jars of substrate?

We boil the jars in order to sterilize them in order to destroy all forms of life in the jars. (molds and bacteria, spores and bacterial endosporse). This is done, so we can inoculate the now sterile substrate with the desired fungus.
These organisms which live in the soil, in water, etc. can invide and digest a food source like the one we are providing with the PF-tek recipe. This we call contamination.
Boiling water reaches a temperature of 212° F, which is adequate to kill molds and spores which may reside in the water, vermiculite and the brown rice flour.

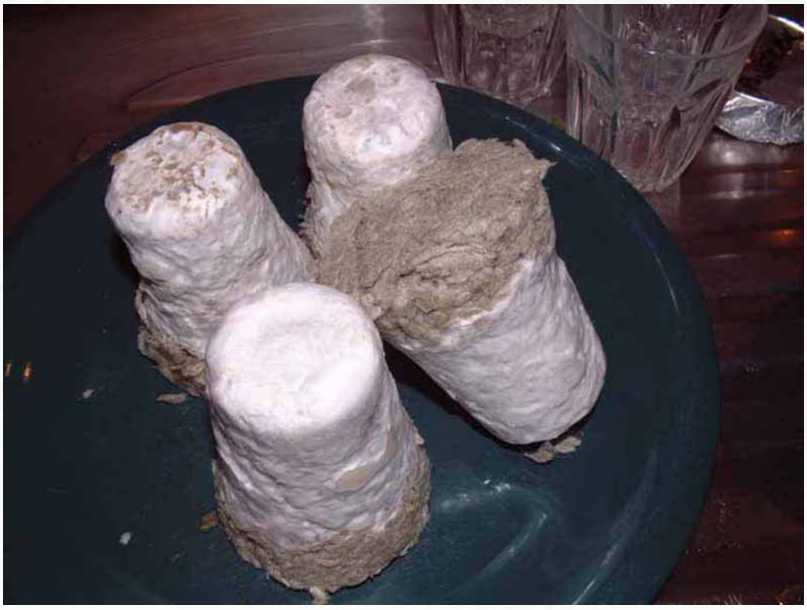
Can I substitute any ingredients in the PF recipe?

Vermiculite:
Coco coir has been tested as a replacement for vermiculite in the PF-tek substrate, but it colonizes more slowly and is more apt to contaminate than vermiculite is. It needs to be sterilized longer. It performs poor in comparison with vermiculite.
Perlite holds far less water than vermiculite, you will to lower the water content. It has been used, but the results pale compared with vermiculite.
Grow wool (a hydroponic medium) has been shown to work:
By Starter:
"An alternative (in my fun so far) is growool. It's 100% inert and pH neutral.



Growool
HORTICULTURAL ROCKWOOL
Premium Floc
12.5 kg
CSR Bradford Insulation Health and Safety Warning

It's a glass fiber material. Same as insulation, but pH neutral and horticultural grade i.e. contains no fire retardants like monoammonium phosphate.
Holds 1/3 more water than vermiculite.



Colonises much the same as standard PF vermiculite cakes. Just pack it loose, as you do with regular PF vermiculite cakes -- a high air filled porosity profile is a must in any cake.

The top layer can be growool too. 100% vermiculite free cakes. Can be dunked after birthing like a regular cake. They weigh noticeably more."

Brown Rice Flour:
Dark rye flour has been reported to have favorable to excellent results when used to replace BRF (1:1 ratio) in the PF-tek, also other ground grains can be used like ground millet or ground millet based birdseed. Also corn flour. Wheat flour is not as good since it makes the substrate very greasy and clumpy, difficult to mix.

Water:
In addition to any water suitable for human consumption (including mineral water) clean water from natural sources (river, pond) can be used.

What are the different ways to sterilize a PF jar?

You can sterilize the jars by boiling (steaming) them in a pot with boling water or using a pressure cooker which guarantees a better sterilization.

What precautions should I be aware of when inoculating?

In the open air, you should take care to be as clean as possible, as the air itself contains contaminants which would love to colonize your lovely PF substrate and kick your mycelia's ass. So, spray an anti-bacterial spray in the air around you, work as quickly and efficiently as possible, and be sure the only thing that touches the needle is the substrate, which is sterile (if your procedures are correct). You do face the off chance of a contaminant landing on the needle, which is then introduced to the sterilized substrate. When using a sealed glovebox or flow hood, there is minimal to no chance of contamination through inoculation procedures. Basically, the more time and effort you put into keeping your procedure sterile, the less chance you will encounter of contamination.

****NOTE**** Open air inoculation is never recommended. Spend the time to make yourself a glovebox and follow sterile technique. You will have much better results.

Is is it ok to use the syringe right out of the fridge or should it warm up some?

It's ok to use it right out of the fridge.
The small amount of the inoculum warms up to the substrate temperature immediately upon inoculation.

Just remember to shake up the spores, and flame sterilize the needle red hot before inoculation.

How much spore suspension from my spore syringe should I use?

PF recommends using 1ml per jar, which, for 4 holes is $^1/_4$ ml per hole. The more spore suspension you have, the quicker colonization will occur. But, that's not to say that using an entire syringe will make your jars finish in a week. It just means that using more suspension will make the initial colonization of mycelia occur more quickly, which *may* mean it has a better hold against potential contaminates. But, using too much spore solution can be detrimental - as is upsets the water ratio balance within the jars. Too much water is not good, and can actually hinder growth by making the rice flour too "pasty" to be colonized effectively. Also, using more spore suspension means it is less cost effective in the long run - $^1/_4$ ml per hole means 10 jars, while 1 ml per hole means 2.5 jars. Economically speaking, and especially if you buy spore syringes and not make them, it becomes less and less cost-effective for using more solution (to eventually achieve the same result). $^1/_4$ ml per hole will result in colonization, given that all of the parameters are met. So, using anywhere from 1ml - 4ml per jar ($^1/_4$ ml - 1ml per hole) should be safe.
Remember, some times less is more.

How long should the jars cool before inoculating?

Jars need to cool before inoculation because spores are killed by excessive heat (such as the temperature inside a PF-tek style jar after being boiled for 45 minutes to an hour). So, you need to let the jars cool on their own, preferably for at least 6 hours, and hopefully overnight. It is recommended to cool jars directly in the pot in which you boiled them, since this will reduce the chance of airborne contaminants landing on the lids of your jars (contaminants can't land on jars that are kept cooling in a covered pot). A jar cool to the touch may still be too hot inside for spore life, so do not judge the internal temperature of the jars by touching the glass. And do not open the jars for obvious reasons. FINALLY, DO NOT COOL JARS UNDER COLD WATER OR IN THE REFRIGERATOR. Cold water/air + hot glass = cracked glass and unusable substrate. Trust us on this one, the glass WILL break if made too cool too quickly. A mantra in this hobby - "patience, young jedi."

What methods are there to inoculate PF jars?

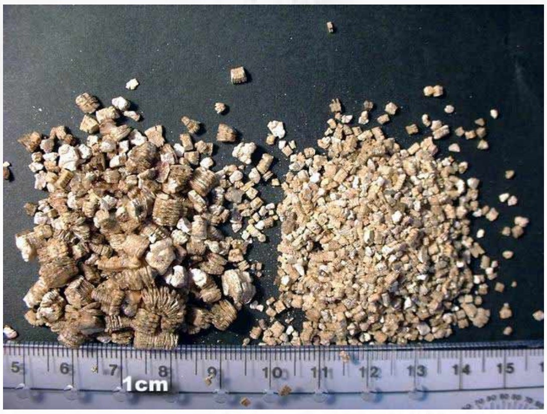
PF jar ingredients, once sterilized properly, are completely sterilized inside the sealed jar. So you do not want to introduce any possible contaminants to the jar from the outside -in.
The PF-tek provides for inoculation using a spore syringe guided through the pre-stamped holes in the lid and directly into the substrate. Since you would not want to open a PF-tek jar (and risk airborne contaminates), this is the most foolproof way to inoculate PF jars. Now, if you had a sterile environment, such as a glove box or flow hood, you could simply open the sealed jar and inoculate with a spore syringe directly onto the substrate. But, there would be no point in this - as inoculation of the substrate is achieved by using a spore syringe.
You should not attempt to scrape a print directly onto PF-tek substrates. First, the spores may not rehydrate themselves adequately using the moisture content in the substrate, and hinder colonization. Second, opening the lid of the jar defeats the purpose of the PF-tek - to create a completely sterile environment within the glass jar. Opening a jar in a glove box or a flow hood would also render pointless, as you should have a vermiculite seal to ward off contaminates - spreading spores on the dry vermiculite layer will produce nothing (vermiculite is non nutritive and should have very little water in it - eliminating the requirements for colonization).

Can I use coarse grade vermiculite for substrate?

Yes, you can. Both types, the finer type, individual particles measuring around 1-2 mm, and the coarser type, with particles measuring around 5-8 mm are suitable for substrate.
The coarser type will hold a little less water, so make sure to adjust the amount of water used.

Does fine vermiculite hold more water than coarse?

It has been a consent among the users of the PF-Tek, that the fine vermiculite can hold more water than the coarse variety. I wanted to quantify this, and made a test:
120 ml of vermiculite were measured, weighed and then water was added to it until the vermiculite was saturated. (according to the PF-Tek for Simple Minds).
The 2 varieties used are the ones in this photo:



Test results:

Fine variety:
120 ml vermiculite, weighs ***14*** g, can hold **54 ml** water.
Coarse variety:
120 ml vermiculite, weighs ***14*** g, can hold **46 ml** water.

As you can see, the water holding ability varies **considerably** between the 2 varieties. If you don't take this into account when preparing substrate, it will be either too wet or too dry.

Should I sterilize the needle, and how?

When you buy a syringe from a vendor, most vendors attempt to keep the needle as sterile as possible when they create the syringe. When you create the syringe yourself, you also should try to avoid contamination of the needle (which can occur as easily as handling the needle with unclean hands, etc.) Syringes can and do leak as well during shipment through the mails, leading to spore water dripping on the needle and in the needle sheath. That being said, it is probably a good idea to sterilize your needle before inoculation.
Flame sterilizing is just that - applying an open flame to a needle until red hot. This method will kill any spores that may be inside the needle (the 1.5" space between syringe and tip of the needle), so take that into account when inoculating your jars. Flame sterilization also may lead to a char build-up on the needle (a blackening of the metal's surface), which is attributable to using a butane lighter (bic lighters, etc.) The char can be avoided by using a "torch" style lighter. Remember, when using flames, use common sense. The needle will be hot after, don't touch it and let it cool before inoculating.

You should sterilize the needle between each jar. This is advised as it helps stop cross contamination.
After flame sterilising, you can let one or two drops out of the syringe to cool the needle down before inoculation.

What recipe should/can I use for PF cakes?

The basic PF recipe is 1/4 cup brown rice flour (measure the flour itself, not the brown rice if you grind it yourself), 1/2 cup vermiculite (fine is prefered), and 60ml (4 tablespoons) of water per jar.
For 5 jars, you use the 2:1:1 recipe. Thats 2 cups of verm, 1 cup water, and 1 cup of brown rice flour. 1 cup is 240ml.

Depending on the vermiculite used, the amount of water needed can vary. To prevent a overly dry or wet mixture you can prepare the substrate this way:
Put the required amount of vermiculite in a bowl (all at once, NOT for each jar separately!). Use a spatula or spoon to mix in enough water to saturate the vermiculite to the field capacity, mix well.

The field capacity is reached when a small puddle, barely visible, forms at the bottom of the bowl when you tilt it. Then add the appropriate amount of BRF and mix together. (This works best if you use 1/2 cup vermiculite and 1/6 cup BRF per 1/2 pint jar).
The idea is to coat the wet vermiculite particles with the dry powder as you stir the mix with the spatula.

Can I mix different cubensis strains in a PF cake?

Yes, you could.
But there is not really a reason to. Most likely one strain will prevail, if you inoculate the jars each on 1 side you might get 2 strains fruiting from 1 cake.
But in general it's better to inoculate each jar with its own strain.
Besides, when it comes to harvest time and you want to make your own spore prints, you wont know what they are. And no they wont be a new strain you created. Its a whole lot more complicated than just that.

Can I use a non-organic brown rice flour or white rice flour for the substrate?

The amounts of pesticides in anything sold for human or animal consumption are so minute that they don't affect fungal growth, especially not the one of higher fungi. The pesticides used in grain cultivation are mostly highly specialized herbicides and fungicides (for molds).
White rice flour *can* be substituted for brown rice flour, but healthier and faster growth has been observed with brown rice flour.
See also What is the difference between brown and white rice?

How many jars will a spore syringe inoculate?

A spore syringe containing 10cc of spore-water suspension can be used to inoculate around 10 jars.

Common mistakes

This document will briefly touch upon the common mistakes made by newbies when using the pf tek.

Note: One of the biggest reasons people fail is because they skip steps or change this or that in the tek. Some parts of the process are concrete and others you can experiment with. It is best to first come to grips with the process before innovation :)

Did I make a poor choice of jar?
A wide-mouth half-pint (~234ml) is recommended for vermiculite and brown rice flour cakes (PF TEK). Larger jars will take longer obviously and with Vermiculite BRF this could lead to contamination.

Is my mixture too wet?
You must gradually add water until saturated, then add the flour. If you saturate the mix too much, either add more substrate to account for this or alternatively microwave for a minute or two uncovered.

My mixture is not airy/looks like sludge?
Use large chunk vermiculite, and don't shake or compress the substrate by squashing it down. You will learn throughout the process that fresh air is important to healthy mycelium growth, the more you pack the substrate the less air is available to it.

Water gets in during sterilization?
Make sure to cover your jars with foil! Don't fill your pressure cooker up too high; most pressure cookers only require about an inch of water for more than an hour of cook time.

Incomplete Sterilization?
Give it an extra bit of time to be sure. A stitch in time saves nine. If you are forced to sterilize at a lower setting, always add more time. Remember, if using a pressure cooker, read the directions! If they are not available, a general rule is to let the cooker come to pressure, then start your timer;)

Inoculating Too Soon?
Let the jars get to room temperature after boiling/pressure cooking. Mycelium has a thermal death around 106°F (41.1°C). Your hands are not great temperature gauges, so do not inject until you are absolutely sure they have cooled.

No pins even 10 days after birth?
Check your three triggers (light, temp, air exchange) and inspect for contaminations and pests. And make sure you have a pinning strategy! Try to control every factor and you will succeed.

The 86-degree myth
Too often I see people posting that they keep their jars at 86F and are having problems. This is because 86F is too warm for jars.

The explaination - the original experiment was done on agar plates. Growth was measured at different temperatures, and it was found that the mycelium grew fastest at 86F.
The problem is, that was in an agar plate and not a jar. On the flat plane of mycelium in the agar plate, temperatures remain constant. In a jar environment, the interior of the jar becomes warmer than the exterior due to heat generated by the growing mycelia. So if you keep a jar at 86F, the interior of the jar could get to 90F and above, more if the jars are stacked tightly.
Keeping the jars between 70 and 75F avoids this overheating, and produces the best results in jars.

How long will my colonized jars live?

Ideally you should schedule your grow so you are able to birth your cakes a week after 100% colonisation.
If you wait too long the cakes will begin to dry out and sometimes fruit in the jars, diminishing future yields.
In a pinch you can wait up to a week or two extra, but any longer may lead to stunted flushes. If you're going to invest the time and money in growing mushrooms, it is recommended that you plan to be available so you can attend to your setup.

Incubation through Birthing

original source: http://www.shroomery.org/8516/Incubation-through-Birthing

How long does it take to see signs of mycelium growth?

First mantra of the hobby - "Patience."
Germination can occur as early as 2-3 days, but it may take up to a week or more for the first signs of germination to show.

Please note that some have had to wait up to 3 weeks to see growth in some jars.
It depends on a multitude of factors - some of which are: temperature, substrate, spore concentration, age of the spores, etc. There are so many different relevant factors it is very hard to determine within the 1st 2 weeks why you have not shown germination. Give it at least a week before you worry, and at least 2 weeks before you panic. All you need are 2 spores to germinate and take over the entire jar - and luck is on your side when proper procedures are followed.
Please be patient and do not panic after only 2 days, no matter how fast you've read other people's colonization was. Their setup, factors, everything varies just slightly from yours. Now, after a period of time with no germination, analyze all of the possibilities (such as temperature, water content, sterilization procedures, etc.) that would hinder growth. This is your best bet on learning the life cycle, and also learning the peculiarities of your personal setup (as far as variations go).

How important is gas exchange during the colonization?

Shroomery thread: How important is gas exchange during the colonization?

There's rust on the lids of my PF jars, is that okay?

Don't worry, a little rust won't do any harm.

How come my jars started growing mycelia, but for some reason have stopped?

Mycelia can stop or slow to a halt for various reasons. Some can include: drying of the substrate, an overly wet substrate, internal temperatures in and out of the recommended ranges, substrate that may have been "cooked" by direct heat during the sterilization process, etc. Generally, the bottoms of jars colonize much more slowly than the tops. So if you have slowed growth around the bottom/bottom sides of the jar, an easy method to help kick-start the mycelia is to "flip" jars. Simply place them on their lids, resting on the dry vermiculite layer. This should act as a vacuum, forcing CO_2 out and fresh O_2 in the jar (as CO_2 can build up in jars). The cake will slide down, forcing air out and, by the laws of physics, drawing it back in as well. (Can't have a negative space of air, the jar itself is not sealed). Other factors that are not so easily "cured" are the ones listed prior. Generally, you cannot add materials to colonizing substrate without risking contamination by opening the jar/breaching the vermiculite layer. Avoid these possibilities by mixing your substrate as evenly as possible (to avoid over-/under- water content), keeping the jars incubating in a not too dry environment, keeping the jars stored in a warm area (not hot, not cold), and also making sure water does NOT splash on your jars if you elect to boil to sterilize. Water splashing into the jars can make them too wet for the mycelia to colonize.

How long does full colonization take?

Full colonization of a PF jar can take anywhere from 2 to 5 weeks, depending on your own factors. It can vary widely, so don't use these as scripture when evaluating your own setup. A good rule of thumb to determine full colonization is the time it takes for all the sides of the jar to become covered with mycelium, and wait 1 week after the outside is fully colonized. This will allow for the inside (which has less access to CO_2 release/fresh air) than the outside layer does, and takes longer.

What if I need to birth before the jar is fully colonized?

There are many reasons why you shouldn't birth a jar before it is fully colonized. Non colonized substrate outside of the sterile mason jar environment is very susceptible to contamination from outside, and should be avoided at all costs. Don't birth cakes that aren't fully colonized because the other jars you have are already done. (Remember: "patience".) If you do deem it necessary to pre-birth (there really isn't a very good reason; there are reasons, but more often than not the one you may have is not a good one) it is possible. Birth the cake, and remove the non colonized substrate from the colonized part of the cake with a sterile instrument, like a spoon. Be sure and remove all of the non colonized part, otherwise the colonized part becomes more susceptible to contamination when the non colonized part becomes contaminated.

Is condensation inside the incubating jars harmful?

To some extent water vapor condensing to small drops inside the jar is normal. As long as the condensation isn't so strong that the water begins to accumulate at the bottom of the jar, there's nothing to worry.
If you experience excessive condensation, the incubation temperature might be to high, also try to use a tad less water with the recipe.

What are those little brown/red dots pushing into the glass of the jar from the cake?

Those are pins, and are good things. They look like "red headed worms". PF has some nice, illustrative pictures of what primordia (pre-mushrooms) look like.

What if I can't get the cake out of the jar in one piece?

If you are growing from cakes, it is best to remove the entire cake in one piece. This is why "tapered" mason jars (the types detailed on PF's page) are better than straight or shouldered jars. If you are crumbling your cakes to inoculate a bulk substrate, you can simply use a spoon to remove pieces of the substrate - this will serve as your crumbled spawn.

What if I can't get all the vermiculite seal off of the cake?

The vermiculite seal doesn't need to be totally removed. It can be attached to the cake when growing from cakes.
What ever comes off while birthing, rinsing before the dunk, during the dunk, and the rinse after the dunk should be just fine.

What is "birthing," and how do I do it?

The term "birthing" refers to the removal of the fully colonized PF cake from its glass jar. This can be achieved very simply. If you are going to keep the cake intact (growing as a cake) be sure to be careful and not break the cake (its hard to break if it's fully colonized, so don't be too gentle). You'll need a fork (or something to scrape the dry vermiculite layer off with), a wastebasket, and perhaps a large ziploc bag. Unscrew the jar lid, and turn the jar upside down (on its lid) while supporting it with your hand. The cake should slip down and fall onto the lid being held by your hand. Slide the glass jar off of the cake. Remove the excess vermiculite into the wastebasket, and handle the cake as little and as gently as possible. Overhandling can cause a bruising and bluing of the mycelium. Alternately, you could birth the cake into a ziploc to reduce waste - unscrew lid, place upside down lid and jar in bag. Simply open the jar up in the ziploc, where all of the vermiculite and excess will fall into the bag - instead of having to hold it over a wastebasket.

Which way should cakes be birthed, vermiculite side up or down?

They are birthed the vermiculite side down.
This way they can be birthed without handling them and risking contamination through dirty hands.

See also CHAPTER 3 - THE BIRTHDAY CAKE.

Birthing through Harvest

original source: http://www.shroomery.org/8517/Birthing-through-Harvest

What is an easy way of humidifying my fruiting chamber?

Probably the easiest way is using a layer of moist perlite at the bottom of the fruiting chamber along with manual fanning several times a day.

Read more about using perlite in conjunction with a Shot Gun Fruiting Chamber here.

What conditions are optimal for pin formation?

The relative humidity should be from 95%-100%, temperature between 70°F and 75°F, the fruiting chamber should be vented 2-3 times a day at least to displace the CO_2. They should receive 12 of hours of either indirect sunlight or fluorescent light.

What are the optimum conditions for a cake to fruit in?

Cakes like and need a high humidity environment, however it is provided. You need about 95% RH (relative humidity) for cakes to produce optimally. They need more humidity because they do not produce as much RH themselves (as casings and bulk runs do), and because you cannot easily supplement their moisture content (without having some inner reservoir or wet vermiculite on top and bottom). The humidity must be provided either by means of a passive humidification like moist perlite or clay in a sealed terrarium or an active humidification like a setup where fresh moist air is provided by a cool mist or ultrasonic humidifier.

The appropriate fruiting temperatures for *Psilocybe cubensis* (TMC) are 74 -78 °F but temperatures as cold as 68 should work out.

Can a PF cake become contaminated after birthing?

Yes, it can. The most frequent contaminant to encounter at this stage is green mold and it seems to happen more often if the cake wasn't colonized throughout, the cake was already contaminated during the incubation phase or if the cakes are handled at birthing with dirty hands or tools.

Usually though the cakes only contaminate after a few flushes when they are exhausted.

Make sure to separate a contaminated cake from the others as soon as possible and to discard it outside of the room you use for growing to prevent the mold spores from spreading.

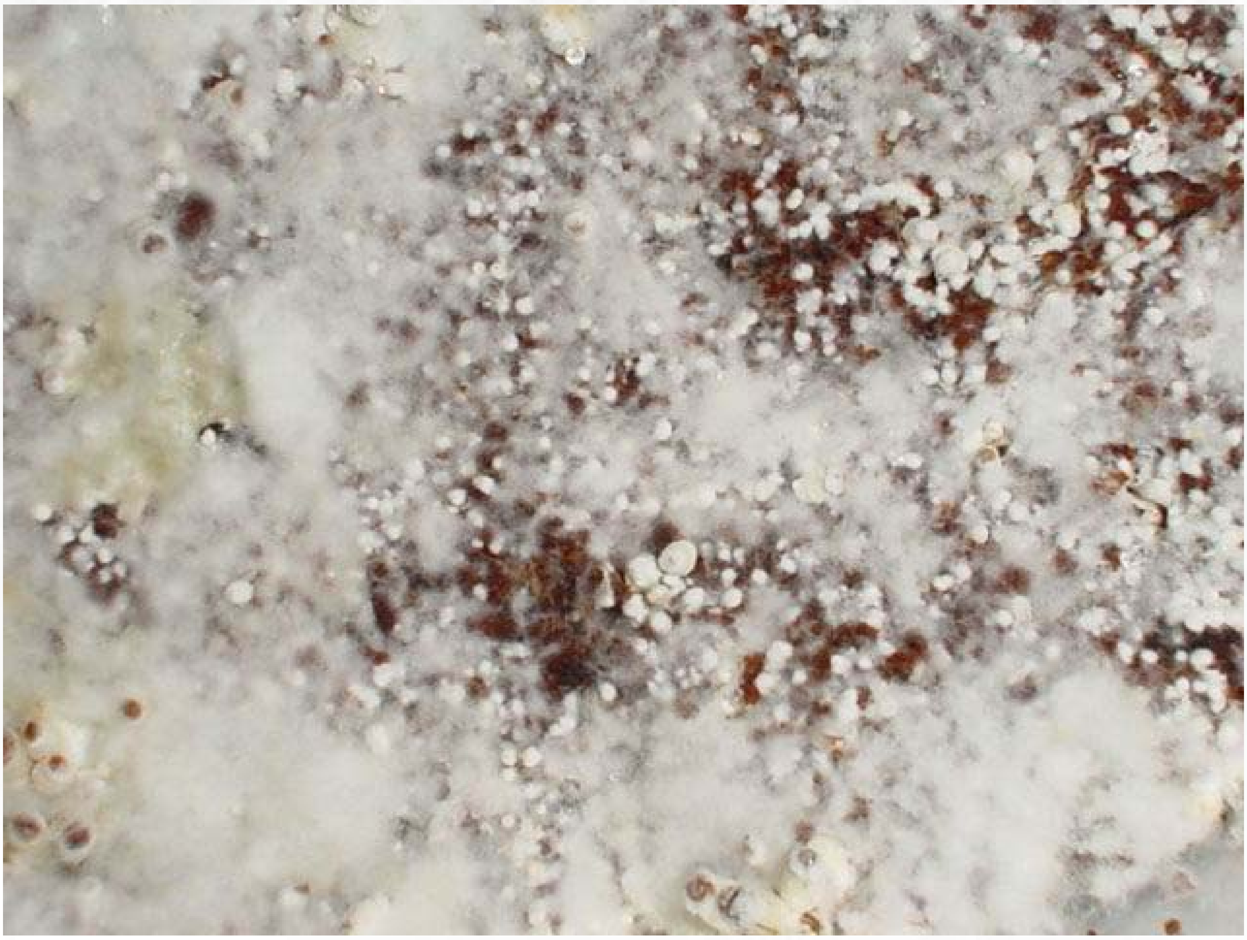
Why do my cakes get fluffy mycelium growth and delayed pinning after birthing?

Lack of fresh air exchange. Fan more.

What do primordia/pins look like? I don't know...

The growing of the mushroom from the cake starts as a tiny accumulation of mycelium, called hyphal knot, which then develops to primordium, and this further develps to pinheads.

In the picture of a casing surface underneath, the primordia are the small white bumps scattered across the casing surface, and the pinheads can be seen bottom left and bottom middle. They already have small brown caps.



How long does it take for a pin to grow into a fully grown fruitbody?

It takes anything from 2-5 days for a *Psilocybe cubensis* pin to mature. This depends on the strain, substrate, humidity and temperature.

Why is there mycelium growing on the stems?

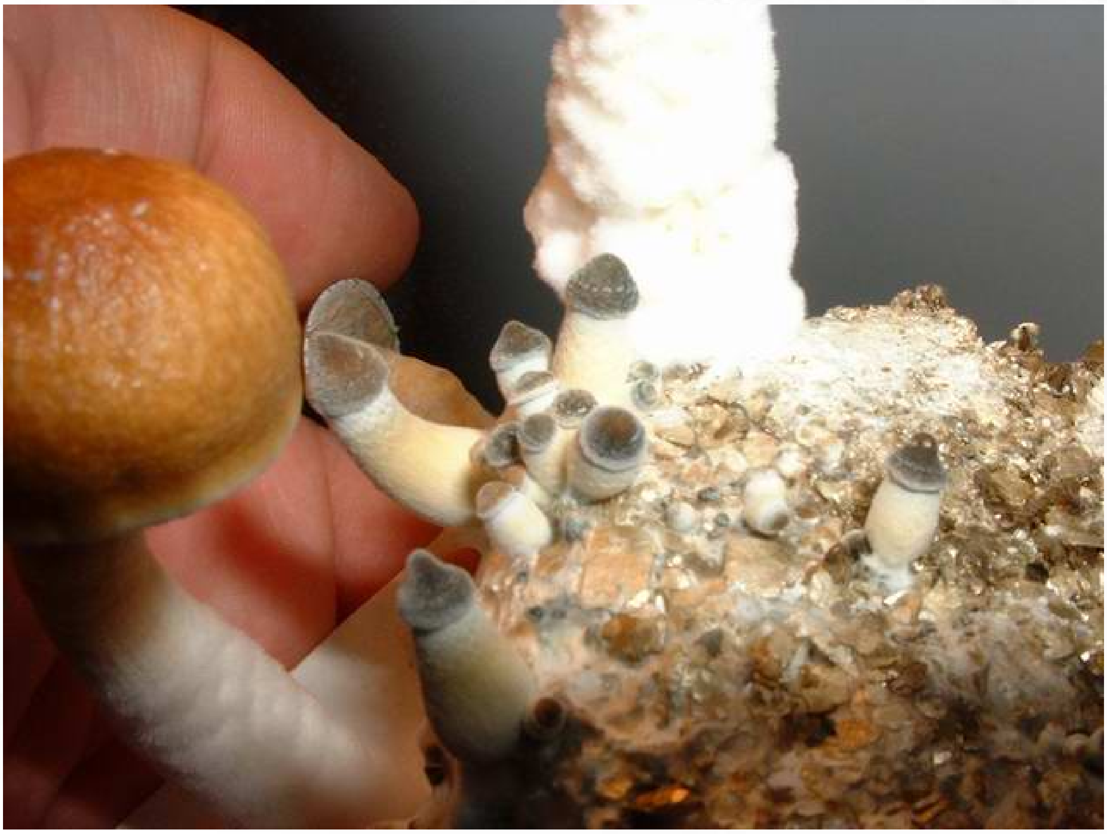
Lack of fresh air exchange. Fan more. Generally it doesn't do any harm. You can try to lower the humidity a bit by providing more fresh air, but in general the condition isn't something you should be too concerned about.

When should I harvest?

Harvest can occur when the veil breaks, up until full maturity when the cap becomes almost convex and already drops its spores.
You should wait this long if you want to take spore prints.
There are conflicting reports as to when to harvest the mushrooms for highest potency.
Some reports suggest that the mushroom reach their peak potency right before the veil breaks. Others report the potency of full grown mushrooms to be the best.
There is no real evidence though for either of these claims.

How do I recognize an abort?

Aborts are fruitbodies that for some reason cease to grow and never reach maturity.
They can be recognized by their blackish heads and the fact that they stopped growing at some point. Still they are good to use unless they are rotten.
When the cap is roten, it is very soft, sometimes smelly and detaches very easily from the stem. If the aborts are in such condition, discard them.
Allways pick all aborts after a flush is over.
The aborts in the picture are still good to use.



What is the "dunk tek"?

The cake is dunked [or dunked2] in water overnight to rehydrate and enable bigger and more flushes.

How much does 1 PF cake yield?

This question cannot be answered accurately because it depends on a number of factors including - but not limited to - the recipe used, the mushroom strain, enviromental conditions and luck. If you absolutely must have an answer, a PF tek fruited directly can yield anywhere from 3-7 gram dry per half pint cake. Yield can be increased by using the PF cake as spawn or by crumbling it up and casing it.

Why do cakes and bulk substrates require different humidities?

Cakes have no casing to keep them from drying out! That is the only reason they need a higher humidity then bulk substrates during the MATURATION stage of mushroom developement.
Both need a high humidity to form PINS. But pins require a good evaporation rate to mature. This is why the humidity is lowered after buttons have formed with casings. Ideally, cakes should have there humidity lowered below 100% also during the Maturation stage, but NOT at the expense of cake moisture content. You can't have them dry up.
The humidity reccomendations are ranges! 95 for pinning, and anything below that for fruiting. Fruits will develope alot faster at 85% humidity then at 90% humidity, but only if casing moisture content can be maintained.
It is the difference between mushroom moisture content and air moisture content that enables mushroom expansion. It is a concentration gradient, from high to low. As the surface area of the mushroom increases with maturation, this process speeds up.
If you are growing with cakes, cover them with wet vermiculite, and allow the humidity to drop a little during the maturation stage. Don't keep it at 100% at least get it down a little, your mushrooms will get larger, and they will grow faster.

What is "Dunk and Roll"?

This is in no way meant to take the place of casing but it can help cakes put out a little more for those who don't want to case or are just starting out.
Take a fully colonized cake and do a dunk [or dunk2] before birthing. When done dunking simply roll the cake in dry vermiculite, or coco coir. Use a mister and mist the dry vermiculite or coir till it's moist.
This allows the cake to fruit from all sides a little easier.

Table of Contents:

VOLUME I
Preliminaries
The Mushrooms
Hypsizygus ulmarius (Elm oyster)
Pleurotus eryngii (King oyster)
Hericium erinaceus (Lion's Mane)
Agaricus subrufescens (Almond mushroom)
Lentinula edodes (Shiitake)
Pleurotus ostreatus (Oyster mushrooms)
Ganoderma lucidum (Reishi mushroom)
Coprinus comatus (Shaggy Mane)
Hypsizygus tessulatus (Shimeji)
Stropharia rugosa-annulata (King stropharia)
Agaricus bisporus (button mushroom, Portobello)
Psilocybe mushrooms
Equipment You Will Need
Specialized Supplies You May Need
The Basics on Peroxide
What peroxide does
Biological effect of peroxide
Advantages of using peroxide in mushroom culture
Contaminant resistance to peroxide
What peroxide does not do
The need for caution when exposing mycelium
Peroxide is not a sterilant at mushroom-growing concentrations
Safety and environmental considerations for hydrogen peroxide
Peroxide and the spirit of organic growing
Lack of effect of peroxide on substrate or mushroom cultures
Stability
In pure solution
At higher temperatures
In the presence of peroxide-decomposing enzymes
Guarding the purity of peroxide stock solution
Variations in peroxide concentration from commercial sources
Growing and Maintaining Agar Cultures
Preparing agar plates
MYA Medium
Use the lowest effective concentration of peroxide in agar
No pressure agar medium
Hazards of agar drips and importance of clean plates
Reusing peroxide agar medium
Acquiring mushroom cultures
Importance of starting with good strains
Cloning Mushrooms
Cloning mushrooms
Strain storage
Distilled water method
Keep storage cultures peroxide-free
Inoculating and handling agar cultures
Cooling hot scalpels
Inoculating from storage cultures or peroxide-free medium
Preventing occult contamination with bottom inoculation
Incubating inoculated plates and storing uninoculated plates
Making Mushroom Spawn
Economic advantage of making your own spawn

Advantages of sawdust-based spawn
Ten Minute Spawn
Nitrogen supplements compatible with Ten Minute Spawn
Importance of clean containers in making Ten Minute Spawn
Pressure-sterilized sawdust spawn
Grain Spawn
Difficulties of grain spawn and pitfalls in spawn making
Spawn containers
Inoculating spawn
Agar chunk method
Use peroxide-adapted mycelium for spawn inoculation
Incubating and shaking the spawn
Liquid culture
Colonization of bulk substrate
Importance of choosing substrates lacking peroxide-decomposing enzymes
Pasteurizable substrates compatible with peroxide
Recipes for fruiting substrates
Wood chips and substrate density
Preparing supplemented sawdust with peroxide
Nitrogen supplements for bulk substrate
Calculating how much supplement to add
A note on measuring pH of substrate
Culture containers
Trash bags as culture containers
Excluding fungus gnats
Plastic buckets as an alternative to bags
Inoculating supplemented sawdust
Breaking up spawn for inoculation into fruiting substrates
Adding the spawn to the substrate
Mushroom formation
General procedures for fruiting oyster-like mushrooms and Hericium
Protecting yourself from spores
Mushrooms needing a casing layer
Seasonal planning
Outdoor growing vs. indoor growing
Harvesting
Trouble shooting
Conclusion

VOLUME II
Introduction
Acquiring, Storing and Maintaining Mushroom Cultures
Using slants instead of agar plates
The drawbacks of Petri dish culture
Advantages and disadvantages of slants
Making peroxide slants
Making transfers to and from slants
Cleaning the mycelium with slants
Making slants
Making transfers to and from slants
Cleaning the mycelium with slants
Beer-Based Medium (BBM)
Starting with Spores
Advantages and disadvantages of spore culture
Peroxide and spores revisited
Collecting spores

VOLUME I

When I first took an interest in growing mushrooms, I checked out a well-known book on mushroom cultivation from the library and eagerly read through it. But my interest soon turned to general discouragement as I read about all the equipment and procedures the book insisted were necessary to grow mushrooms without getting the cultures contaminated. I would need a sterile laboratory space with a laminar-flow hood fitted with electrostatic and HEPA filters and an ultraviolet light. This space would need a sterile air-lock entry way with a foot wash, and I would need to have special clothing to enter it, so that I could wash down the floors with chlorine bleach every day. My fruiting mushrooms would have to be grown in a separate building altogether, so as to avoid getting spores into the sterile laboratory. These fruiting cultures would have to be grown in specially designed plastic bags with microporous filter patches attached, so that the mushroom mycelium could get oxygen without letting mold spores or bacteria get in. Of course, I would need an autoclave or at least a specially designed pressure cooker to sterilize the media that went into these bags.

After considering these requirements briefly, I put aside the thought of growing mushrooms. I wasn't about to get all that equipment, and I figured I probably wasn't cut out for the job anyway. From what I could gather, my house would be a death trap for mushroom cultures. Neither my wife nor I are careful housekeepers. We have unabashed dust and clutter, and green and white fuzzy things can be found in and outside the refrigerator. Although I was skilled at sterile technique from my years as a graduate student in biochemistry, I didn't think that would save me from the legions of eager contaminants that would surely dog my every movement should I attempt to grow anything so delectable as mushrooms.

Still, the thought of growing mushrooms didn't disappear entirely. Instead, a year or so later, it resurfaced again in the form of a new idea. I had read that culture media used for growing orchid seeds could be rendered free of contaminants if hydrogen peroxide was added to the medium. While the peroxide killed bacteria, yeast, and fungal spores, it left the orchid seeds viable because they contained enough peroxide-decomposing enzymes to protect themselves. Then the orchid seeds could be germinated and tended easily by relative beginners without the need for strict sterile technique.

So here was a question: could added peroxide be used to keep mushroom-growing media, like orchid-seed media, free of contaminants? If it could, then perhaps mushroom growing could be made accessible to beginners, just like orchid seed germination. So I resolved to try it with mushroom mycelium.

What followed was a fairly complicated and non-linear process of learning about growing various mushrooms, experimenting with adding hydrogen peroxide, trying different concentrations, learning about different culture media and how they interacted with the mushrooms and the peroxide, trying various degrees and techniques of pasteurization and sterilization, going back over earlier ground with better pH measurements, experimenting with supplements, tracking down sources of contamination, tightening my procedures, and on and on, until I developed some fairly reliable guidelines for what I was doing. It all took far longer than I ever would have guessed. But the upshot of it was that, yes, mushroom growing can be made accessible to beginners without the need for sterile facilities, air filtration, or even a pressure cooker, if one adds hydrogen peroxide to help keep the mushroom culture media free of contaminants. Using the techniques I developed, all the stages of mushroom culture can now be carried out by relative beginners, with a wide variety of mushrooms, and without investing a small fortune in equipment and facilities.

I have written the current book as a guide for the home hobbyist interested in mushroom growing, one that could serve as a basic stand-alone primer on home cultivation of several delectable mushroom species, and one that anyone can use, including the beginner. My previous manual, Growing Mushrooms with Hydrogen Peroxide, was written for the mushroom grower who is already familiar with traditional methods of mushroom cultivation, and its focus is on the use of hydrogen peroxide as an improvement to the traditional methods. While that manual made it possible for the first time to perform all phases of gourmet mushroom cultivation in the home without sterile facilities and air filtration, the current book goes even further and presents procedures that do not require pressure sterilization.

Of course, not all of the procedures described in this book were created by me. In particular, any procedures not specifically required for using the peroxide technique, or not specifically made possible by the peroxide technique, are likely to have originated elsewhere.

For in depth accounts of the traditional methods of mushroom cultivation, as well as the growth requirements for a wide range of mushroom species, please consult Stamets, Growing Gourmet and Medicinal Mushrooms, Chilton and Stamets, The Mushroom Cultivator, or another basic text. These books are valuable reference volumes for anyone who seriously wants to pursue mushroom growing in detail. Also, as you glance through these books, with page after page of discussion of elaborate sterile procedures and sources of contamination, you will enhance your appreciation for the simple techniques contained in this manual.

Note that sterile or aseptic technique, which the procedures in this book require to some extent, is always better demonstrated than described. It is my hope that the reader will seek out direct instruction in this regard. Your local mycological society may be helpful to that end.

Also note that this book is not intended as a guide for commercial cultivation of mushrooms, although the methods described here may well prove valuable to small scale commercial growers as well as to home hobbyists.

Table of Contents

Preliminaries

The Mushrooms

Just about any mushroom that is currently cultivated can be grown in the home. However, some are easier to grow than others, and some, though easy, are not as rewarding as others that are more difficult.

I currently focus on four mushrooms in my own home growing. These are:

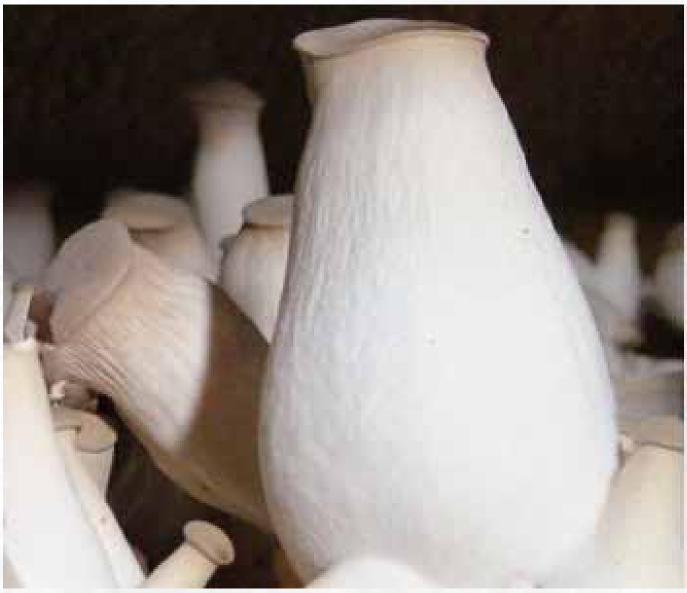
Hypsizygus ulmarius (Elm oyster)

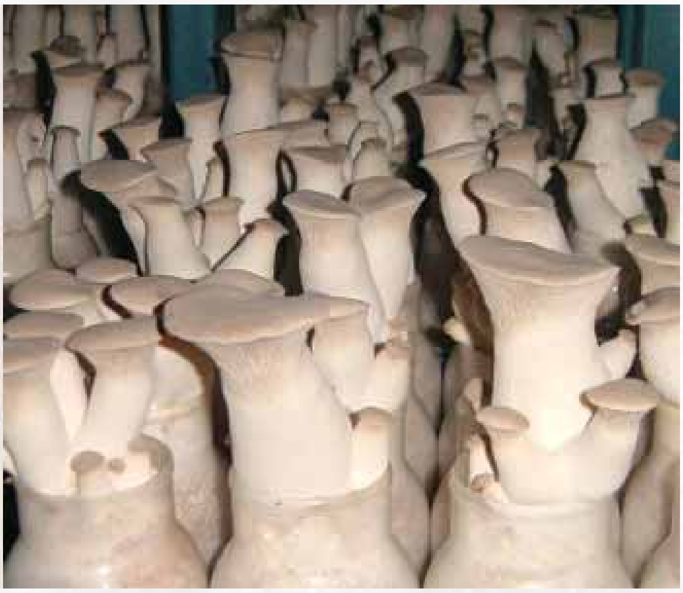
Hypsizygus ulmarius - the elm oyster or white elm mushroom: although it is not a member of the oyster mushroom family, it is an oyster-style mushroom in appearance and habit. It grows aggressively on sawdust or straw, it rarely has contamination problems following the techniques described here, and it does well in a variety of conditions and temperatures, fruiting either vertically or horizontally. When well cultivated, the mushrooms are large and attractive, rather like strange white flowers, and they are in my opinion the most delicious of the oyster-style mushrooms (not counting *Pleurotus eryngii*).

**original manual do not contain these pictures, they are placed only here.*

Pleurotus eryngii (King oyster)

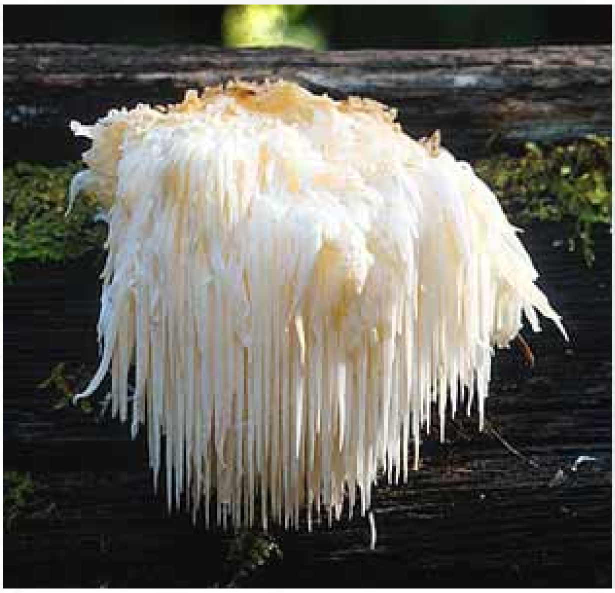
Pleurotus eryngii - or King oyster: a member of the oyster mushroom family, but it does not have the usual oyster mushroom appearance or habit. A native of Europe, it grows up from the ground in a regal stance, rather than on trees and logs. It is large and thick-fleshed. Its substrate requirements are more narrow than other oysters, as are its temperature requirements. I have read that it prefers sawdust to straw, although I have not experimented enough with it on straw to confirm or deny this. It fruits best in fall or spring temperatures, growing at a glacial pace in the cold of winter, and dying back in the hotter parts of the summer. It is one of the most delicious of cultivated mushrooms if cooked properly, sauteed rapidly in a wide pan, without being allowed to stew in its own juice, then lightly salted.

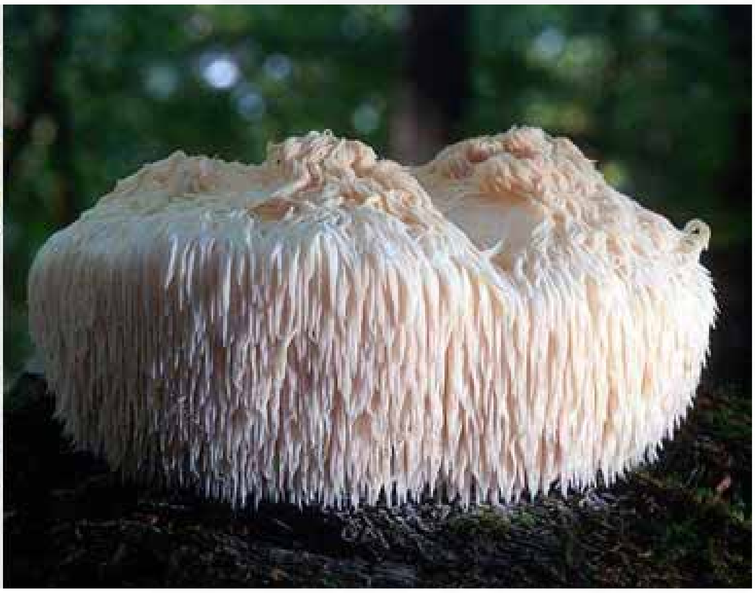




Hericium erinaceus (Lion's Mane)

Hericium erinaceus - or Lion's Mane, also called Pom Pom mushroom: a fungus that lacks the stalk and cap of a traditional grocery store mushroom, instead appearing as a kind of snowball covered with white icicles. It grows rapidly on sawdust substrates, and fruits easily over a range of temperatures. I have heard that it can be grown on straw as well, although I have never tried it. Chefs love this mushroom, and indeed it has a delicious gourmet flavor sometimes tasting like lobster.





Agaricus subrufescens (Almond mushroom)

Agaricus subrufescens - or almond mushroom: a member of the family that includes the domestic button mushroom and the Portabellas. It is distinguished by its unmistakable flavor of almond extract. Like the domestic mushroom, it prefers to grow on compost, but it can also be grown on straw, wood chips, or supplemented sawdust. It is a warm weather mushroom, but it will also fruit indoors in the winter in a heated room, making it a good candidate for year-round cultivation. This mushroom generally needs a casing layer - a layer of friable, soil-like mixture usually containing peat-applied to the surface of the culture in order to form fruiting bodies.

Some other mushrooms to consider include:

Lentinula edodes (Shiitake)

Lentinula edodes - or Shiitake: ever popular, grown by many people and written about extensively elsewhere. I am not a shiitake grower, but the methods of culture handling, spawn and substrate preparation described here will all work for shiitake as well as for the mushrooms that I normally grow. Be sure to get a shiitake strain selected for growth on sawdust if you decide to grow this species using pellet fuel as your bulk substrate. Warm weather and cool weather strains are available.

Pleurotus ostreatus (Oyster mushrooms)

Pleurotus ostreatus - and other oyster mushroom species: like *Hypsizygus ulmarius*, these are among the easiest mushrooms to grow, racing through sawdust or straw or any of a variety of other substrates. They were the first mushrooms I fruited using the peroxide method. Strains exist for most temperature ranges. The spores of *Pleurotus ostreatus*, which are released in great quantity from mature fruiting bodies, can cause health problems.

Ganoderma lucidum (Reishi mushroom)

Ganoderma lucidum - or Reishi: a top flight medicinal mushroom with immune stimulating properties. This mushroom grows on hardwood sawdust in warm temperatures. A related species from the Pacific Northwest, Ganoderma oregonense, prefers cooler temperatures. The woody mushrooms are broken up and made into tea.

Coprinus comatus (Shaggy Mane)

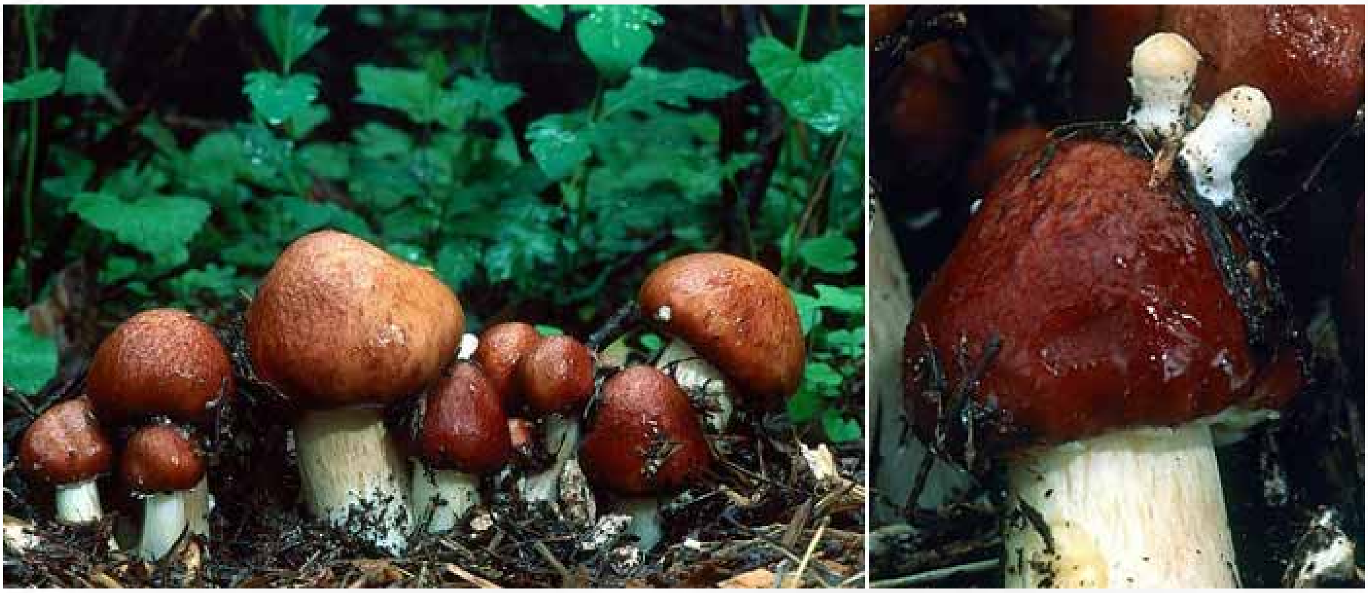
Coprinus comatus - or Shaggy Mane: a mild tasting, short-lived mushroom that grows best on compost. I never got it to fruit indoors, but after I discarded the cultures in my yard, it appeared in my garden for a couple of seasons.

Hypsizygus tessulatus (Shimeji)

Hypsizygus tessulatus - or Shimeji: a cute, small round mushroom with a crunchy texture, grows on straw or sawdust-based substrates. The strain I bought required near freezing temperatures to initiate fruiting, so I didn't experiment much with it, but there are presumably others that will fruit without that.

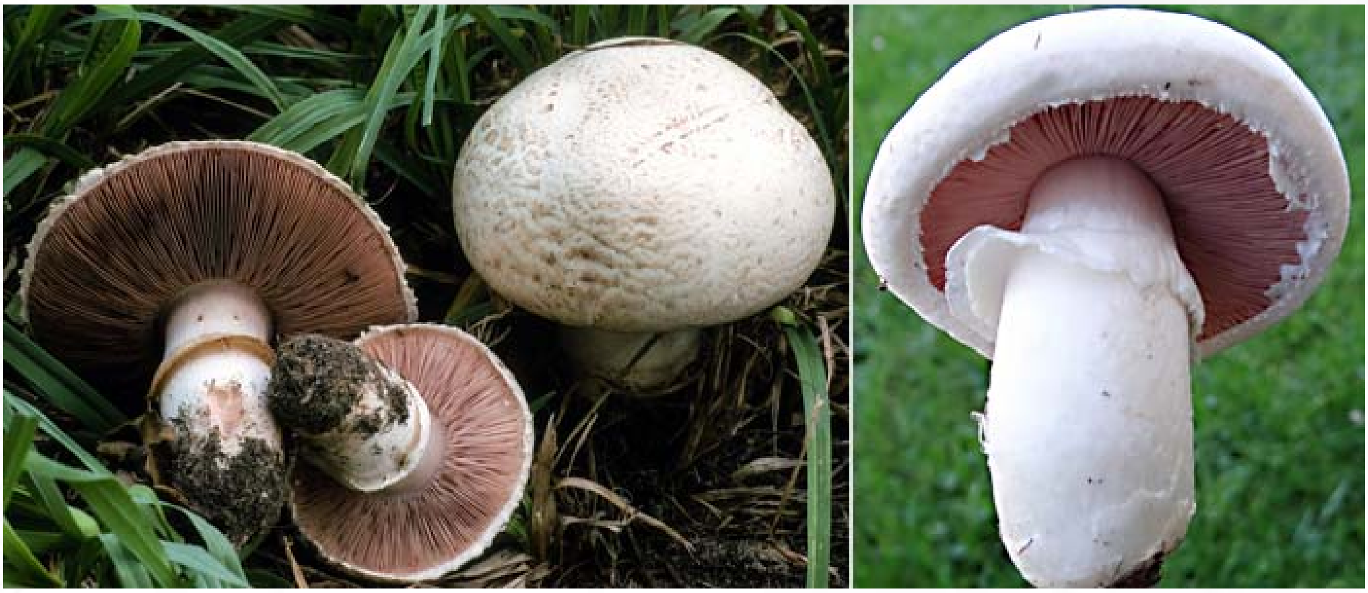
Stropharia rugosa-annulata (King stropharia)

Stropharia rugosa-annulata - or King Stropharia: a large mushroom that grows on beds of wood chips or straw and requires a casing and warm weather to fruit. The mycelium grows slowly, and only one variety is currently known to fruit indoors without regards to season of the year.



Agaricus bisporus (button mushroom, Portobello)

Agaricus bisporus/Agaricus brunnescens, or the white button mushroom, also the brown button mushroom, crimini and portobellos: so many button mushrooms are now grown by large commercial farms in the US, and sold so cheaply, that these companies can no longer make a profit. Like the almond mushroom, the preferred growth substrate for button mushrooms and portobellos is compost. Preparation of quality compost is a complicated and labor-intensive process that is beyond the scope of this manual. But button mushrooms can also be grown on straw prepared by the peroxide method (see Volume II). The yield will not be as high as on compost, but straw is so much easier to prepare at home that you probably won't miss the extra yield. As with the almond mushroom, a casing layer is required for fruiting, but button mushrooms require cooler conditions. Spawn can be prepared with pressure cooked grain (this volume) or with steamed instant rice (see Volume II, "Ten Minute Grain Spawn").



Psilocybe mushrooms

The autor of the manual do not mention them, but methods described here are suitable to cultivate them also. Below ***Psilocybe azurescens*** and ***Psilocybe mexicana.***

Table of Contents

Equipment You Will Need

WOOD
PELLET
FUEL

Some materials and equipment you may need for the peroxide method.

The methods described in this manual require very little in the way of equipment for growing your own mushrooms at home. Handling and measuring hydrogen peroxide requires only a measuring pipette (10 ml volume) and a graduated cylinder (probably 100 or 250 ml volume). These can be purchased from scientific supply stores. To measure the peroxide concentration in the bottles you get from the drug store, you will also need a small test tube with a lip, and a balloon. Preparing mushrooms spawn requires jars with lids (pint, 26 oz, or quart jars), a covered pot for steaming big enough to hold the jars, a small scale or balance for weighing, and some clear plastic food storage bags. Preparing agar cultures requires in addition a set of petri dishes. I recommend reusable plastic petri dishes if you can find them. I purchased mine at my local scientific supply store. A pressure cooker, although not absolutely necessary, will be useful. These can often be found used at second hand stores that carry kitchen implements, or new in the kitchenware section of hardware stores and department stores. Make sure the cooker you get is tall enough to accommodate your jars. You will NOT need a glove box, HEPA filters, ultraviolet lights, a sterile laboratory, laminar flow hoods, air locks, foot washes, etc.

etc.

Preparing and handling bulk pellet fuel substrate requires a covered pot for boiling and cooling water, a second pot such as a teapot to boil water for pasteurizing containers, and a larger container such as a five gallon plastic bucket with a tight-fitting lid. Five gallon buckets can often be scavenged or purchased cheaply from ice cream factories and various other kinds of food preparation establishments (avoid buckets that have been used for paint, solvents, or other toxic substances).

For growing out the bulk substrate, you'll also need some small boxes (usually no bigger than about 500 cubic inches, or 8" x 8" x 8") and some fresh 0.5 mil or less high density tall kitchen bags (avoid the thicker soft plastic bags), or a set of 2 to 3 gallon plastic buckets with lids. For helping the mushrooms along, you'll need a hand mister, and a cool space. Later, if you are growing a lot of mushrooms, you may want a fan and an automatic misting system.

Table of Contents

Specialized Supplies You May Need

For making agar medium, you will need agar, light malt powder, and (if you plan to pressure cook your medium) yeast extract flakes, among other things. Agar is available at some health food stores, or through scientific supply houses, or commercial mushroom supply dealers. Note that although agar by itself is more expensive than ready-mixed MYA medium, the latter is only half or less agar by weight, so it is not necessarily a better deal. Malt powder is available from home brew supply stores or scientific supply houses. Yeast extract flakes are available from health food stores.

For spawn making and bulk substrate, you may need paper fiber pellets and wood pellet fuel. The paper fiber pellets are sold in my area as Crown™ Animal Bedding or Good Mews™ Cat Litter. (Check grocery stores, pet supply stores, farm and garden supply stores, etc.) In rural areas of the U.S. and Canada, wood fuel pellets can be found in grocery stores, hardware stores, farm supply stores, stores that sell pellet stoves, etc. In urban areas, check your phone book for distributors of wood pellet stoves, or check with your rural friends. It may take a drive out of town to get some. Try to find out what kind of wood they are made from, and look for hardwood for most mushrooms (fir pellets, however, will work well for *Pleurotus eryngii* and *Agaricus subrufescens*).

The Basics on Peroxide

What peroxide does

The peroxide radical is a reactive form of oxygen which attacks various organic compounds. In living cells, it damages the genetic material, cell membranes, and whatever else it finds to react with. By doing so, peroxide in sufficient concentration can kill bacteria, bacterial endospores, yeast, and spores of fungi, including mushroom spores. It apparently can also kill small airborne particles of fungi, and the contaminants associated with human skin cells, which are said to be continually flaking off of the mushroom cultivator. Hydrogen peroxide thus acts to some extent against all commonly-encountered airborne contaminants of mushroom culture, including mushroom spores themselves. By contrast, antibiotics generally act only against bacterial contamination, and fungicides act only against yeasts and fungi.

The beauty of peroxide is that it does not kill established mushroom mycelium or interfere with its growth and fruiting. Despite peroxide's wide range of action against the common contaminants of mushroom culture, there is a relatively wide range of concentrations at which peroxide will allow the growth and fruiting of mushroom mycelium. The established mycelium, because of its ability to produce high levels of peroxide-decomposing enzymes, is evidently able to defend itself against much higher concentrations of peroxide radical than can isolated spores, cells or tiny fragments of multicellular organisms. So we can add hydrogen peroxide to mushroom cultures, and the mycelium will grow but the small contaminants will die.

This arrangement has a number of advantages. Most obvious is that it reduces the need for costly and elaborate facilities and equipment for environmental contaminant control. By adding hydrogen peroxide to mushroom culture media, it becomes possible to perform all phases of traditional mushroom cultivation, from isolation to fruiting, successfully in non-sterile environments with unfiltered air. Gone is the need for special clean rooms, HEPA filters, pre-filters, laminar-flow hoods, UV lights, air locks, glove boxes, or any other equipment associated with environmental control of microbial contamination - even microporous filters on bags and jar lids become superfluous. Using peroxide, the equipment minimally required for contamination control comes down to some measuring implements, a source of boiling water, and a large pot for steaming (or a pressure cooker for added security) - little more elaborate than is found in many kitchens. And whereas the traditional methods of mushroom culture required skillful sterile technique and immaculate personal cleanliness for success with agar cultures and spawn, use of peroxide allows success with only modest sterile technique and only minimal attention to personal hygiene. What's more, it becomes possible to fruit mushrooms - even those that have the highest spore load - in the same building used to maintain agar cultures and grow spawn, without the fear that spores released by the fruiting bodies will diffuse into the agar cultures and ruin them. Hydrogen peroxide uniquely will kill the spores of the very same mushrooms whose mycelium it protects.

Do contaminants develop resistance to peroxide, the way they do to ordinary antibiotics? Yes and no. Many of the contaminants are already resistant to peroxide, and once they have established a colony, they will grow vigorously. Live Aspergillus (blue green) mold is very resistant to peroxide. But evidently peroxide at sufficient concentration overwhelms the resistance mechanisms of the single-celled organisms and isolated spores, and those of very small, isolated multicellular organisms as well.

Table of Contents

What peroxide does not do

One thing peroxide does NOT do is eliminate all need for concern about sterile technique. To repeat, although added peroxide will kill isolated spores, yeast, and bacteria that find their way into your cultures, and these are a big part of routine contamination problems, peroxide does NOT kill established live multicellular organisms (such as green mold) beyond a certain size. It also will not do very well against high local concentrations of mold spores. Evidently multicellular organisms and high concentrations of germinated spores are able to produce enough peroxide-decomposing enzymes to defend themselves against high concentrations of external peroxide. And since both multicellular organisms and concentrations of spores can be microscopic and reside on your hands or on particles of dirt or dust, you still have to take sensible precautions to keep your hands and all non-sterile particulate matter out of your early-stage cultures, even with peroxide added. Although you don't have to be afraid to leave cultures open to the air for brief times, to perform manipulations or otherwise check on them, you'll still want to use common sense in avoiding contamination. You wouldn't want to use the lid to a petri dish after you dropped it on the floor, for instance. Neither would you want to allow visible, non-sterile debris of any sort to fall into your cultures, or insects of any kind to enter them. It is a good idea to periodically wipe the dust off shelves used to incubate cultures. You will still need to flame or otherwise sterilize whatever instrument you use to transfer chunks of mycelium from one culture to another. And I make it a regular practice to wipe my fingers with rubbing alcohol before performing inoculations of spawn or agar cultures. I do the same with any counter surfaces I use to perform manipulations with my petri dish cultures. This reduces the chances of larger particles making it into the cultures and helps protect the exposed mycelium.

It is also especially important to know and remember that peroxide does NOT protect the mushroom mycelium itself from aerobic contaminants. The mycelium decomposes peroxide that comes in contact with it, so any aerobic contaminants associated with the mycelium will be shielded from the deleterious effects of peroxide. Thus, as a general rule, peroxide only protects the culture medium or substrate from aerobic contamination. So your most careful procedure should be reserved for transferring mycelium, or performing any operation which exposes mycelium to unfiltered air. And once your mycelium is contaminated, you will need to start over with a fresh, uncontaminated culture, or purify your mushroom tissue in some way to free it of contaminants. I'll discuss this more later.

Finally, peroxide is not a sterilant except at concentrations too high to use for mushroom growth. That is, you generally cannot use hydrogen peroxide by itself to sterilize culture media or mushroom substrates. At the concentrations that are compatible with mushroom growth, hydrogen peroxide will not kill live mold contaminants resident in the medium, and the peroxide itself will be rapidly destroyed by the peroxide-decomposing enzymes in non-sterile organic materials. Although some spores and bacteria may be killed by adding peroxide to non-sterile medium, there will be far more contaminants that will easily survive and grow within a short time. Therefore the general rule is: all culture materials and containers must be pasteurized before adding peroxide or peroxide-containing medium to them; culture materials that contain raw, unprocessed organic matter must be pressure-sterilized to destroy the peroxide-decomposing enzymes. And a corollary: any water used without pressure-sterilization in peroxide-treated medium should be clear and free of obvious particles, since any bits of organic or even inorganic material introduced with the water could harbor live contamination and/or peroxide-decomposing enzymes that would not be destroyed by pasteurization.

Table of Contents

Safety and environmental considerations for hydrogen peroxide

There are no special safety precautions required for handling 3% hydrogen peroxide. Its toxicity is very low, and it decomposes completely to water and oxygen when it is spilled or ingested. It is odorless and does not stain or burn. It is generally not even active as a bleach until it reaches 60°C, the temperature of very hot tap water. Every evidence suggests that it is environmentally benign.

Since commercial peroxide is prepared chemically, rather than extracted from natural sources, it probably would not be considered compatible with organic certification standards following the criteria currently in vogue. However, I consider the use of peroxide to be in the spirit of organic cultivation. Since the peroxide added to mushroom cultures decomposes entirely to water and oxygen as the mushroom mycelium occupies the substrate, there can be no trace of the added peroxide left in the mushroom crop, beyond what is naturally there due to metabolic processes. Moreover, hydrogen peroxide itself is found naturally in all aerobic living organisms and in a variety of natural environments. From time immemorial, honeybees have secreted enzymes which add peroxide to their nectar, protecting it from bacteria, yeasts, and mold, and imparting antibacterial properties to the resulting honey. The mycelia of at least certain mushrooms produce their own peroxide to help break down the woody substrates the organisms encounter. And peroxide is even a part of the healing defenses of the human organism. Indeed, around the world, thousands of proponents of a system of healing called oxygen therapy actually ingest food-grade peroxide solution on a daily basis to cure various ills and promote vitality, and some people have done so for many years (I do not necessarily recommend this, however). Finally, the use of peroxide circumvents the need for resource-intensive equipment, facilities and supplies, simplifying every stage of the mushroom cultivation process.

There is some question as to the effect peroxide oxidation may have on the mushroom substrate itself. Chlorine, when it reacts with organic materials like paper pulp, produces small amounts of dioxin, a very dangerous, cancer-causing chemical. Hydrogen peroxide does not produce dioxin, and as a result, environmentalists are campaigning to get paper companies to bleach their paper fiber with peroxide rather than chlorine. Still, it is conceivable that peroxide could produce some other harmful substance when it reacts with the organic materials in mushroom substrates. I have not ruled out this possibility, but I consider it unlikely. For one thing, aerobic living organisms have evolved for millions of years with hydrogen peroxide both in and around them. Peroxide is generated by normal aerobic metabolism, and it is also naturally formed by the reaction of water with oxygen in response to the ultraviolet rays in sunlight. This means that aerobic organisms most likely have developed metabolic machinery to deal safely with the variety of oxidation products that result from the reaction of peroxide with biological materials. In addition, hydrogen peroxide is chemically quite stable in sterilized mushroom substrates, and the concentration of peroxide we're using is so low that the amount of substrate oxidation going on has to be very low indeed. Finally, I have seen absolutely no evidence of any mutagenic or toxic effect of peroxide-treated mushroom substrate on the mycelium or fruiting bodies. Agar cultures containing hydrogen peroxide give fine, healthy halos of mycelium, and the final fruiting cultures produce mushrooms as beautiful as any grown by traditional methods.

Stability

The 3% hydrogen peroxide solution available at supermarkets and drug stores, with phosphoric acid stabilizer added, is quite stable on the shelf when kept relatively cool. When added to heat-sterilized and cooled mushroom culture media, hydrogen peroxide evidently decomposes only slowly. Precisely how long it will last is presumably a complex function of media composition, peroxide concentration, and temperature. However, my experience so far is that peroxide continues to exclude contaminants for long enough to allow the mycelium of a variety of mushroom species to safely colonize their substrates.

On the other hand, hydrogen peroxide should generally not be added to hot culture media, unless you are going to add extra to compensate for losses from decomposition. Since peroxide becomes active as a bleach above 60°C, it will decompose readily when in contact with complex organic materials at this temperature and above. So wait until your medium has cooled - if not to room temperature, then at least to a temperature that is comfortable to the touch - before adding peroxide.

In contrast to its behavior in pure solution or sterilized media, peroxide breaks down rapidly in the presence of peroxide- decomposing enzymes, as happens when you put peroxide on a wound. The broken skin cells and blood vessels of a wound contain peroxide-decomposing enzymes in abundance, and they rapidly break down peroxide solution and release oxygen bubbles. Similar enzymes, known as catalases and peroxidases, are found in all kinds of living or once-living material, unless it has been heat treated or extensively processed. So, uncooked grain, flour, sawdust, wood, etc. all will destroy peroxide in short order. This means that you will need to keep all such materials out of your stock peroxide solution. It also means that if you want to incorporate such materials into a culture medium, you have to be sure everything in that medium gets thoroughly heat-treated or cooked clear through to destroy peroxide-decomposing enzymes before you add peroxide.

I take several measures to guard the purity of my stock peroxide solution. When I am about to withdraw peroxide, I first wipe down the lid and upper part of the bottle with rubbing alcohol, to keep out particles that might contain live contaminants. Then I either free-pour to a pasteurized measuring vessel or I use a clean, pasteurized pipette with the mouth-end plugged with cotton to draw up the solution. Pipettes do not need to be autoclaved, but they should be at least steeped in boiling water (filled somewhat beyond the top graduation, but below the cotton plug) for a few minutes, then cooled, before using them to withdraw peroxide. A one hundred milliliter graduated cylinder makes a convenient vessel for steeping a 10 ml pipette in boiling water. The heat will kill any live organisms in the pipette, while the peroxide itself will kill remaining heat-resistant spores. I also take care never to set the peroxide bottle cap down unless I am certain it will not contact contamination.

Table of Contents

Variations in peroxide concentration from commercial sources

One annoying fact of life when using peroxide is that the solution you get from the drugstore or supermarket, labeled as containing 3% hydrogen peroxide solution, U.S.P., may or may not actually contain a 3% solution. The concentration can vary considerably, both above and below 3%. You can protect yourself somewhat from buying "worn out" peroxide by looking for the expiration date on the bottle, and getting one with the latest date, if there is a date at all. (The bottles of peroxide I get list only the month of expiration, not the year). However, even the expiration date gives no absolute assurance that the concentration is really 3%. It is important, therefore, to have a way to measure the peroxide concentration in the solution. This can be readily done by decomposing a sample of the peroxide and measuring the released oxygen, which I do with a simple balloon technique.

Here is my method for getting a rough measurement of peroxide:

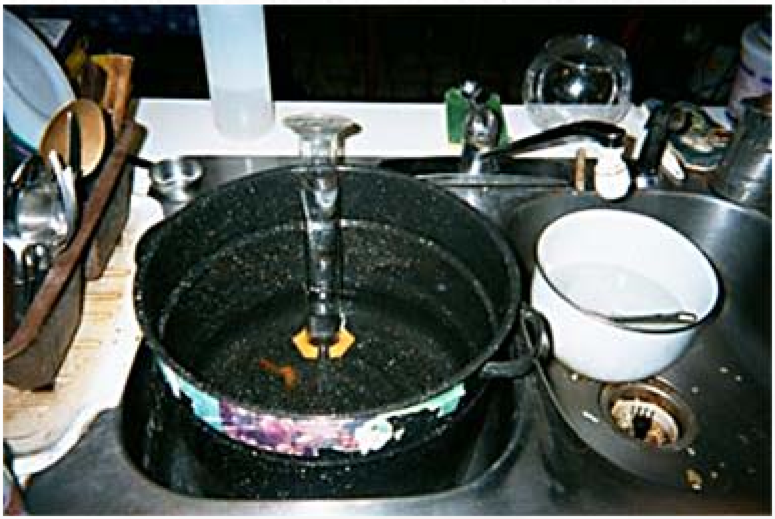
Get a clean test tube (preferably one with a lip or screw cap), a small birthday-party type balloon, and a slice, small enough to fit into your test tube, of the stalk of any mushroom you have handy (for best results, use a young, rapidly growing mushroom and take a piece of stalk, trimming off the natural skin to expose plenty of broken cells). If you don't have any mushrooms, a piece of banana or other skinned vegetable should do just as well). You will also need your peroxide solution, a rubber band, a pasteurized measuring pipette, a 100 ml graduated cylinder, and a pot of water.

1. With the pasteurized measuring pipette, withdraw 5 ml of the peroxide solution from the bottle and transfer it into the test tube.
2. Place the slice of mushroom in the upper part of the tube (don't let it slip into the peroxide yet).
3. Make sure the balloon is empty of air and stretch the mouth of the balloon over the mouth of the tube (tilt the tube to keep the slice of mushroom from slipping into the solution until the balloon is in place.
4. Put a rubber band around the mouth of the balloon on the tube, to keep gas from escaping as the pressure builds (I have found it most effective to use a broken rubber band that can be wound tightly around the threads of the tube, over the mouth of the balloon).
5. Once the balloon is sealed in place, let the mushroom slice slip down into the peroxide solution. The solution should begin bubbling oxygen immediately.
6. Agitate the tube. The peroxide solution should be largely decomposed in five to ten minutes, depending on the amount of catalase/peroxidase in your mushroom slice.
7. When decomposition is almost complete, you'll see that the bubbling will have slowed and the bubbles will have become quite small. Meanwhile, the balloon should have become taut as it began to fill with released oxygen.

Testing peroxide concentration.

Now, my college chemistry training tells me that 5 mls of a 3% solution of hydrogen peroxide should generate about 49 mls of oxygen when the peroxide decomposes completely at room temperature and one atmosphere pressure. To measure the oxygen released from your peroxide solution:

1. Fill a graduated cylinder with water and turn it upside down in a pot of water, making sure all bubbles are out.
2. Twist the balloon on your test tube to trap the released oxygen, remove the balloon from the tube holding the twist tightly, and put the balloon under the water in your pot.
3. Carefully release the gas from the balloon up into the inverted graduated cylinder, displacing the water inside it.
4. Keeping the open end of the cylinder under water, read the volume of oxygen off the graduated cylinder.



Measuring released oxygen in an inverted graduated cylinder.

The first time I did this, I got 52 mls of gas inside my graduated cylinder from 5 mls of peroxide solution. Given that there may well have been about 3 mls of air in the flat balloon before I started, the peroxide solution probably generated pretty close to the theoretical amount of oxygen for 5 mls of 3% solution.

Here's how to calculate the amount of peroxide solution you will need, if you solution tests higher or lower than 3%:

1. Divide the volume of oxygen expected for 5 mls of 3% solution (49 mls if the balloon is completely empty to begin with, or 52 mls in the above example, counting the few milliliters of air initially trapped in the balloon) by the volume of oxygen you actually got.
2. Multiply the previous number by the volume of peroxide solution you would add to your medium or substrate if it were really a 3% solution (this volume is given in appropriate section of this manual, for instance, in the section on agar culture, you will find that you would need to add 6 mls of 3% peroxide for 1 liter of pressure-cooked agar medium).

Knowing the precise concentration of peroxide is most important when you are making agar plates (see below), since you will be working at concentrations close to the lower limit of effectiveness. When you are making spawn, you will be working at a considerably higher concentration, so there will be much more leeway for variation. I use less peroxide for bulk substrate than for spawn, but there is still some room for variation there, as well. I recommend you do the balloon test to check each new bottle of peroxide solution you use for making agar plates, and check the peroxide you use for making spawn and bulk substrate at least until you know how reliable your local product is. That way, you will know for sure that you are giving your cultures the protection you expect. Also, you may want to experiment with the peroxide sources in your local area to see who sells the most reliable product. Paradoxically, cheapest may be best, because there will be regular turnover of the stock where the price is lowest. If peroxide is not readily available at local stores where you live, you will probably want to order it from a chemical supply house. They will often carry 30% or 35% solution, which can be diluted. Swimming pool supply stores also may carry similar solutions. Note, however, that these concentrated solutions are considerably more hazardous than the standard 3% solution. Read all the precautions and warnings on the container and act accordingly.

Table of Contents

Growing and Maintaining Agar Cultures

The first stage of mushroom growing is the propagation and maintenance of mushroom tissue (the mycelium) on agar as petri dish cultures. These first-stage cultures are used to store, propagate, and maintain the mushroom strains in a healthy state by serial transfer, and to inoculate the second stage cultures, the spawn.

Preparing agar plates

There are many recipes for agar medium that can be used to grow mushroom mycelium on petri dishes. I have tried several of these, but I currently use only one: malt yeast agar medium, also known as MYA. This medium has worked respectably for every mushroom species I have attempted to grow. It is not so rich that it contaminates instantly, yet most strains grow across a petri dish of MYA in two or three weeks. In my opinion, if you are using peroxide in your medium, there is not much point to growing the mycelium any faster than that, since it will just force you to make up more agar plates sooner, to keep the mycelium fresh. Also, after repeatedly transferring the mycelium from plate to plate, some growers recommend that you start anew with mycelium from a storage culture, to avoid problems of senescence (aging) of the mycelium. The faster the mycelium grows, according to this view, the sooner one has to go back to storage. If this is true, I would just as soon have the mycelium grow relatively slowly.

I maintain all my petri dish cultures on peroxide-containing medium. Contamination on peroxide plates is rare, as long as a few precautions are followed, and you won't need to buy a laminar flow hood or build a glove box to keep contaminants out. You can pour your plates in the open air in your kitchen, and you can store and incubate your plates almost wherever you like, as long as the spot is relatively clean and the environment is compatible with mycelial growth. However, see my recommendations at the end of this section.

MYA Medium

Here is the recipe I use for one liter of MYA medium:

- 12 gms (0.42 oz) agar
- 12 gms (0.42 oz) light malt powder
- 1 gm ((0.035 oz) nutritional yeast powder
- 0.5 gm (0.017 oz) grain flour (I rotate between wheat, rye, corn, rice, oats, and millet)
- 0.5 gm (0.017 oz) rabbit feed (or other animal feed pellets)
- 4-5 gms wood fuel pellets (0.15 oz - the number of wood pellets can be increased for those wood-decomposing species that do poorly on agar)
- 1 liter tap water

If you purchase ready-mixed MYA medium from a mushroom supply house, it will probably only contain the first three ingredients: agar, malt, and yeast. (You can add the others). Check the instructions to see how much of the powder the manufacturer recommends you use per liter of water. Usually it will be something like 40 to 50 gms. Depending on the proportion of agar to malt powder, you should be able to cut the recommended usage in half and get a medium that is actually better for the long term health of your mushroom cultures.

I prepare the agar medium for plates as follows:

1. I add all the ingredients to a jar with the desired amount of water. The jar should hold about twice the volume you will actually use, to keep the agar from boiling over when it cooks.
2. I adjust the pH with a little baking soda (my water is acidic, but you could use vinegar if yours is alkaline. Also, see my "Note on Measuring pH of Substrate" below in the section on preparing bulk substrate).
3. I then use my ordinary kitchen pressure cooker to melt and sterilize the medium. (I use tap water and have not had any problems with it. In fact, when I grew mushroom mycelium on medium prepared with distilled water, growth was noticeably slower). I put lids loosely in place and pressure cook at 15 psi for no more than 10 minutes, allowing an initial ten minutes of steaming to melt the agar before putting on

the pressure regulator. (If you are using ready-mixed MYA medium, the instructions may say to pressure cook for much longer times, for example, 45 minutes. Don't do it! 20 minutes is the most you'll need, and any longer will produce carmelization products in the medium that are harmful to the mycelium). I also sterilize a set of petri dishes along with my medium, placing the dishes in a large tomato can covered with aluminum foil (I use plastic reusable petri dishes, and a liter of medium fills up about 30 plates).

4. When the cooking is finished, I gently slide the cooker off the burner and allow the pressure to drop. I carefully remove the jar containing the medium and let it cool in the open air on my counter top. There is no need to avoid entry of unsterilized air, assuming there is not a great deal of heavy dust, since the peroxide will kill the airborne contaminants when it is added.
5. When I can handle the jar quite comfortably, I usually put the jar of agar in a pot of warm water for the last part of the cooling process, since the agar is close to solidifying at this temperature.
6. Then I add my peroxide solution with a pasteurized pipette and quickly mix the peroxide into the medium by moving the jar with a circular motion, reversing directions a couple of times (but doing my best to avoid making a lot of bubbles, which will end up on the surface of the agar).
7. Once I've added the peroxide, I go straight to my petri dishes, which I have set out on a clean counter, and I free-pour the medium into the dishes, closing the lids as I finish.
8. When the agar has solidified, I set aside the plates to dry for a few days in a lightly covered tray.

Pouring melted agar into Petri dishes.

To be on the safe side with my plate cultures, I use the lowest concentration of peroxide that I have found effective in agar medium, which is about 0.018%, or 6 mls per liter of medium. (You can add twice this much without visible harm to the mycelium of the species I have grown, but note that very slow-growing species such as Stropharia may be more sensitive to peroxide exposure. The production of protective peroxide-decomposing enzymes seems to be roughly parallel to the rate of growth of the organism). When the plate is inoculated, the concentration presumably begins to drop slowly below the initial level as the peroxide is decomposed by the spreading mycelium. Eventually, the peroxide should disappear completely when the agar is overgrown, if not earlier. Once this stage is reached, colonies of mold may begin to appear at the edge of the agar plate.

Table of Contents

No pressure agar medium

If you do not own a pressure cooker, or do not want to use one, you can still make serviceable agar plates by boiling/steaming the agar medium, provided you alter the above recipe somewhat. You will need to replace the ingredients that contain peroxide-decomposing enzymes with other ingredients that are free of those enzymes. In the above recipe, agar, malt powder, and pellet fuel do not contain peroxide-decomposing enzymes, but yeast powder, flour, and rabbit chow all do. In order to use peroxide in our agar medium, we ordinarily have to pressure cook the medium to destroy the peroxide-decomposing enzymes in these ingredients. However, other ingredients can be used in their place. The yeast powder provides vitamins, so this ingredient can be replaced by a bit of a fresh synthetic B-complex vitamin pill. Because it is synthetic, it will not contain enzymes. Grain flour and rabbit chow provide protein/nitrogen, so these ingredients should be replaced by other peroxide-compatible protein sources. Typically, only highly processed substances are free of peroxide decomposing enzymes, substances like gelatin, soy milk powder, non-fat milk powder, low sodium soy sauce, etc. To test for the presence of the enzymes, mix a little of the substance in question with some 3% peroxide solution and watch for evolution of bubbles. No bubbles means you are in the clear.

Here then is a recipe for one liter of "No pressure" agar medium:

- 12 gms agar
- 12 gms light malt powder
- 0.5 gm processed nitrogen source (rotate between gelatin, soy milk powder, milk powder, low sodium soy sauce, etc.)
- 5-7 wood fuel pellets
- small chip (0.1 gm? enough to turn the solution slightly yellow) from synthetic B vitamin complex pill
- 1 liter clear water, free of particulates

1. Let your jar containing this medium (and your petri dishes, if reusable) sit in boiling water in a covered pot with a heavy lid for about forty-five minutes, which allows time to melt the agar and kill any live organisms in the medium (it may be advisable to steam reusable petri dishes even longer).
2. Then remove the jar and let it cool, adding the peroxide as in the first recipe. The peroxide will kill any spores remaining in the medium. I add slightly more peroxide to non-autoclaved plates, about 8 mls per liter of medium. In general I find that non-autoclaved peroxide plates contaminate more often than autoclaved peroxide plates, but they still do considerably better than plates made without peroxide.

Watch out for drips of agar medium that land on the outside of your petri dishes. If these are not cleaned off, they will grow mold within a few days, and the spores will diffuse into the plates and start germinating at the outer edge of the agar.

If you are working with reusable petri dishes as I am, clean them carefully after you take out the old agar. Even the smallest amount of old medium left in a plate, if it is not in contact with the peroxide in the new agar the next time you use the plate, can grow mold and become a jumping-off point for contamination.

A benefit of pouring plates when the agar is so cool, is that there is considerably less condensation on the inside of the lids, than if you pour hot. This obviously means that you won't have to take special measures to get rid of condensation, such as shaking out the lids, or warming the plates to evaporate the droplets. And you'll be better able to see what is happening in your plates. However, the agar surface still needs some drying, so I let the plates sit at room temperature for a day, lightly covered with a sheet of wax paper to keep dust off, before I use them. Plates with agar medium that has been steamed will be wetter than plates with medium that has been pressure cooked, because of the lower cooking temperatures and shorter cooking time, so they will need to be dried for a longer time.

If you have extra agar medium after your plates are poured, the excess will remain sterile stored in the refrigerator. When you get around to using it, you can melt the agar again, but note that you will need to add peroxide again, because the heat of melting will have destroyed what you added the first time.

Table of Contents

Acquiring mushroom cultures

There are several ways to acquire a culture of mushroom mycelium to grow out on your agar plates. Spores from a mushroom can be germinated in nutrient medium. Tissue can be cut aseptically out of a fresh mushroom and coaxed to sprout mycelium on nutrient agar. Or a mushroom tissue culture can be purchased from a commercial supplier, usually in the form of an agar tube culture or a petri dish culture.

Since peroxide-containing nutrient medium kills mushroom spores, I have not worked with germinating spores to acquire mushroom cultures. Instead, I prefer to purchase tissue cultures from a reputable supplier. The way I see it, the supplier has already gone to the trouble of isolating a mushroom strain with desirable characteristics, and by purchasing a tissue culture, I am relatively assured of obtaining a mycelial isolate carrying the same desirable characteristics. By contrast, if you try to grow a mushroom strain you've isolated from spores or cloning and it doesn't fruit, you won't know whether it is the conditions you are providing, or the strain that is causing the problem. (Spores are like seeds: they may or may not have the same genetic characteristics as the parent). And you can waste enormous amounts of time trying to fruit a worthless strain.

Moreover, once you work out the conditions for growing an isolate in your situation, if you ever lose the culture, unless you purchased from a commercial supplier, you can't go back to the same supplier and get another "copy." You'll have to start all over and work out the conditions again for a new strain.

When you purchase a tissue culture from a commercial supplier, it is generally understood that you will use that culture to grow - and sell if you choose to - spawn, fruiting cultures, and fruiting bodies of that mushroom strain. It is also presumed that you will not take that culture and use it to establish your own commercial strain bank, selling agar cultures to others. If you want to sell agar cultures, the ethical route is to isolate your own strains by cloning from the wild or germinating spores.

Cloning mushrooms

It can be fun, regardless, to clone your own mushroom culture from a specimen you collect in the wild. Perhaps it will provide you with a first-rate fruiting strain. If you'd like to try it, you will need some nutrient agar plates containing peroxide (see below), a scalpel, an ethanol-fueled alcohol lamp, and a fresh mushroom.

To clone a mushroom:

1. Clean off the external surface so that there is no loose debris.
2. Break open the mushroom cap (or base of the stalk) as cleanly as you can.
3. Light your alcohol lamp and flame your scalpel blade. Then cut out a small piece of clean tissue within the mushroom that does not contact any external surface. This will obviously be easier with thick, fleshy mushrooms than with thin ones.
4. When you have piece of mushroom on your scalpel, transfer it to the middle of one of your nutrient agar plates. Since the chances of failure are high, take a few more pieces if you can and transfer each one to its own agar plate.
5. Finally, stack the plates, wrap them in a clear plastic bag, and set them in a convenient place to incubate at room temperature.
6. Mycelial growth, if it occurs, should become visible in a number of days, spreading out from the chunk of mushroom tissue. Mold or bacteria may grow as well, in which case you may have to cut out a bit of clean mycelium and transfer it to a fresh plate. If you decide to subclone the mycelium away from mold contaminants in this way, be sure you do it before the mold has matured enough to darken in color and form spores. Otherwise you will simply be transferring mold with the mycelium.

If you are trying to clone mushroom mycelium from the wild, remember that hydrogen peroxide in your medium will not by itself clean your mycelium of resident contaminants. If your material is dirty, and you can't get a piece of clean tissue by breaking open the stalk or cap of the mushroom you want to clone, peroxide in the agar will not improve matters. It is not a sterilant. However, if your material is basically clean, peroxide in your agar will at least reduce the incidence of background contamination on your cloning plates.

Table of Contents

Strain storage

Once you have acquired a mushroom culture, you will need a way to safely preserve samples of it for long periods, so that you can go back to these preserved samples if anything happens to the active culture you use every day. The storage method I use simply requires scraping a bit of mycelium off an agar plate and transferring it to a screw cap tube of sterile distilled water (thanks to Joe Kish for bringing this technique to my attention). Once in the distilled water, the mushroom mycelium goes dormant and will last indefinitely for some strains (oyster-type mushrooms last only about a year in my experience). Refrigeration is not even required.

Although agar slants are the "traditional" way to store cultures for those who don't have liquid nitrogen, slants do not preserve strains very long - six months at best.

Now, when you make storage preparations of strains you want to preserve for long term storage, I recommend that you prepare these without resort to hydrogen peroxide. The reason for this is that I don't really know what long term effects peroxide exposure may have on mushroom storage cultures. Could it accelerate senescence? Does it weaken the strains gradually? Are there gradual genetic changes? I am simply not in a position to rule out all the problems that could occur with all the different species you may want to store. In addition, actively growing cultures are better able to defend themselves against added peroxide than dormant storage cultures, which may be more subject to damage. So, although slants and distilled water storage tubes can easily be prepared with peroxide, peroxide-free storage of strains is the safest course. Besides, it is so easy to prepare good clean distilled water storage tubes by dispensing the distilled water into the tubes, lightly screwing on the caps, then pressure cooking for half an hour (if you don't have a pressure cooker, I would try boiling for an hour with a few drops of 3% peroxide; the peroxide will kill the heat-resistant spores, and then the lengthy boiling will destroy the peroxide). And unlike petri dishes, screw cap tubes can be flamed on opening and closing, making it easier to keep them sterile without air filtration while inserting mycelium. I wrap the final storage tubes, containing mycelium, in clear plastic "food storage" bags before putting them in a safe spot in my basement.

Inoculating and handling agar cultures

I inoculate agar plates and slants by sterilizing a scalpel with the flame of my alcohol lamp, then transferring to each fresh plate or slant a small chunk of mycelium-impregnated agar cut from a plate that has a healthy halo of mycelium growing across it.

Transferring mycelium by way of an agar chunk.

When using a flamed scalpel to cut out agar chunks, I first cool the scalpel by plunging it into the agar of the plate containing the culture I want to transfer. (Traditionally, you would cool the scalpel by plunging it into the agar of the new, unused plate. But the hot scalpel may decompose some peroxide in the plate at the site of the cut. In unfiltered air, this spot then might become a locus for contaminant growth, since it is less protected. This is not a problem with the plate I inoculate from, since it will be discarded. But it may be a concern with the new plate. So I cool the scalpel in the old plate).

If you are inoculating a plate from a storage culture devoid of peroxide, don't use an inoculating loop except to fish out a large clump of mycelium. In my experience, the minor mycelial fragments picked up by an inoculating loop are not enough to establish colonies readily in the presence of the concentrations of peroxide that are effective against contaminants, especially when the culture has not been growing on peroxide previously. The mycelium has a much better chance of taking hold if you can transfer a clump of mycelium from a distilled water storage tube, or a chunk of mycelium-containing agar excised from a slant using a scalpel or other sharp sterile implement. (Admittedly, it is somewhat awkward and sometimes frustrating to dig pieces of agar out of a slant with a scalpel).

Cultures that have not been exposed to peroxide medium previously will often lag at first, as the mycelium adjusts to this new feature of its environment. Sometimes the mycelium will appear to be trying to grow away from the peroxide agar at first. (You may observe similar behavior when transferring from a plate that originally contained peroxide but that has been overgrown with mycelium for a few days so that all added peroxide has decomposed). Sooner or later, however, the mycelium will settle down and grow normally over the surface of the new medium.

I have never observed any problem with my strains which I could attribute to continuous peroxide exposure. Typically, I transfer my strains about ten times on peroxide-containing medium before returning to peroxide-free storage cultures, although the choice of ten transfers is an arbitrary one, and returning to storage cultures may not be necessary at all.

Note that peroxide protects only the portion of an agar plate that does not have mycelium growing on it. The mycelium itself is unprotected, since it decomposes the peroxide as it grows. Therefore, older plate cultures that have been overgrown with mycelium for more than a few days have an increased likelihood of harboring contaminants.

Table of Contents

Preventing occult contamination with bottom inoculation

It is also possible for contaminants to accumulate on mycelium if you transfer it repeatedly in unfiltered air, even if there is always peroxide in the agar and the mycelium never covers the entire plate. Although you may never see contaminants growing on the mushroom mycelium in your plates, invisible contaminants will slowly build up. This "occult contamination" can be a problem whether or not you are using peroxide in your spawn and in your fruiting substrate as well. However, if your spawn or fruiting substrate will be peroxide free, there is an even greater chance that the occult contaminants could bloom when they enter the unprotected medium.

To guard against the possibility of such occult contamination, I use a simple trick: I regularly inoculate the bottom of the agar when I do my transfers (How often you do this depends on how you store your plates, and for how long. The safest course is to perform this operation at every transfer, at least with those plates used for transferring mycelium to subsequent plates. But you may be able to get away with putting it off for two or three transfers before it starts affecting your success rate). I perform the bottom inoculation as follows:

1. Turn the plate upside down.
2. Lift one side of the plate bottom as if it were hinged to the top, and gently pry the agar disk out into the lid of the plate with a flamed scalpel. (If your agar regularly tears or breaks at this step, you will need to increase the amount of agar you add for making your medium.)
3. Close the plate back up until you're ready, then transfer a chunk of mycelium to the exposed underside of the agar with a flamed, cooled scalpel.
4. Finally, after inoculating the underside, close the plate, turn it right side up again, and gently pry (again with a flamed scalpel) the agar disk back to its usual position in the bottom of the plate, now sitting on top of the chunk of mycelium.

This arrangement forces the mycelium to grow up from the bottom of the agar through the medium to the surface of the plate, leaving any accumulated contaminants behind in the process. Certain strains may not respond well to this arrangement, but so far I have not had any problem as long as the strain I was using was able to grow vigorously on the medium. However, because of the amount of manipulation involved, this procedure does carry an increased risk of contamination compared to simple transfers. Whereas I rarely see contamination on peroxide plates inoculated in the usual way until they are old, I lose perhaps one in five plates inoculated on the underside of the agar. Wiping down your counter surfaces and your fingers with rubbing alcohol before you begin may help cut down on such failures.

A tricky but important point in the bottom-inoculation procedure is to avoid scraping bits of agar onto the rim of the petri dish bottom when you close the plate after inoculating the bottom of the agar. Bits of agar that get on the rim, or outside of it, tend to sprout contaminants because of their proximity to ambient air. It is also advisable to use plates that have been dried sufficiently to eliminate obvious surface drips. If the agar is still very wet when pried into the lid, it may leave enough medium behind in the lid to cause troubles at the edges of the plate later on.

One final point: Be sure not to cut all the way through the agar when you remove wedges for inoculation from a bottom-inoculated plate. Doing so will defeat the whole purpose of the procedure by bringing along the occult contaminants we're trying to confine to the bottom of the plate. To leave these contaminants behind, excise wedges only from the top of the agar.

Once my agar plates are inoculated (I keep four at a time for each strain), I place them inside fresh clear-plastic food-storage bags, which I close with twist ties. The closed bag provides a still-air environment and helps keep out marauding fungus gnats and mites. I put three or four petri dishes in a single bag. They then can be incubated anywhere that is convenient - on a bookshelf, in a closet, on a counter top, etc. However, I do not recommend storing plates in the refrigerator, because of the condensation that is produced, and I also don't recommend incubating plates on a shelf above a heater, because the on-off cycles of heating and cooling will cause contaminants to be drawn into your plates.

Being able to store fresh (uninoculated) plates easily is one of the benefits of peroxide. I keep a set of fresh plates stored in a cool spot - again, not the refrigerator. Like the inoculated plates, I keep these wrapped in plastic food storage bags. Each time I use one of my growing cultures to inoculate spawn, I also take out one of these fresh plates and inoculate it to replace the culture I've used. At the same time, I replace any cultures that may have developed mold colonies at the edge. This way, the number of plates I have growing remains constant, and I rarely find myself short.

Making Mushroom Spawn

Production of spawn is the second stage in mushroom growing. Spawn is the "starter" used to inoculate bulk fruiting substrates, or to make more spawn. Traditionally, spawn making was best left to commercial spawn suppliers, who had the sterile facilities to keep spawn free of contaminants. With the development of the peroxide method, however, spawn making is just another step in the mushroom growing process, and an easy one at that.

Being able to make your own spawn without a sterile facility has a significant economic benefit for the small grower or hobbyist. At $20 to $25 for a few pounds of spawn, purchasing spawn represents a significant expense. If you make the same few pounds yourself with the help of peroxide, grain will cost you about a dollar or two, and the peroxide - ten cents. (Sawdust, if not free, will cost quite a bit less than grain). And you won't have to spend a small fortune building an air filtration set-up or special clean rooms for incubating the spawn.

For my own mushroom growing, I have switched almost entirely to using sawdust-based spawn. With my current methods, sawdust-based spawn medium can be prepared more quickly and easily than grain spawn, without soaking of grain, and even without autoclaving or pressure sterilizing (see below). Also, mature sawdust spawn colonizes sawdust-based substrate more quickly, and in my experience, with a lower incidence of mold contamination, than grain spawn. And contamination of the spawn itself is rare, perhaps one jar in one hundred, as might be expected just from occasional, inevitable mistakes in technique. True, sawdust spawn does not contribute as much nutrition to the bulk substrate as grain, but it is not particularly difficult to add the missing nutrition directly to the substrate from other sources that do not require pressure cooking.

Jars of peroxide-treated sawdust spawn on a bookshelf.

For most mushroom species, grain spawn is recommended for straw, since the grain adds to the nutritional base of the substrate. And that grain has to be pressure sterilized. Still, there are two good species that will grow well on straw using sawdust-based spawn instead of grain: *Hypsizygus ulmarius* (the elm oyster) and *Hypsizygus tessulatus* (Shimeji). Since *Hypsizygus ulmarius* grows every bit as easily and tastes considerably better than traditional oyster mushrooms of the Pleurotus family, I can see no reason to incur the added difficulty of grain-spawn making simply to grow oyster mushrooms on straw.

Table of Contents

Ten Minute Spawn

My own procedure for preparing sawdust-based spawn originally required sterilizing separately enough water to add diluted peroxide to the spawn after it had been pressure-cooked and cooled. This is an awkward procedure at best, so I sought alternatives. My search lead to the development of "10 minute spawn," a form of sawdust-paper pellet spawn that only requires a ten minute steaming and no pressure cooking at all. This is probably the fastest method yet in existence for preparing sawdust-type spawn. In this "one step" procedure, all the solid ingredients are placed in a jar, then peroxide is added with all of the water, and the spawn medium is briefly steamed and cooled. Enough peroxide evidently survives the brief steaming to keep the spawn contamination-free.

Here's the recipe for making "ten minute spawn:"

- Wood fuel pellets - 1.5 oz (42.5 gm, or about 4 tablespoons)
- Paper fiber pellets - 3 oz (85 gm, or about 1/2 cup plus 1 tbs)
- Ground limestone - 0.015 oz (0.4 gm, or about 1/4 teaspoon)
- Gypsum (optional) - 0.015 oz (0.4 gm, or about 1/4 teaspoon)
- Nitrogen supplement - 2% by weight (see below) - (usually about 3/4 tablespoon total)
- Hot water - 150 mls, mixed with 3% hydrogen peroxide - 20 mls
- Jar with lid containing fitted cardboard disk (see below under "Spawn Containers")

1. Place into a 26 oz or similar size jar the wood fuel pellets (ordinary sawdust will NOT work), paper pellets (Crown™ Animal Bedding or Good Mews™ Cat litter, etc.), lime, gypsum (optional) and nitrogen supplement (see below). The wood fuel pellets must be made of a relatively light wood, such as

cottonwood or fir, so that they disintegrate easily as well as heat up and cool down quickly. Fresh ground oyster shell lime will substitute for limestone.

2. Add the hot water with peroxide to the jar, and mix slightly.
3. After allowing a few minutes for the liquid to be absorbed and the wood fuel pellets to disintegrate, shake the jar with a temporary lid in place to mix the ingredients, then knock the jar on a padded surface to dislodge substrate from the upper part of the jar back down into the rest of the substrate.
4. Slightly moisten the cardboard disk in the final lid and put the lid loosely in place on the jar.
5. Place the jar in a steamer pot containing about a half inch to an inch of water, cover the pot with a fitted lid, bring the pot to steaming temperature, and let it cook for just ten minutes over a rolling boil. (I want the pot to reach steaming temperature quickly, so I start with hot tap water. The jars sit on a rack that elevates them slightly from the bottom).
6. When the ten minutes are up, withdraw the jar and let it cool rapidly to room temperature.
7. Wet the cardboard disk inside the jar lid with some 3% peroxide by free-pouring a little peroxide into the lid and wiggling the lid to spread the liquid. Pour off any excess.
8. The spawn is then ready to inoculate.

In the above procedure, I mix one part sawdust with about two parts pelletized paper. The pellets allow the spawn to break up on shaking in jars after the mycelium has grown through the substrate. Of course, you can also prepare your sawdust spawn in heat-resistant plastic bags, and then you won't need paper pellets, since you can break up the spawn by manipulating the bag.

Agar colonizes sawdust by itself with difficulty, which is why I have added an additional nitrogen source to my sawdust spawn in the procedure. The standard recipe calls for one part bran for every four parts sawdust, but if you use any such "raw" supplement as bran, you will have to pressure sterilize your spawn after all, to eliminate peroxide-decomposing enzymes. Therefore, I have identified several nitrogen supplements that do not require pressure sterilization.

Two readily available choices are powdered soy milk and powdered cows milk. I have used each of these substances successfully in the above recipe for 10 minute spawn by adding 0.3 oz (or a little less than a tablespoon) to the specified amounts of paper fiber pellets and wood pellet fuel.

Sylvan Corporation sells two processed supplements, one based on denatured soy protein (Millichamp 3000), and the other based on corn gluten (CG60), and these serve the purpose quite well (I add 0.30 oz in the above recipe for "10 minute spawn"). Neither of these commercial supplements decomposes peroxide when the supplement is fresh, although older Millichamp 3000 and a third supplement sold by Sylvan, CS36, does.

Artificial fertilizer can also provide a workable nitrogen source (for example, about 0.1 oz of "Schultz Instant" brand 20-30-20 fertilizer works well in the above recipe). I have used this successfully with both *Pleurotus eryngii* and *Hypsizygus ulmarius*. However, be forewarned that mushroom mycelium takes some time to adapt to chemicals such as these, so the growth will start off quite slowly.

Perhaps you don't like the idea of using artificial fertilizer. Well, since human urine contains nitrogen primarily in the form of urea, it can be used as an organic supplement in place of the fertilizer. In that case, you could replace roughly half of the water required with fresh urine.

To use other supplements, the idea is to add enough to bring the percent nitrogen in the spawn medium to about 0.4, or the percent protein to about 2.5. See the section on supplements under bulk substrate preparation for details of making this kind of calculation.

Two final notes on this ten-minute spawn procedure: first, be careful to use clean containers and implements, use only clear water, free of particulate matter, and if you are working in a kitchen, make sure you don't get flour, crumbs, or other organic matter into the jars or the containers you use for weighing out the medium. Also, make sure none of your ingredients (or your cardboard disks for the lids) is so old it has had a chance to get moist and start to decompose. This will introduce live contaminants containing active peroxide-decomposing enzymes. The procedure works because there are no peroxide-decomposing enzymes in any of the ingredients, so you need to ensure that this remains the case.

Second, the procedure also works because the small amount of material I am using for a 26 oz. jar can be heated and cooled quickly, so that some intact peroxide remains after the steam treatment. Larger quantities of spawn will both take longer to heat through and longer to cool, so they will likely require the addition of greater amounts of peroxide to assure that any survives. You will have to perform your own experiments to determine the amount of peroxide to add.

Table of Contents

Pressure-sterilized sawdust spawn

If you are not going to use wood pellet fuel as a source of sawdust, or if you want to use an unprocessed nitrogen supplement like bran, you will have to pressure sterilize your sawdust spawn, and add diluted peroxide to the medium after it has cooled. You'll want to sterilize enough water separately to dilute the peroxide in about one-third to one-half the total water added to the substrate. After measuring out the diluted peroxide you need, pour it into the spawn medium and then shake well to distribute the liquid.

Here's the procedure as I used to do it:

1. Add roughly half the total water you'll need to the spawn medium in as many containers as you want to prepare.
2. Measure out and sterilize enough water to add the other half of the total water, with peroxide, to each of the containers later.
3. Dilute your peroxide into the sterile water when it is cool, to make a 1 to 10 dilution (that is, add a volume of 3% peroxide that is roughly a tenth of the total volume of the water).
4. Measure out the individual amounts of water for each spawn container in a graduated cylinder pasteurized with boiling water.
5. Free-pour the measured water into each spawn container (resulting in an additional 1 to 2 dilution, since the containers already contained half of the water) making sure to wipe off drips running down the outside of the cylinder so they won't fall into the spawn during pouring, and mix immediately. The total dilution comes to about 1 to 20, or a peroxide concentration of roughly 0.15%, same as for grain spawn.

Grain Spawn

Now, if you have decided that you need grain spawn, I have to caution you - especially if you have never made grain spawn before - that making grain spawn can prove difficult even with peroxide addition. This is because the grain available to you locally may carry a high load of endogenous contaminants that cannot effectively be eliminated by pressure cooking.

So, although I have employed lengthy sterilization periods and plenty of peroxide, I have not been able to consistently make contamination-free rye spawn with the rye grain I get locally. Fortunately, I have been able to substitute a grain called soft white wheat. It has a much higher initial moisture content than rye berries (30% vs 8%), but for whatever reason it is much cleaner than the rye I can get. Soft white wheat has worked well for me when I have added a measured amount of hot water and let the grain stand overnight before pressure cooking, or when I have steeped the grain with excess hot water. I get contamination-free grain spawn virtually every time with this grain. Unfortunately, soft white wheat is sometimes unavailable, and store personnel are prone to mix it up with hard red wheat, a low moisture grain which gives me the same problems as rye.

Whatever grain you choose, you'll want to be sure that
1) your substrate is completely sterilized before you add peroxide, and
2) you have removed all traces of medium on the outside of your containers.

Of course, the problem of thorough sterilization also exists in preparing spawn in filtered-air environments. If there are mold spores or bacteria inside the grain kernels or other substrate particles, and these are not killed by autoclaving/pressure cooking, they can germinate and spoil the spawn despite filtered air or added peroxide. With peroxide as well, however, incomplete sterilization means that some peroxide-decomposing enzymes are left in the grain, creating pockets of medium that are unprotected by peroxide.

The second problem also exists in conventional cultivation practice. If traces of culture medium get on the outside of culture containers, these bits of medium can become loci for contaminant growth and spore dispersal. If this happens with peroxide-protected substrate, the culture will often remain clear until it is shaken to distribute the mycelium. But a few days later, the contaminants will bloom, taking advantage of the lack of peroxide protection in the newly multiplied zones of mycelial growth. This problem can be prevented by cleaning reusable containers carefully, both inside and out, before use, and wiping down the outsides of the containers with rubbing alcohol after the spawn has been inoculated.

Here's how I make soft white wheat spawn:

1. I weigh out 7 oz of grain into a 26 oz jar.
2. I then add an excess of hot tap water and a tiny amount of baking soda to offset the acidity of my tap water.
3. Next, I steep the grain at near-boiling temperatures for an hour or two to swell the kernels, draining off the excess water when the grain has about doubled in volume.
4. Finally, I sterilize the jar of grain in a pressure cooker for an hour. The exact length of time you use will depend on your grain and pressure cooker.
5. When the jar has cooled, I add 10 mls 3% hydrogen peroxide (or 20 mls peroxide for every 16 oz grain initially added), then shake well to coat the grain.

One grower adds food color to his peroxide, so that he can see whether he's done a thorough job of distributing the peroxide over the grain. (If your grain clumps significantly, it will be difficult to coat the kernels completely, so take care to adjust your water content, and don't soak or cook your grain too long). The final peroxide concentration is high, about 0.15%, but mushroom mycelium still grows well, if somewhat more slowly than without added peroxide. (If you make your spawn by adding a measured amount of water, remember to subtract the volume of peroxide from the water you add, to achieve the correct moisture content). You may well be able to get away with adding less peroxide, but if you add less than 20 mls 3% solution for each 16 oz of grain, you will most likely need to dilute your peroxide into a larger volume of sterile water before addition, to assure thorough coating of the grain by the solution. On the other side, you can add up to 40 mls peroxide without seriously affecting mycelial growth in most cases.

Table of Contents

Spawn containers

I grow my spawn in 26 oz pasta sauce jars, since I can get these readily. They have one-piece lids. Quart canning jars will work just as well, especially if you have one-piece lids, but a two-piece lid can be serviceable if you put a slightly oversize cardboard disk inside the lid, so that it holds the top of the lid within the band. Be sure to keep the inside of the lids clean for each use, as well as the lid threads on the jars. Traces of old medium around the mouth of the jar or in the lid can cause major problems. Rusty spots on the insides of the lids can also catch such traces of medium and provide a place for microbial growth.

Note that peroxide addition makes unnecessary the use of lids fitted with microporous filters as were traditionally required. However, the jar lids are a vulnerable area, even with peroxide added to the medium, since you will be shaking the jars to distribute mycelium, and the shaking can bring airborne mold spores that have diffused inside the lid (or bits of mold that have grown in the crevices of a poorly cleaned lid) into contact with the mycelium (which itself is unprotected). To compensate for lid vulnerability, I do the following:

1. I prepare a set of thin cardboard disks cut to fit inside my jar lids (cereal box cardboard works well; just trace a circle around the lid onto the cardboard with a pen, then cut slightly inside the traced circle with a scissors).
2. For "10 minute spawn," I mix the ingredients with a separate lid, then I put the lids with cardboard disks in place just before steaming.
3. As the spawn cools, I open the lids and wet the cardboard disks with 3% peroxide by free-pouring a

couple milliliters into each lid. The peroxide-moistened disks then form a barrier to airborne contaminant entry.

For grain spawn or other spawn that requires pressure sterilization, I wrap the disk-containing lids individually in aluminum foil, sterilizing them separately from the jars of spawn, which I sterilize with temporary lids in place. Then, after adding peroxide to the sterilized spawn substrate and shaking it in, I remove the temporary lid and put in place one of the sterile lids with a cardboard disk. I then wet the disk with 3% peroxide solution.

Inoculating spawn

Inoculating jars of "Ten Minute Spawn" by the agar chunk method.

Sterile containers of spawn medium can be inoculated in a couple of ways. You can cut chunks of mycelium out of agar cultures with a sterile scalpel and drop the chunks into the container. (If you do this, first tip the jar or bag to make the substrate slope to one side, so you can get the chunks of agar a ways down into the substrate, but still at the side of the container where you can check for growth). Or you can shake the container after adding the chunks. I prefer not to shake the container, because the chunks often end up sticking above the medium, unprotected by peroxide, and they are difficult to dislodge by further shaking. With peroxide addition as well, there is no clear benefit from shaking the chunks with the substrate. The small fragments of mycelium that are broken off this way seem to be too small to effectively recover and grow in the presence of peroxide at the high concentration used in spawn medium. Therefore, I drop the agar chunks (three pieces has been adequate for slow growing strains) down into the substrate and close the container. With sawdust spawn of *Hericium erinaceus*, I then tap the jar on my counter to pack down the spawn medium around the agar chunks, since the organism seems to prefer a dense, closely-packed substrate.

Note that peroxide-treated spawn medium should only be inoculated with peroxide-adapted mycelium, that is, mycelium that has grown out on peroxide-containing agar. Otherwise, the unadapted mycelium may die off or take a very long time to initiate new growth when confronted with the relatively high concentration of peroxide I have suggested for spawn making. (Peroxide-treated bulk substrate, however, contains a much lower concentration of peroxide, so it can safely be inoculated with spawn that has not been adapted to peroxide.)

My original procedure was to put my inoculated jars inside fresh plastic food storage bags tied closed. (I would do this immediately after wiping down the jars with rubbing alcohol). I used the plastic bags to provide a still-air environment, and to keep out stray fungus gnats. (The bags can be reused, provided they are still clean). Lately, however, I have been incubating the spawn jars without enclosing them in food storage bags, and this appears to work almost as well.

Finally, I make sure the jars are sealed completely and I let the mycelium grow out from the agar for several days. Decomposition of the added peroxide provides oxygen to support mycelial growth up to this stage, and carbon dioxide levels are not yet very high. When I have a halo of growth about a centimeter wide, I then shake the spawn, and this now results in new growth appearing at many new places in the medium within a few days. (Don't wait too long to shake your spawn, as the amount of peroxide left to protect the mycelium steadily declines as the halo of mycelial growth from the agar chunks grows wider). I used to loosen the lid to the jar slightly after shaking, to allow gas exchange, but I now find this to be unnecessary. The cardboard disk evidently allows enough gas exchange even with the lid tightened down.

The spawn is ready to use when the mycelium has grown through the spawn medium lightly but completely. I usually wait until the mycelium has started to extend about a half a centimeter or more above the top surface of the medium before I use a spawn jar for inoculation.

If you are using spawn bags, rather than jars, the procedure is essentially the same. You won't have to worry about contaminants entering the bags as they cool - any that do enter will be killed by the added peroxide.

What about using peroxide to make liquid cultures? I have not pursued this possibility, for two reasons. The first is that any method of inoculating a liquid culture is likely to require blenderizing the inoculum (or in some other way breaking up the mycelium), which releases significant quantities of peroxide-decomposing enzymes into the medium upon inoculation. The second reason is that, even assuming the first problem could be overcome, I would still expect the peroxide concentration to decline rapidly in a liquid culture as the intact fungal material with its internal peroxide-decomposing enzymes circulates throughout the liquid. (With solid substrates, the mycelium is confined to one area, and the peroxide concentration in the remaining substrate stays at a desirable level). The decline in peroxide could be compensated for by regular addition of fresh peroxide, but this might require a method of measuring peroxide concentration in very dilute solutions.

Table of Contents

Colonization of bulk substrate

Colonization of bulk fruiting substrates is the third stage of mushroom growing, leading directly to the production of edible mushrooms.

Because hydrogen peroxide solution is so cheap, it is economically feasible to add enough peroxide solution to fruiting substrates to help keep them free of contaminants. And from a technical standpoint, doing so can make it possible to grow a number of wood decomposing mushrooms without having to autoclave or pressure-cook the substrate. For the procedures in this volume, however, the substrate chosen has to be one that is devoid of peroxide-decomposing enzymes. Peroxide will provide little or no benefit with substrates that still have a great deal of biological activity, such as compost, or pasteurized straw, or fresh wood chips that have been treated with boiling water.

The first material I found to be ideal for use with peroxide was pellet fuel for wood pellet stoves. This substrate comes previously heat-treated, so it will not cause peroxide to decompose, even without autoclaving. As a result, pellet fuel can be conveniently pasteurized for use as a fruiting substrate by adding boiling water, which becomes part of the process of bringing the substrate to the proper moisture content. (When you add boiling water to fuel pellets, they turn back into the sawdust they were originally made from). Hardwood fuel pellets are generally the best bet for most wood-decomposing mushrooms, but pellets made primarily from Douglas fir may work for your strains too. (I suspect that the heat and pressure used in creating the pellet fuel may break down some of the mushroom-inhibiting resins in the fir). Look for a brand of pellets that does not have any additives - that is, plastic binders. Most do not.

Another substrate that I have used with peroxide is recycled pelletized paper fiber. In my area, this is sold as Crown Animal Bedding™, and as Good Mews™ Cat Litter. These products have been sanitized by a double heat treatment (according to the promotional material). The pellets are still about 30% moisture before adding any water. As with the pellet fuel, the material has no residual peroxide-decomposing activity. The drawback here is cost, as the animal bedding is usually priced about three times higher than pellet fuel on a dry weight basis.

If no pellet fuel or paper fiber pellets are available in your part of the world, you should plan to use one of the procedures presented in Volume II for your substrate preparation. Those procedures allow a greater variety of possible materials as substrates, including some that contain peroxide-decomposing enzymes. Indeed, one of the only materials that will NOT work with any of my peroxide procedures is raw sawdust, that is, the sawdust produced by the milling of raw logs.

If you have another substrate you'd like to use with peroxide, say paper waste or cardboard, but you plan to pasteurize it rather than autoclaving, you will need to be sure it is free of peroxide-decomposing enzymes after pasteurization. You can test it simply by putting a small amount of the substrate in a cup and adding some fresh 3% peroxide solution. If nothing happens right away, let it sit for a while. When peroxide-decomposing enzymes are present in the substrate, the mixture will bubble and froth. If the enzymes are all gone, the mixture will look no different from substrate mixed with water.

Recipes for fruiting substrates vary from one mushroom species to the next. For wood-decomposing mushrooms, most recipes include sawdust (which we will now derive from pellet fuel), at least 1% powdered lime, water sufficient to give a final moisture content of about 60 to 65%, and from 5-20% of the dry weight as some kind of nitrogen rich supplement like rice bran (which provides about 0.1% to 0.4% nitrogen overall).

Higher nitrogen levels in supplemented sawdust generally translate to higher yields of mushrooms, but traditionally, high nitrogen has also translated to greater risk of contamination. With the peroxide method, the danger of contamination may not increase appreciably with higher nitrogen levels. However, to be on the safe side, I seldom raise the nitrogen level above 0.4%.

Wood chips and substrate density

Traditional recipes often call for wood chips, but I have never included them in my substrate since it would require the inconvenience of pressure-cooking the chips separately and adding them to the pasteurized bulk substrate later. Some growers believe wood chips are crucial for good growth of shiitake. I have not found them necessary for *Hypsizygus ulmarius*, *Pleurotus eryngii*, or *Hericium erinaceus*. However, for *Hericium erinaceus*, I have found it beneficial to gently but firmly compress the sawdust in my cultures after inoculation by pressing with my hands on the outside of the bag, removing the air space (but not the absorbed water) in the substrate. This may serve something of the same purpose as adding wood chips, by creating a substrate of greater density. I can well imagine that an organism like *Hericium erinaceus*, which can grow happily through woods as dense as walnut and cherry, might prefer a dense substrate and thus do better on compressed rather than fluffy sawdust.

In traditional methods without peroxide in the sawdust, it would not have been advisable to compress the substrate, because of the danger of creating anaerobic conditions favorable to deleterious organisms. With peroxide in the substrate, however, decomposition of the peroxide provides a beneficial level of oxygen even in compressed substrate, thus making it possible to provide the density some of the organisms prefer without inducing anaerobiosis.

Preparing supplemented sawdust with peroxide

So here's what to do with the pellet fuel:

1. First, find a container such as a five gallon plastic bucket with a tight-fitting lid, and clean it thoroughly. (For my routine cleaning, I wipe down the inside of the bucket with a scrub sponge and biodegradable dish detergent, then rinse this out.)
2. Next rinse the container and its lid with boiling water - a teakettle-full should do. From here on out , you will need to avoid touching the inside of the bucket or the rim.
3. Place the loosely-closed bucket on a scale and scoop in about 8.0 pounds dry weight of pellets if you have oak, or 6.0 to 6.5 pounds if you have a lighter wood like fir (six pounds is roughly a gallon of pellets, if you prefer to measure by volume. I use a one quart glass pot that I've boiled some water in on the stove to do my scooping, but it doesn't really need to be pasteurized). You will probably have to make your own adjustments for your local pellet fuel, setting the weight you use according to the amount of sawdust you can fit in your bucket along with your supplements and spawn, while still leaving

enough room to mix the contents of the bucket efficiently.

4. If you are using a solid, denatured nitrogen supplement like Sylvan's CG60 or Millichamp 3000, it can be added to the pellet fuel at this stage.
5. Add your lime to the pellet fuel. I use powdered oyster shell lime, but before I use it, I bake my supply at 400 degrees F for a couple of hours to eliminate any peroxide-decomposing enzymes resulting from microbial growth on the shells. Crushed limestone is also a good choice if you can get it. Do not use dolomite lime, which contains magnesium that can inhibit mushroom development. For mushrooms grown on oak pellet fuel, I use 2 oz of lime, or half that much for lighter pellet fuel such as cottonwood.
6. Boil in a covered pot half the amount of water you want to add to the pellets. (Your water should be clear and free of any obvious particulates. In some cases this may necessitate filtering). For this step, I boil about 3.5 quarts (or about 3.5 liters) for 9.0 lbs of the oak fuel pellets. (If you are using a soluble nitrogen supplement such as artificial fertilizer, it can be added to the water before boiling). Fir pellet fuel sawdust is less dense, so I use only about 6.5 lbs of it, boiling 3 quarts of water. You may want to experiment with different moisture contents for the species you are growing. One advantage of adding peroxide to your cultures is that you can add more water than you could otherwise, without developing anaerobic areas in your substrate that might lead to contamination. However, the pellet fuel sawdust tends to clump as more water is incorporated, which makes it harder to pour into the bags later on without spilling).
7. When the water has boiled for a minute, set the lid of the bucket carefully to one side and pour the boiling water over the substrate. Seal the lid and mix the substrate by turning the bucket for a couple of minutes to distribute the water.
8. Boil in a separate covered pot the other half of the water you want to add to the pellets (e.g., another 3.5 quarts/liters of water). When the water has boiled for a minute, turn off the heat and set this pot of water aside to cool with its cover in place. You'll use this water to add peroxide later.
9. Set the bucket of substrate aside to cool, with the lid in place. Cooling usually takes several hours. The bottom of the bucket can still be somewhat warm to the touch at the time of peroxide addition.
10. With a boiling-water-rinsed measuring cup, add about 1/2 cup of 3% peroxide solution to the pot of cooled, boiled water you've set aside.
11. Pour the peroxide mixture into the cooled bucket of substrate and mix thoroughly by turning the bucket. This gives a final peroxide concentration of about 0.03%, or a one to one hundred dilution.
12. Let the substrate finish cooling to room temperature. It is now ready to use.

Perhaps you are wondering at this point whether this procedure can be simplified along the lines of the Ten Minute Spawn procedure. If the peroxide concentration were raised to compensate for decomposition in the hot substrate, maybe peroxide could be added at the beginning of the procedure with all of the water. This may indeed prove possible with a high enough initial peroxide concentration. However, the substrate takes more than twice as long to cool when all of the moisture is added initially as boiling water. Under these conditions, I suspect the peroxide will have a difficult time surviving the exposure to heat, even if the initial concentration is raised several fold.

Table of Contents

Nitrogen supplements for bulk substrate

If you are using traditional nitrogen supplements like millet or rice bran, you will have to pressure cook them. While still hot, the sterilized supplement gets poured into the cooling pasteurized substrate. Be careful to wipe drips off the outsides of the jars before pouring.

Most of the traditional nitrogen supplements for mushroom culture require pressure cooking to eliminate the endogenous peroxide-decomposing enzymes before pasteurization. (These enzymes are remarkably stable, and standard pasteurization procedures are generally not enough to inactivate them, even with delicate supplements like bran). However, as I discussed in the section on making sawdust spawn, I have now found a few supplements that are free of enzymes and so can be added without pressure sterilization, in this case mixed in with the wood pellets. Two of these are commercially manufactured nitrogen supplements already in use in the Agaricus mushroom industry (Sylvan's Millichamp 3000 and CG 60). They contain denatured soy protein and corn gluten, respectively, and evidently the denaturing process destroys the peroxide-decomposing enzymes. These supplements are an excellent value, but home hobbyists may have difficulty obtaining them. Also, care must be taken to keep them from spoiling in storage, especially with Millichamp 3000.

Some more expensive forms of processed protein are more readily available, such as Texturized Vegetable Protein, powdered soy milk, or powdered cows milk.

Another type of supplement that can be used without pressure sterilization is simply chemical fertilizer, such as a standard 20-20-20 fertilizer. Since these fertilizers do not come from living organisms, they contain no peroxide-decomposing enzymes. Nevertheless, for the most part the nutrients they contain can be utilized by mushroom mycelium after a period of adaptation. If you are going to try this method of supplementation, I recommend that you prepare sawdust spawn using the same supplement, so that the adaptation period will have already taken place by the time you inoculate your bulk substrate. Also, you will get a chance to see how the particular fertilizer you have chosen will work for the organism you are growing. Fertilizer formulations vary quite a bit, even with the same NPK rating, so it is probably advisable to test your selected fertilizer with a small culture before going on to bulk substrate.

Urea is a common source of nitrogen in the formulations for chemical fertilizers, and it probably can also be used by itself as a supplement without pressure sterilization.

If you want something more "organic" than artificial fertilizer (and there is good reason to avoid dependence on substances which require energy from petroleum for their manufacture), human urine and animal urine can also serve as supplements that don't need pressure cooking. However, they must be kept relatively free of micro-organisms until use. Addition of peroxide provides one way to do this.

Calculating how much supplement to add

How do you calculate how much of the various supplements to use? Calculations are only approximate, and you will ultimately need to make decisions based on your actual yield of mushrooms at various levels of supplementation. But you can get an idea of what you'll need by consulting Stamets's Growing Gourmet and Medicinal Mushrooms, where the appendices reveal that rice bran has an NPK rating of roughly 2-1.3-1. So, if substrate would ordinarily get supplemented with 5 to 20% rice bran, which Stamets suggests, then a 20-20-20 fertilizer, which has 10 times as much nitrogen as rice bran, would be added at one tenth the rate of rice bran, or 0.5 to 2% of the dry weight of substrate. If you were adding one pound of rice bran to a bucket of pellet fuel, then you would add 1.6 oz of 20-20-20 fertilizer instead, that is, one tenth of a pound. With the commercial supplements, you will need to find out from the manufacturer what percentage nitrogen the material contains, and divide that number into 2.0 to learn what fraction of the amount of rice bran you would add. Sylvan's Millichamp 3000, made from soy, is about 7.3% nitrogen, so it will need to be used at about one quarter the rate of rice bran.

You can also directly calculate the amount of the material needed to give 0.1% to 0.4% nitrogen in the final substrate, without reference to the amount of rice bran used by Stamets:

1. Divide the percent nitrogen in the supplement by the final percent nitrogen desired in the substrate.
2. Divide the previous number into the total weight of substrate to be supplemented to get the weight of supplement to be added.

Thus, to get 0.2% final nitrogen (which requires a supplementation rate of roughly 10% of the dry weight of substrate with rice bran), how much soy flour would we need to add? If the soy flour is 7.6% nitrogen, 7.6 divided by 0.2 gives 38. If the total weight of substrate is 6.5 pounds, then 6.5 divided by 38 gives 0.17 pounds, or 2.72 oz soy flour to be added.

A note on measuring pH of substrate

I use ColorpHast strips with a pH 4 to 10 range to measure the pH of all my media and substrates, aiming for a pH at make-up in the 6-7 range in most cases. ColorpHast strips are inexpensive and convenient, and with a three-color comparison, I am usually confident of my reading. However, it is not a good idea to try to measure the pH of medium with a color indicator strip once peroxide has been added, as the peroxide may change the chemistry of the indicator. With agar cultures and spawn, you can easily measure the pH before sterilization. With pellet fuel, use a small scoop such as a measuring cup (one that has been rinsed with boiling water) to take a small amount of substrate out of the bucket after adding and mixing in the boiling water plus lime. You can then use your color indicator strips to measure the pH of the removed substrate. Be aware, however, that the reading will only give you a relative idea of the pH eventually experienced by the mushroom mycelium if you have added granular lime which dissolves only very slowly. Addition of Mason's lime (CaOH, available in large sacks as "builders' lime" from construction supply stores) gets around the latter problem, as it dissolves and reacts much more quickly, but with some mushrooms there may be an advantage to providing a "delayed release" source of alkalinity such as granular lime provides. Then you will simply have to calibrate the amount of lime you used against the ultimate yield of mushrooms to determine the optimal dose.

Culture containers

Traditionally, sawdust cultures have been grown in special plastic bags with microporous filter patches, to allow gas exchange without letting contaminants gain entry. With peroxide in your fruiting substrate, however, you should be able to use ordinary trash bags (at a savings of $.50-$.80 per bag) to grow your mushrooms. Evidently the process used to produce trash bags pasteurizes them to the point that they do not harbor significant live-organism contamination. If you do use plastic trash bags, I recommend using the kind that are made from high density plastic, 0.5 mil thickness or less. These bags are thin enough that oxygen can diffuse through them, so that the cultures can be grown to maturity with the bags sealed closed by twist ties. Also, the thicker, softer bags are apparently made from PVC, which can leave estrogenic residues in the mushroom cultures, and certain of these softer bags are impregnated with fungicides.

Unless you use traditional gusseted mushroom bags, you will need to put your bags inside containers of an appropriate size to provide a form for the substrate. Small boxes which will hold 5-6 pounds of substrate can often be scavenged from health food stores or the like, or you can buy plastic containers such as nursery pots.

Filling a plastic trashbag, propped inside a box, with pellet fuel substrate.

Disposable bags create considerable waste for the landfill. An alternative is to use plastic buckets with lids, 2 or 3 gallon in size, preferably HDPE plastic, recycling number 2. (Five gallon buckets are easier to come by, but they are a little too big for your average sawdust culture). These can be cleaned with detergent and reused after rinsing with boiling water. If the lids are left slightly loose during the spawn run to allow gas exchange, the buckets are excellent culture vessels for mushrooms species that fruit vertically, such as *Pleurotus eryngii*. *Hericium erinaceus* will also grow in them if you open the bucket and turn it on its side when fruiting time comes. (I fill the bucket only about a third to half way full with substrate, so the upper part of the bucket provides a moisture barrier). *Hypsizygus ulmarius* would be a little cramped for space in one of these buckets, unless you were to fill substrate nearly to the top, so that the mushroom clusters could grow out above the rim. To get a second flush, then, you would need to take the round block out of the bucket and turn it upside down, since *Hypsizygus ulmarius* doesn't like to fruit from the same surface twice.

Inoculating supplemented sawdust

I prepare spawn for inoculation in the traditional way:

1. The day before I want to use the spawn, I break up the spawn by whacking the jar against something hard protected by something soft.
2. When the particles are separated, I put the jar back on my spawn shelf and incubate overnight to give the mycelium a chance to put out some new growth. This makes a considerable difference in how fast the mycelium will surge into the new substrate. If I am working with grain spawn, it also gives me a chance to see bacterial contamination in the form of "wet" or greasy looking grain kernels that haven't acquired a new fuzz of mycelium. When your spawn has been grown using peroxide, the presence of two or three wet kernels will probably not interfere with the subsequent success of your colonization of bulk substrate, since the bacteria that are able to survive peroxide exposure are generally fairly benign organisms when present in small quantities. However, if you have quite a few more wet kernels than two or three, the bacteria will likely slow the colonization of bulk substrate substantially, which then may give a chance for mold to gain entry. So you will probably want to discard spawn with any significant quantity of wet kernels.
3. I inoculate the pellet fuel sawdust by breaking up the spawn briefly, then pouring it directly into the 5 gallon bucket with the substrate. I close the lid and mix everything together by rotating the bucket.

Inoculating a bucket of pellet fuel substrate with spawn.

4. I pour the mix into bags. Each bag gets opened up and set inside of a box of the appropriate size to receive the substrate.
5. When I have filled the bag to the capacity of the box, I close the lid on the remaining inoculated substrate, and taking care not to touch the inside surface of the bag, I shift the bag a bit to fill any gaps, then twist the mouth of the bag closed and seal it with a twist tie.

Bag of inoculated substrate sealed with twist tie.

6. Lastly, I compress the sawdust by pressing down on the bag, gently but firmly. I find that this speeds growth of some cultures, especially with a light sawdust like fir or cottonwood.

After labeling, the box is ready to incubate, and from here on out, I follow standard mushroom-growing procedures. You can use the resulting blocks of mycelium either directly for fruiting mushrooms, or the blocks can serve as spawn for inoculating logs or beds of fresh wood chips outdoors.

Table of Contents

Mushroom formation

For most commonly cultivated mushroom species, mushroom formation begins soon after the cultures are shifted to cooler temperatures, given more light, and given more fresh air, provided the substrate has been thoroughly colonized. There is not much need for hydrogen peroxide during this phase, since the mycelium is well established.

The precise procedures for inducing mushroom formation differ from one species to another, and it is beyond the scope of this manual to review them all, but I will give guidelines for my favorite species. Two of the mushroom species most familiar to me are also among the easiest to fruit: *Hypsizygus ulmarius* (the White Elm mushroom) and *Hericium erinaceus* (the Lyon's Mane or Pom Pom mushroom). Many oyster mushroom species follow similar procedures to that required by *Hypsizygus ulmarius*. The other species most familiar to me, *Pleurotus eryngii* (King Oyster) and *Agaricus subrufescens* (almond mushroom) follow a different fruiting pattern. Shiitake follows yet another.

Most of the "easy" mushroom species are ready to fruit when the bulk substrate is thoroughly grown through. Often the blocks look white at this time, rather than the original brown of the substrate. How long it takes for a culture to reach maturity depends on the organism, the substrate, and the incubation temperature. Hericium can take as little as 2-3 weeks to form small white, globular fruiting initials on the upper surface of the block, but I like to wait until a month has elapsed before opening the bags. *Hypsizygus ulmarius* takes about 5 weeks on fir sawdust or straw and six weeks on oak sawdust (at ordinary room temperature), after which small clusters of pinhead primordia will begin to form spontaneously. By cutting an "X" or a single slit with a clean knife through the bag on the side of the block, *Hypsizygus ulmarius* and various Oyster mushroom species will usually form primordia at the site of the cut within a week or two, and mushrooms will soon develop. Provide mist spray when the mushrooms are about an inch high.

Hericium will also form mushrooms at the site of a cut in the bag, but in the winter I find it easier to grow large fruiting bodies by allowing the organism to fruit inside the bag. Simply turn the block on its side and open the bag a bit, allowing air exchange but still providing a moisture barrier. Fruiting bodies will form at random from the fruiting initials that have already developed.

If you grow only a few blocks of mushrooms, ventilation will not be much of an issue. But with more blocks, the need for ventilation to remove carbon dioxide increases. If your mushrooms are not getting enough air as they develop, they will become deformed. *Hypsizygus ulmarius* and other oyster mushrooms, for instance, will grow long stalks and irregular caps when the carbon dioxide concentration is too high. When you have enough blocks to need a fan, then an automatic misting system can't be far behind.

Note that if you decide to grow *Hypsizygus ulmarius* or another oyster species in your home, you will probably need to take precautions to protect yourself from the tremendous amount of spores produced by these organisms. Harvesting the mushrooms when young can help keep the spore load down. Covering the fruiting cultures with Reemay™ or other row cover material will keep the bulk of the spores within the covering, while allowing gas exchange sufficient for fruiting. However, if you or someone in your family is sensitive to the spores, you may need to acquire an air purifier to eliminate the spores from the air in your living space, or else keep the cultures in an out-building.

The almond mushroom, the white button mushroom, as well as King Stropharia and Shaggy Mane, and sometimes King Oyster all need something called a casing layer applied to the mushroom culture to stimulate fruiting body formation. Casing is a mixture designed to imitate a moist, friable, loamy soil. It contains microorganisms that promote mushroom formation, and it provides a moisture reservoir for mushroom growth. It generally contains little available nutrition for the growth of mushroom mycelium, and this feature also sends a signal to the mushroom culture to begin mushroom formation.

Almond mushrooms growing from a casing layer.

Most casing contains peat moss, and a simple formula I have used for almond mushrooms simply calls for one part peat mixed with one part garden soil, plus a handful of gypsum (calcium sulfate) for two or three gallons of mixture, all moistened until damp but not clumpy. The casing is applied to the top of the mushroom culture to a depth of two inches at the most. Be careful not to tamp it down, as the porous structure is essential for encouraging formation of mushroom primordia.

Peat bogs are an endangered habitat worldwide, so we need to find alternatives to the use of peat in casing. Growers in different parts of the world have begun to devise alternatives, as one can discover by searching the US patent database (see http://www.uspto.gov/). In some cases, soil alone may suffice as a casing, or soil plus vermiculite. Vermiculite by itself is a possible alternative (although it will not supply microorganisms). Almond mushrooms and King Oysters do not absolutely require a casing (the casing does tend to accelerate primordia formation with *Pleurotus eryngii*, however), so manipulation of conditions may lead to good fruitings without it for these organisms.

If you do apply a casing, you will then need to wait a week or two for the mycelium to grow up into the casing before mushrooms will begin to form. With the almond mushrooms, this is the time to warm up the cultures (I put my apple-box cultures of almond mushroom on an electric "cat warmer" to be certain they are warm enough). It is also the time to sprinkle the casing lightly with water every couple of days to keep it moist. (With *Pleurotus eryngii*, warming and sprinkling are not necessary). Mushrooms usually begin to form a few days after the mycelium begins to reach the surface of the casing.

Seasonal planning

I you are only growing a few mushrooms, and you have a cool, insulated indoor space such as a lighted basement, you will probably be able to grow your favorite mushrooms all year. However, if your are growing outdoors, or you are growing a lot of mushrooms indoors (so that you need ventilation from outdoors), you may need to plan ahead to have the appropriate mushroom cultures ready in the right season. I fruit my mushrooms in a basement with open windows and a fan to bring in fresh air, so the mushroom growing gets harder in the hottest part of the summer and the coldest part of the winter. Closing the windows is not an option, as carbon dioxide will build up and inhibit mushroom formation. Heating or cooling the incoming air is certainly possible, but it runs up the energy bill too much for my taste. So all my mushrooms do best in fall and spring.

In the coldest part of the winter, both the temperature and the light levels fall. All the mushrooms take longer to finish colonizing the bulk substrate. *Pleurotus eryngii* fruits with difficulty, and *Hypsizygus ulmarius* grows very slowly, producing longer stalks (and deformed caps, if the light and temperature levels are too low). *Hericium erinaceus* also grows slowly at this time, but this species still produces normal, but small, fruiting bodies even in very cold weather. *Agaricus subrufescens* needs warmth, but paradoxically it makes a good indoor mushroom for winter, because it will fruit in heated room and it doesn't need as much air or light as the other mushrooms.

In the hot parts of summer, there is plenty of light, but it can be a problem to initiate fruiting at the higher temperatures. Keeping humidity up can be difficult, too. However, I have had *Hericium erinaceus* blocks fruit on a dry compost pile in 90 degree weather; evidently the fresh air initiated fruiting in that case, since my indoor *Hericium erinaceus* blocks refused to fruit until the temperature came down substantially. *Agaricus subrufescens* likes warm weather and tends to fruit as the peak temperatures pass. *Ganoderma lucidum* also prefers warm weather, as does Stropharia.

Outdoor growing vs. indoor growing

I used to grow almost all of my mushrooms indoors. This allowed me to grow them year 'round because of the more moderate temperature, and it also saved me from having to deal with slugs and snails, which love mushrooms and grow in great numbers in my area. (Actually, I still get a few slugs that manage to climb in my windows, travel down the cement basement wall and across the cement floor, and eventually enter my fruiting cultures). Deer may also eat mushrooms, and fungus gnats can be a problem in outdoor mushroom patches. So in the past, I have always recommended indoor growing. But outdoor growing has its advantages, too. For one thing, mushrooms fruited outdoors have a distinctly superior flavor to mushrooms grown indoors. Also, mushroom formation can be more robust in the fresh air of the outdoors. There's more physical space for crops. And there is little problem with breathing mushroom spores. Fungus gnats can be reduced somewhat by covering cultures with a fine light fabric such as Reemay™ or other row cover materials. And if you live in a temperate region on the seacoast, you may be able to grow mushrooms outdoors all year 'round. So if you think you can keep all the pests away, go ahead and fruit your cultures outside. You will just need a shaded area that can be kept damp.

Harvesting

Knowing when to harvest mushrooms is largely a matter of knowing how large they grow and what changes they go through as they mature. With *Pleurotus eryngii* and *Hypsizygus ulmarius*, the uncurling of the margin of the cap is usually a sign that the mushroom has reached maturity, but you will need to correlate this change with the size of the mushroom to be sure. With *Agaricus subrufescens*, the cap opens and the gills begin to turn reddish in color. With *Hericium erinaceus*, small "icicles" form and the mushroom softens.

Most mushrooms are said to be tastier if harvested before they start releasing many spores, although they may still gain more mass if left to grow further. It is certainly true that *Hypsizygus ulmarius* is tastier when young, but I haven't personally made taste comparisons with the other mushroom species I grow.

Table of Contents

Trouble shooting

Despite my use of hydrogen peroxide to protect my mushroom cultures, there have been many occasions when things did not go as I had planned and contamination appeared. Each time, I had to track down the problem and correct my procedure, and each timed I was relieved to learn that the use of peroxide itself was not flawed. The procedures I have described here to the best of my knowledge incorporate everything I have learned from my mistakes and should cover the key points required to produce contamination-free mushrooms with peroxide-based culture. Nevertheless, troubleshooting is an unavoidable part of mushroom culture, and you will have to do it sooner or later.

I always find it discouraging to read through lists of things that can go wrong, so instead, I have created a list of questions that draw attention to different aspects of the culture process for the purposes of troubleshooting contamination problems.

If you are adding peroxide, and you still suffer significant contamination, you might ask yourself some of the following questions:

Is the concentration of peroxide in your stock solution what it should be? Has it been over a month since you measured it?

Is your pressure-cooking equipment functioning properly?

Is steam able to enter your jars and equilibrate (are the lids loose enough?)

If pressure cooking, do you allow five minutes for steam to equilibrate before putting on the pressure regulator?)

Is your stove element (if electric) heating consistently?

Are you cooking at a high enough temperature and for a long enough time to eliminate resident contaminants and, if necessary, peroxide-decomposing enzymes?

Is your substrate moist enough for steam to penetrate? Has your substrate or supplement spoiled before use?

Is your peroxide getting distributed evenly throughout the medium?

Is your pH reading accurate? (Peroxide is apparently most stable around neutral pH). If your fruiting substrate is getting contaminated, is your spawn clean?

If your spawn is getting contaminated, is your inoculum clean?

If you are free-pouring diluted peroxide into your cultures, are there drips that run over unsterilized surfaces before falling into the culture?

Are your petri dishes free of traces of old medium?

If your agar plates are getting contaminated, is the contamination on the surface or within the agar? If it is on the surface, look for a source of contamination external to the agar medium; if it is in the agar, contamination is getting in before or during pouring.

Are you letting your medium or substrate cool sufficiently before adding peroxide?

Is your water clean and free of particulates?

Have you overlooked some source of unsterilized or unpasteurized material that can get into your cultures?

Are you mushrooms getting enough light (but not direct sunlight), fresh air, and humidity to grow to a good size?

Conclusion

As I reach the end of this manuscript, I am forced to pause for a moment of self examination. I called this volume Growing Mushrooms the Easy Way, and now I have to ask myself whether I wasn't indulging in just a bit of self-serving exaggeration when I chose that name. After all, there are still far more ways for things to go wrong in mushroom cultivation than for them to go right. And I sometimes think it is a wonder indeed that we ever get any of these organisms to respond to our coaxing and produce their delectable fruiting bodies.

Well, it is a wonder. And even with peroxide maintenance of mushroom cultures, the process is far from fool-proof. But I feel gratified that the procedures described here do make it possible for hobbyists with at least a minimal degree of comfort with sterile technique to perform all the steps of gourmet mushroom growing and mushroom culture in an ordinary household, more easily than ever before, with no more special equipment needed for contaminant control than a steaming pot and a measuring pipette. And with the stress taken off of battling contaminants, home growers should be freed at last to focus on the thing that attracts us all to mushroom growing in the first place, the quest for ever more of those beautiful and delicious fungi.

Table of Contents

VOLUME II

Introduction

I've written this second volume of my manual, Growing Mushrooms the Easy Way, both to fill in some of the gaps in the first volume, and to introduce some new ideas for saving time, effort, and money in the process of mushroom cultivation.

As in the first volume, most of the methods in this second volume have been designed primarily for small scale and home cultivation. But I designed two of the methods for preparing bulk substrate specifically for growers who want to work at commercial scales. And nearly all of the remaining techniques presented here could also prove useful in a commercial context.

The procedures are broadly organized within the volume according to the stage of mushroom cultivation they apply to. So, the techniques relating to maintaining cultures and germinating spores come first. Then come the methods for preparing spawn, finishing with the procedures for preparing bulk substrate.

The procedures in this volume largely stand on their own for growers familiar with the peroxide method. But if you are a newcomer, you'll want to refer to the first volume of Growing Mushrooms the Easy Way. It has essential background information on mushroom growing generally and on the use of hydrogen peroxide in mushroom culture in particular.

The peroxide-based methods presented in this volume are my original inventions unless otherwise stated. In general, the non-peroxide methods have been worked out by others and have made there way into the public domain. I am presenting them here because of their obvious value to mushroom growers who use the peroxide method.

Enough said - let's get started!

Acquiring, Storing and Maintaining Mushroom Cultures

Using slants instead of agar plates

It has long been the standard procedure in mycology to grow mushroom tissue cultures in Petri dishes filled with agar medium. But as more and more people seek to cultivate mushrooms without sterile laboratories, this standard has come into question. Perhaps the biggest drawback of agar Petri dish culture for mushrooms is that the dishes have such a large exposed surface area. Because they are incubated for so long, the chance of picking up airborne contamination is high. Even with peroxide in the agar, mold colonies will occasionally appear at the edges of plates. This is especially true after the mycelium has spread over most of the agar, and especially during the "mold season" in the fall.

One solution to the problems of agar Petri dish culture is to switch to agar culture in containers that have smaller exposed surface area. For instance, screw cap test tubes are a good choice. The kind I'm talking about have typical dimensions of 19 x 125 mm. When these tubes are partly filled with molten agar medium which is allowed to solidify at an angle, they are called slants.

Slants are relatively easy to handle and store. It is also easy to hold the mouths of the tubes over the flame of an alcohol lamp for a moment on opening and closing. This gives added security against contaminants. The water in these tubes evaporates much more slowly than in Petri dishes, so the peroxide concentration remains at an effective level for much longer. Even without peroxide, the contamination rate is low. What's more, slants use less agar than Petri dishes, so they save you money. But there is a downside. Some mushrooms don't like the wetter environment in slants (for example, *Hypsizygus ulmarius*). You can't monitor the morphology of the mycelium as closely in slants as on agar plates (changes in morphology can indicate contamination or other strain problems). And it can be frustratingly difficult to dig out chunks of mycelium from slants when you want to inoculate other cultures. This last problem depends quite a bit on the kind of mycelial mat a given mushroom lays down.

Making slants

Here's how to make a set of slants:

1. Measure out the ingredients for MYA medium into a clean metal can. (See below for MYA medium - 250 mls. will make about 20 slants or so.) Squeeze a crimp in the rim of the can to serve later as a pour spout.
2. Put a piece of aluminum foil over the top of the can. Put the can in your pressure cooker with some water. Put your screw cap tubes in at the same time, perhaps sitting in another can.
3. Steam for 10 minutes without the weight in place. Then put the weight on, bring the cooker to full pressure, and cook for 10 minutes more.
4. Remove the cooker immediately from the heat and cool. Open the cooker as soon as the pressure has gone down. Take out the can and the tubes to cool. You can set the can in a pan of warm water to speed the cooling, but don't let it start to solidify.
5. Add 1.5 mls. peroxide for 250 mls. of MYA medium. Add peroxide with a pasteurized pipette that is, one steeped briefly in boiling water. Mix the peroxide in by swirling the can.
6. Finally pour the agar into the tubes. Use the pour spout on the can to get the agar into the narrow mouths of the tubes. Avoid spilling over the tube threads. Hold the screw cap curled in the little finger of your dominant hand while you do the pouring.
7. Replace each cap and set each of the tubes leaning at a low angle for solidifying. A wide low bowl works well for this purpose. When solidified, they are ready to use.

For easy reference, here's the recipe that I use for MYA Medium:

- 12 gms (0.42 oz) agar
- 12 gms (0.42 oz) light malt powder
- 1 gm (0.035 oz) nutritional yeast powder
- 0.5 gm (0.017 oz) grain flour (I rotate between wheat, rye, corn, rice, oats, and millet)
- 0.5 gm (0.017 oz) rabbit feed (or other animal feed pellets)
- 4 gms (0.15 oz) wood fuel pellets (the quantity of wood pellets can be increased for those wood-decomposing species that do poorly on agar)
- 1 liter tap water
- Adjust pH to 6-8 with a bit of baking soda or vinegar (optional)

Making transfers to and from slants

For inoculating slants, and for withdrawing mycelium from them, it helps to have an inoculating loop made of fairly stiff wire. You can make an inoculating loop for yourself. Put a small loop in the end of a wire, then inserting the other end of the wire in a thin glass tube (1/8 inch, for example). Finally, use a flame to melt the end of the glass tube closed over the wire to hold it in place. The glass tube becomes the handle.

For successful inoculation, you will still need to dig out a chunk of agar plus mycelium and transfer it to the slant. This can be a tricky endeavor with an inoculating loop. (If the chunk is too small, or if you simply scrape mycelium off the surface of the agar, it may not be able to establish itself. But if at first you don't succeed, you can always try again with the same slant. The peroxide will keep it free of contaminants. I like to dig the loop into the agar to cut out a piece of the culture. But it can still be hard to catch a good-sized piece on the loop. Many times I've pulled out such a piece only to have it drop off the loop as I moved to transfer it. But eventually you'll do it. Roll the mouth of the screw cap tube in the flame of your alcohol lamp before and after the transfer.

Cleaning the mycelium with slants

In Volume I of Growing Mushrooms the Easy Way, I explained how invisible microbial contamination can build up on the mycelium of cultures grown by the peroxide method. I also presented a method for "cleaning" the mycelium of these contaminants by inoculating the bottom of the agar in Petri dish cultures. With slants, the invisible contaminants should build up quite a bit more slowly than with Petri dishes. But they will eventually accumulate to the point where the mycelium needs cleaning. There is, however, no convenient way to inoculate the bottom of the agar, so we have to use a different method. This method consists of pouring a second layer of agar - when it is almost cool enough to solidify - on top of mycelium growing on the first layer of agar. The mycelium then grows up through the second layer, cleaning itself as it goes.

Here's what to do:

1. Prepare and inoculate slants as described above. Allow the mycelium to grow out a bit over the agar.
2. Prepare a small amount of MYA medium by the standard procedure. But use a can with a crimp in the rim for a pour spout (as for making slants above) to hold the medium. Cover it with aluminum foil.
3. After cooking, when the medium has cooled substantially, add peroxide at the usual concentration. Mix thoroughly by gentle swirling.
4. When the bottom of the can is barely warm to the touch, light your alcohol lamp. Open a slant, holding the cap in the crook of your little finger. Rotate the mouth of the tube over the flame of the alcohol lamp. Then pour enough of the fresh agar medium into the tube to cover the mycelium completely. You can either cover the mycelium with the tube "slantwise" or with the tube standing upright. The less agar you use, the smaller distance the mycelium will have to grow to reach the surface. Beware - the remaining agar in the can tends to solidify rather suddenly! So put it in a pan of water that is slightly warm.
5. Return the screw cap to the tube.
6. Allow the mycelium to grow up through the new layer of agar.

When taking out mycelium for inoculations, be careful not to dig through the top layer of agar into the lower layer. That will defeat the purpose of the layering.

Beer-Based Medium (BBM)

Here's a medium for agar plates that saves most of the weighing and measuring. It is also perfect for those of you who can't find a source of malt extract. And even if you can, malt powder can turn hard as rock in storage. This medium gets around that problem. It comes to you courtesy of Dr. Nenad Vidovic and Sansin Corporation in Ontario, Canada (see Vidovic, N., Specialty Mushrooms - Small Scale Production, Mycelium, 25, 1999, pages 4 and 8). Dr. Vidovic showed that several mushroom species can grow on BBM just as well as they do on commercial malt extract agar medium. I have modified his recipe to include peroxide.

Ingredients:

- 1 part fresh beer
- 3 parts water
- 2% agar by weight (2 gms agar powder per 100 mls of medium, or 1 tsp per 1/2 cup)

1. Mix beer and water.
2. Add agar.
3. Sterilize in a pressure cooker at full pressure (15 lbs psi) after steaming 10 minutes to dissolve the agar.
4. Cool until the container can be handled. Then add peroxide (6 mls/liter of 3%), mix well, and dispense medium into sterile petri plates.

Dr. Vidovic also reports that sterile BBM without agar makes an excellent storage medium. He calls this LBBM, for "liquid beer-based medium." Cultures of both oyster mushrooms (*Pleurotus ostreatus*) and morels (Morchella species) were easily recoverable after two years in LBBM (with no peroxide added). It also works well for spore germination.

Starting with Spores

I usually urge would-be mushroom growers to begin their mushroom explorations with healthy, established tissue cultures of the mushroom species they want to grow. These should be obtained from reputable suppliers of mushroom cultures. Such cultures have been tested and shown to produce good yields of mushrooms under certain reproducible conditions. Unless the culture is subsequently damaged, it will continue producing good yields of mushrooms when you supply the right conditions. And if you lose the culture, you can (in most cases) go back to your supplier and obtain another copy. The copy will then produce mushrooms under the same conditions that worked well for the previous culture. If you start with spores, by contrast, there is no assurance that the mycelial culture you grow from them will fruit in useful quantities. There is also no assurance that the mushrooms produced will have the characteristics of the mushroom the spores came from. Moreover, you will not know the optimal growing conditions for the strain you obtain by spore germination until you have tested the strain yourself. And if you lose the culture, you will have to start over again from scratch.

Still, there are arguments on the other side. Cultures obtained by spore germination are often quite vigorous. With fast growing species like oyster mushrooms, the differences between the parent mushroom and the spore-produced progeny are often small. Spores may cost little or nothing, whereas tissue cultures can be expensive. Spores can be obtained from dried mushrooms whereas tissue cultures can't. And so on. So it is certainly worthwhile to have a simple method of germinating spores.

In previous editions of the peroxide manual, I insisted that spores could not be germinated on peroxide medium. But a couple of people wrote me to say that they had indeed germinated spores in the presence of peroxide. So now I have to acknowledge that yes, it can be done. You may have to apply a concentrated dot of millions of spores to the surface of the peroxide medium, but it can be done. Still, I am not convinced it is a good idea for routine use. The mycelium generated this way could easily be genetically damaged. And as it turns out, it is not especially hard to start clean cultures from spores in the absence of peroxide, even in a non-sterile environment. One good method is to start the spores in screw-cap tubes. Then the chance of airborne contamination entering is greatly reduced compared to Petri dishes (many thanks to David Sar for letting me know about this approach).

Collecting Spores

Here's a way to collect spores:

1. Pressure cook a few Petri dishes for 15 minutes or so in a covered container. Let the dishes cool.
2. Pick a mature mushroom for your source of spores. If possible, choose a clean one that is not likely to be covered with mold spores.
3. Clear a counter someplace in your house where there won't be too many air currents from people walking by. Clean the counter with a sponge and then wipe it down with rubbing alcohol.
4. Open one of your Petri dishes (you can just set the lid, top surface up, next to the dish on the counter). Arrange your mushroom over the dish. If it is big enough, the mushroom can cover the entire bottom half of the Petri dish. Or perhaps you have a cluster that can span the dish. Smaller mushrooms, or mushrooms with odd shapes like morels, can be suspended above the plate by a thread. Use your imagination. Ideally, you don't want the mushroom touching the inside of the Petri dish bottom. And you don't want too much of the Petri dish exposed to airborne contaminants. But you want the mushroom arranged so its spores can fall into the dish.
5. Go ahead and collect spores, ideally until you have a visible coating of spore "dust" in the dish. This takes about an hour for a copious spore-producers like the oyster mushrooms. But you might need to go several hours for some mushroom species, and you might never get a visible coating with others. Close up the Petri dish when you're finished.

Table of Contents

Germinating Spores by the Disk Method

Here's my favorite method for germinating spores. It uses neither agar nor peroxide. You'll put spores onto a small cardboard disk, then pop the disk into a sterile screwcap test tube. The spores will germinate in a few drops of nutrient medium in the tube. I have used this method successfully to germinate shiitake, portabello, almond mushroom, elm oyster, and Pleurotus spores. This is what you do:

1. Make some small disks by punching random holes in a piece of gray (non-corrugated) cardboard. Do this with a paper hole punch, saving the circles that are cut out.
2. Make up about 10 mls of BBM liquid (without the agar).
3. Get together a set of clean screw cap test tubes (19 x 125 mm) or similar narrow mouth containers.
4. In each tube, place 5-10 drops of the BBM liquid.
5. Sterilize the cardboard disks in a petri dish or a small jar with a lid (10 minutes at 15 psi).
6. At the same time, sterilize the screwcap tubes with the BBM liquid in them. The tubes will have a little pool of liquid at the bottom after they have cooled.
7. Once everything is sterile and cool, flame-sterilize a tweezers. Use it to swipe one of the disks across the spores you've collected (or collect your spores directly into the sterile container of cardboard disks).
8. Pop each spore-treated disk into a sterile tube (flame the mouth of the tube on opening and closing). Make sure the disk gets down into the pool of liquid medium remaining. The disk should be wet for good spore germination. Screw the lids on tightly. Make several replicates.
9. You may need to keep the tubes from drying out. This is especially important for slow-germinating species such as shiitake or button mushrooms. For these species, place the tubes inside a larger container with a lid. Add some water to the container and close the lid.
10. Incubate. Change the water in the larger container if it goes bad.
11. Periodically examine the disks in the tubes for small signs of white fuzz (mycelium). Discard cultures that contain mold or bacteria. (Green and blue-green mold will grow quickly in round clumps. These are white at first, then develop a colored center. Bacteria will cause the liquid to become cloudy.)
12. Once you've got some mycelium, remove the disk to a peroxide plate or slant. You can do this with a flame-sterilized tweezers, or you can slide the disk out with a flame-sterilized inoculating loop.
13. Incubate and let the mycelium grow out. Growth will be slow, as the mycelium has to adapt to the peroxide.

The dark color of the cardboard disks helps to reveal the light mycelium when it appears. But be forewarned that the tufts of mycelium sometimes can be very hard to see at first.

On a peroxide-treated agar plate, you can observe the halo of growth formed by the spreading mycelium. The mycelium may not be homogeneous, or it may carry contaminants. If so, the halo will likely show sectors that grow at different rates and with different appearances. You can then take mycelium from the best-looking sector for transfer to fresh plates. The best sectors should have good radial growth, or snake-like rhizomorphic growth. Cottony mycelium is usually to be avoided, but it may be the norm for some species. Once you have stable, non-sectoring mycelium, you are ready to make spawn and test your strain in bulk substrate. And don't forget to make storage cultures!

Ideas Toward Mycelial Culture without Agar

Agar is probably the most expensive ingredient used in mushroom growing. It is relatively simple to handle once you've been introduced to it. But many beginning mushroom growers avoid getting their own cultures because of their unfamiliarity with agar. So I have been thinking about alternatives. Here I suggest one simple choice that shows promise as an alternative to agar medium - it's gray cardboard disk culture. Gray cardboard is cheap and reasonably available. (Other colors of non-corrugated cardboard can also be used). And as long as it is clean, it will not contain any peroxide- decomposing enzymes. Unlike corrugated cardboard, gray cardboard wets easily, and the wet material is soft enough to remove clumps for transfers. It is also a good substrate for the growth of mushroom mycelium, often supporting rapid growth even when very limited amounts of other nutrients are present. And it is a simple matter to add a nutrient solution if you need it.

So, instead of going through all the trouble of weighing ingredients for agar medium, melting the agar, cooling slowly, adding peroxide, pouring plates, waiting for them to solidify, then drying them for a couple of days, you can just cut disks of gray cardboard to fit your Petri plates or jars, and prepare a jar of plain water or a simple nutrient solution. Then, pop the plates and the jar of liquid in the pressure cooker for 10 minutes. Cool rapidly, and add peroxide to the jar of liquid. Finally, dip the cardboard in the liquid to give it peroxide protection. The cardboard plates are then ready to use as soon as the solution has soaked in.

Where gray cardboard is in short supply, newsprint is a possible substitute, but it has several drawbacks compared to cardboard. For one thing, it can be hard to see the mycelium, particularly if the newsprint is light in color. The mycelium can be as wispy as a spider web when it is growing on newsprint anyway. To complicate matters it may spread more beneath the surface, out of view, than in plain sight. Moreover, the growth rarely develops in a nice round halo such as one gets on agar. Nor does it necessarily progress evenly from one layer of newsprint to the next. Instead, the mycelium can spread somewhat capriciously. Apparently it is influenced by small variations in the conditions it encounters between the layers of the newsprint.

I do not yet know whether mycelium can be repeatedly transferred on plain, unsupplemented cardboard without running into nutrient limitations. I would expect cardboard to be close to devoid of nitrogen. So until further notice, it is probably a good idea to add a nutrient solution to keep your mycelium going on cardboard disks.

How to prepare the plates

Here are the detailed steps for making cardboard plates. Note that you can also use small jars in place of Petri dishes.

1. Measure about 250 mls. of tap water into a small jar. Use BBM (described above) if you want to add nutrients to the plates.
2. Find some gray cardboard, the thicker the better, preferably gray on both sides. Trace Petri plates onto the cardboard with a pencil. Cut out several disks somewhat smaller than the tracing.
3. Get together a set of petri dishes, at least one more than than the number of disks you have.
4. Moisten the disks slightly: dip each one in tap water and immediately shake it off. Then close up the disks inside the plates.
5. Pressure-sterilize the jar of liquid and the Petris, including the one empty dish, for 10 minutes at 15 psi (allow the cooker to equilibrate steam for 10 minutes before putting on the pressure regulator).
6. Cool the cooker, and remove the plates and jar of liquid.
7. When the liquid has cooled, add 1.5 mls. 3% peroxide to the jar. Use a measuring pipette that has been steeped in boiling water. You will have a final concentration of about 0.018% peroxide in sterile liquid.
8. Pour some of the diluted peroxide solution into the empty Petri dish that you sterilized. This will serve as a dipping reservoir, to wet the cardboard disks.
9. Sterilize the end of a pair of tweezers in a flame. Use the tweezers to transfer one of the cardboard disks at a time to the dipping reservoir of diluted peroxide solution. Let the solution soak into the disks briefly. Then remove each one and transfer it back to the Petri dish it came from.
10. The disks/plates are now ready to use.

You can store and incubate these plates inside plastic food storage bags as I suggest in Volume I for agar plates. But you will probably find that your cardboard disks dry out too quickly. You can keep them moist longer by storing them in a closed container that has some peroxide solution in the bottom. For instance, find a plastic yogurt container or a jar with a mouth wide enough to let Petri dishes pass. Then create a platform to hold your Petri dishes off the bottom of the container, perhaps by putting a smaller jar inside the larger container. Put the Petris on top of the platform. Then add a small quantity of peroxide solution to the container at the same concentration you use for your plates (roughly 0.018%). Finally, cover the container with a layer of plastic wrap and fix it in place with a rubber band around the mouth of the container (this kind of closure will allow adequate oxygen diffusion). Be careful to set it up so that you cannot knock your Petri dishes off the platform into the water.

Making transfers

Now you are probably wondering how you will remove wedges of cardboard when you want to make a transfer from one of these plates. Well, you won't cut wedges, but here's the trick: you can easily scrape material off the surface of the moist disks using the point of a sterile scalpel. Just draw the scalpel tip firmly sideways across the cardboard a few times in one place. The scrapings can then be transferred to another plate or to a jar of spawn with the scalpel.

Corrugated cardboard turns out to be too tough for easy removal of material from the surface by scraping in this fashion.

Cleaning the mycelium

As I explained in Volume I and in the section on slants above, invisible contaminants from the air can build up on the surface of mycelium that has been grown on peroxide plates. That's because the peroxide protects the medium but not the mycelium. The invisible contaminants have to be cleaned off periodically. Otherwise they will multiply in spawn or fruiting cultures. Mycelium grown on cardboard is no exception.

With agar cultures, we cleaned the mycelium with a rather awkward procedure. This called for prying the agar disk out of the bottom of the Petri plate into the lid, then inoculating the bottom of the agar, then returning the agar disk to its original place. This forced the mycelium to grow up through the medium, leaving contaminants behind. Although this works, it also increases the failure rate because it is such a tricky maneuver.

With cardboard, it is easy to inoculate the bottom of the disk: you can just flip the plate upside down. Then the disk falls into the lid and the bottom of the disk is exposed. Just transfer a sample of mycelium to the exposed surface with a flame-sterilized scalpel, close up the plate, and flip it back over. Voila! But as it turns out, the mycelium takes a surprisingly long time to grow through the disk. Instead it prefers to spread laterally. So rather than waiting for the mycelium to grow to the top, we can simply allow it to spread on the bottom of the disk. As long as it is left undisturbed, the mycelium then will grow entirely under the cover of cardboard. This way it has very little exposure to airborne contaminants. This in itself should keep the mycelium clean, especially if the cardboard disk sits nearly flat on the bottom of the plate. If you routinely inoculate your plates this way, and you take material toward the edge of the mycelial halo for your transfers, I expect you should have little problem with accumulation of invisible contaminants.

You may have trouble getting your disks to sit flat on the bottom of your Petri plates. If so, you may have better luck by creating a sandwich of cardboard with two sterile peroxide-moistened disks. Then you can inoculate the inside of the sandwich, between the disks. The mycelium will grow entirely within the sandwich, keeping it free of airborne contamination. The dry quality of the cardboard surface on both sides of the mycelium, in addition, should discourage the spread of bacteria and yeast. So the mycelium should clean itself as it spreads laterally within the sandwich.

When you want to get at the protected mycelium inside the sandwich, you pry apart the pieces of cardboard. But you cannot see how far the mycelium has grown without opening it. So you will have to be careful about dating your cultures. Then you can be sure you have allowed enough time for the mycelium to grow out before you open the sandwich.

Storage cultures without agar

For long term storage of mycelium, I like to use paper fiber pellets loaded into screw cap test tubes. Here's what I do:

1. Put about 1 oz (28 gms) of paper fiber pellets or sawdust into a small bowl or can.
2. Add roughly 25 mls (2 Tbs) boiling water to the pellets.
3. Break up the pellets into small bits with a fork or something similar.
4. Load the substrate into screw cap test tubes, filling perhaps half way. To load, I put some material on a teaspoon, and hold this at the mouth of the tube. Then I use a finger to press some of the particles through the opening. It is a messy process.
5. Place caps on tubes and pressure sterilize for 10 minutes. Cool.
6. Inoculate each tube with a bit of agar culture. Roll the mouth of the tube in a flame on opening and closing.
7. Store the inoculated tubes in a cool spot (or at room temperature for warm-growing species).

The mycelium will slowly colonize the substrate. Then, when you need a fresh tissue sample, bring out a tube. You can break loose a few bits of the colonized substrate by means of an inoculating loop or scalpel. Then tap them out onto new medium. Finally, you can put the tube back into storage to use another time.

I have had only a limited time to determine how well these cultures hold up in long-term storage. But I suspect they will do better than agar cultures. Paper fiber and cardboard more closely resemble natural substrate for mushroom mycelium than agar does. And if you don't add any nutrient solution, the paper fiber will be low in nutrients. This is usually recommended for storage cultures. It encourages something close to a dormant state. It also prevents an accumulation of toxic waste products that the mycelium would produce in a richer medium in long term storage. At the same time, some species, such as oysters, do not do well in wet storage (that is, distilled water or slants). These species may find the paper fiber or sawdust medium more to their liking, since it has a drier character. In addition, paper fiber cultures of cold-tolerant strains, such as those of oyster mushrooms, can easily be frozen.

Sending cultures in the mail

Cardboard sandwich cultures can easily be stored in plastic zipper seal baggies, and they can be sent out in the mail this way as well. Make a sandwich of mycelium between two thin disks of gray cereal-box cardboard that have been sterilized and moistened with peroxide solution. (The colored side of the cardboard faces out. This helps hold moisture in and keep potential contaminants sealed out.) Then, with a tweezers, pop this sandwich into the smallest zipper seal bag you can find. Zip it closed, and let the mycelium grow out for a few days. (Caution: the sandwiches can dry out quickly. To prevent this, put them into a larger container with some water. For instance, add a small amount of water to a plastic yogurt tub. Place the zipper-seal bags in the container with the seal well out of the water. Close the lid and incubate. Change the water if it goes bad.) Instead of a zipper bag, you can also use an ordinary plastic food storage bag. Cut off a corner section of the bag, fold it over neatly, and tape it closed. Finally, send your culture off in the mail. The recipient at the other end will just need to transfer the mycelium to a fresh plate. To do so, he or she will need to remove the sandwich to a sterile Petri plate or jar. Then they'll pry the sandwich open with a tweezers to get at the mycelium, which has been kept clean and protected inside.

This method of mailing cultures in ordinary envelopes is probably limited to species whose mycelium can tolerate the low temperatures reached in the cargo hold of a jet plane. Warm-growing species such as the almond mushroom (*Agaricus subrufescens*) may need to be packed in insulated containers to keep them from freezing.

Re-sterilizing Disposable Petri dishes with peroxide

Here's a way to re-use those disposable plastic petri dishes. Of course, you can sterilize other containers this way, too.

Wash out each dish, taking care to remove the old agar. Rinse.
Pour in a little fresh 3% peroxide and slosh it around in each dish.
Place the dishes in the microwave and heat until the peroxide has all been driven off. The exact power setting should not matter much.

Now the petri dishes are sterile and can be used for pouring medium.

One correspondent pointed out that microwaving alone should sterilize these petri dishes, without the peroxide. I pointed out in return that peroxide alone should sterilize them as well (and this could come in handy if you don't have a microwave oven). The two treatments combined provide an extra margin of security.

Spawn Preparation

Spawn in plastic bags - "Eight Minute Spawn"

In Growing Mushrooms the Easy Way, I presented a procedure for preparing pellet-fuel based spawn quickly and easily using glass jars as containers. This is still my own preferred method for making spawn. But I have worked out variations on this method so that it can be adapted to additional situations.

For instance, perhaps you don't have a collection of jars, but you can easily get fresh clear plastic bags ("food storage bags"). You can use these bags as spawn containers - in fact, they offer certain advantages over jars. For one thing, you don't need to add paper fiber pellets to the spawn recipe when using bags. This simplifies the formulation process, saves money, and gives you a more finely divided spawn at the same time. (The pellets were there to make it possible to break up the spawn by agitating the jars. With plastic bags, you can break up the spawn by manipulating the bags). For another thing, air exchange into the plastic bags seems to be greater than that into jars. Oxygen can enter directly through the plastic but not through glass. This speeds up growth of spawn somewhat in the plastic bags. And, the spawn bags heat and cool more quickly than jars, so the steaming process can be completed even more quickly than before. The bags also save the trouble of preparing cardboard disks to fit in the jar lids, and of cleaning the jars. And finally, the bags allow you to smell the spawn without opening it. The fragrance escapes through the plastic. This allows you a way to check for purity of the spawn other than just by looking at it. Bacterial and mold contamination will introduce a sour or moldy smell, and each mushroom species has a characteristic fragrance.

On the other side of the equation, the bags create non-biodegradable waste (although they can be washed and re-used). The bags also can get pin-holes in them which you can't see. And, they are not especially convenient when you want to remove just a small portion of the spawn at a time (with jars, you can remove the lid, shake out some spawn into a waiting container, then replace the lid). For the latter reason, I still make my spawn masters (which I use for inoculating additional spawn) in jars.

Making the spawn

Here's a recipe for preparing six small bags of Eight Minute spawn, each just the right size to inoculate a 5-gallon bucket of pellet fuel or roughly 6-9 pounds dry weight of substrate.

- 22 oz (624 gms.) pellet fuel (or other peroxide-compatible material)
- 3-4 Tbs. (45-60 mls) peroxide-compatible nitrogen supplement (see Volume I for options)
- 0.4 oz (11.4 gms.) powdered limestone or oyster shell lime
- 0.2 oz (5.7 gms.) gypsum (calcium sulfate)
- 990 mls. hot tap water
- 110 mls. 3% hydrogen peroxide

1. Measure the pellet fuel into a bucket or pot. Add the liquid ingredients and allow the water to get absorbed.
2. Add the remaining dry ingredients and mix them in thoroughly with a spoon or spatula. Keep mixing until the pellets have broken down into sawdust.
3. Measure 9-10 oz (255-283 gms., or roughly 2.75 cups) of the resulting substrate into six clear food storage bags. Twist the bags loosely closed.
4. Heat about 3 inches of water to a rolling boil in a large pot or canning cauldron. Put some sort of rack or heat diffuser at the bottom. Place all of the bags at once into the boiling water. Lower them in by holding the necks of the bags together.
5. Cover the pot and boil for 8 minutes.
6. Immediately remove all of the bags and float them on cold water in a wide pan. Take care not to let the mouths of the bags get into the water.
7. When the bags have cooled substantially, remove them from the water. Tie off the mouths of the bags about an inch or so from the tops with twist ties.
8. When the bags have cooled completely, they are ready to inoculate.

Using the spawn

To use your bag spawn, break up the mycelium the day before you will inoculate. You can do this by manipulating the bag to turn the clumps of mycelium into lumps, and the lumps into smaller particles. Take care not to puncture the bag with your fingernails, or with the twist tie. The next day, you are ready to pour out the spawn from these bags. Be aware that the mouths of the bags are not sterile above the twist ties. So you shouldn't use them like pour spouts. Instead,

1. pull open the mouth of the bag by grasping from the outside surfaces
2. fold the mouth of the bag back on itself, and
3. push the spawn out while turning the bag inside out.

"Ten Minute" Grain Spawn

Here's one way to prepare grain spawn without a pressure cooker: use "instant brown rice," which lacks peroxide-decomposing enzymes. Just add water, gypsum, and peroxide to the rice, and steam it in a jar or plastic bag. Then cool, and you're ready to inoculate. The idea for this procedure comes to you courtesy of René Rikkelman.

1. Get together a set of jars with lids - or use fresh plastic (twist tie) food storage bags.
2. For the jars, trace the circle of the lids onto cereal box cardboard (or similar thin cardboard). Cut out disks somewhat smaller than the traced circle. Fit a disk like this inside each jar lid. Later, you will wet these disks with hydrogen peroxide, so they will serve as a barrier to contamination. If you have two-piece lids, the disks will also help hold the lids together when you open them.
3. Get some "instant brown rice" from the grocery store. Krafts or Uncle Bens are well-known American brands. There's not much rice in each box. Regular rice will NOT work because of the enzymes. Instant WHITE rice does not have enough nutrition in it to support some mushroom species.
4. Put your rice into a large bowl or yogurt tub. Add powdered gypsum, about a gram for every 200 mls (about a cup) of rice.
5. In a container such as a pitcher, measure out one volume of hot tap water for every two volumes of rice you are using. Add enough peroxide solution to make a final concentration of about 0.30 to 0.35 percent (about 0.1 volumes of 3% peroxide).
6. Add the liquid to the rice in the bowl. Mix the rice with a spoon to get it wet with the solution. Most of the liquid will eventually soak into the rice. Just stir it now and then to keep it evenly distributed.
7. When the rice has absorbed all or most of the water, divide it up between the jars or bags. Fill the jars about 2/3 full. Screw the lids with their cardboard disks LOOSELY onto the jars.
8. For bags, skip to 12) below. For jars, add about an inch of water to a large lidded pot. The pot will need a rack or something to keep the jars from sitting directly on the bottom. Place the jars in the pot with their lids loosely in place. Put the pot's lid in place.
9. Bring the water in the pot to a boil. When it has reached a consistent rolling boil, let the pot continue to boil for just 10 minutes. Then immediately remove the jars from the pot to a heat resistant surface like a cutting board. (CAUTION: Steam from the pot can burn you, and the jars are also hot. Thick rubber gloves are a good way to remove and handle the jars at this stage.)
10. Allow the jars to cool thoroughly.
11. Open each peroxide-treated jar lid briefly. Pour a little 3% peroxide onto the cardboard disk inside the lid. Wet the disk completely. Shake off any excess peroxide into the sink.
12. For plastic bags, add about three inches of water to the pot, and bring it to a boil. Place your bags of rice into the pot so that they float on the boiling water (do this wearing thick rubber gloves to avoid burns). Loosely twist the necks of the bags around each other. Make sure they don't droop into the water. Replace the lid on the pot and boil for just 8 minutes.
13. Remove the bags to a wide pan of cold water for rapid cooling. Seal with twist ties when cool.

Inoculating straw without spawn

Here's a trick for growing oyster mushrooms on straw when you don't want to make spawn. Or maybe you just want to try something different: inoculate your straw with chopped up mushrooms. I have only seen this work with oyster mushrooms. And it works best when the mushrooms you use are very young. They should not yet be fully formed, just one or two inches high. At this stage, the mushroom tissue is growing rapidly. If the young mushrooms are cut and tossed into some prepared straw, they will throw out mycelium in just a couple of days. Here's what you do:

1. Prepare a batch of straw by the room temperature peroxide soak method presented later in this volume.
2. Pick a young cluster of oyster mushrooms.
3. Dip the cluster briefly in warm soapy water to clean it, then shake off the liquid.
4. Place the cluster on a fresh piece of wax paper or some other clean surface.
5. Using a clean knife, chop up the mushrooms into bits (exact size doesn't matter). Hold the cluster by the base. Try not to touch the mushrooms themselves with your bare hands.
6. Sprinkle the mushroom bits into your prepared straw. Manipulate the straw with disposable gloves as needed to distribute and mix in the bits.
7. Incubate the straw as you would an ordinary culture.

Notes keyed to the steps:
2) I don't have a precise formula for the amount of mushroom tissue to use. This will depend on how finely you chop the tissue. But you can start with about 15% of the substrate dry weight as mushroom pieces.
3) This sudsy bath prevents transfer of mites and other insects at inoculation. It probably also reduces bacteria and mold contamination.
5)-6) It is also possible to use a food processor to finely chop your fruiting bodies, and this is probably a good idea if there is any chance your fruiting bodies contain fungus gnat larvae. Just clean the cup and blade of the food processor thoroughly with hot sudsy water before use. I don't especially recommend creating a slurry of mushroom tissue - the extra water in the slurry will have to be drained out of your straw after inoculation.

Will repetition of this method lead to senescence (age-related deterioration) of the mushroom culture? I favor the idea that most of what is called senescence by mushroom growers is really caused by poor cultivation practices. It is clear that mushroom cultures can be transferred for years on quality medium. It should just be kept lean to prevent accumulation of toxic metabolites. It also should be cooked only lightly to prevent carmelization of sugars.

Although I can't rule it out, I think senescence is not likely to be a problem for several years at least. Some of the largest organisms on earth are single fungi covering vast tracts of land; these organisms must have taken many years to reach their current size. So it is quite possible that even if fungi do age, their lifespan is similar to the human lifespan, if not longer.

Preparation of Bulk Substrate

Bulk Substrate I: Preparing straw with peroxide - at room temperature

Next we come to a method for using peroxide to prepare straw for use as mushroom substrate. This method should be attractive to both the home grower and the commercial cultivator. The procedure can be carried out entirely at room temperature, with no heating and cooling step, and no caustic solution required. This makes substrate preparation very easy and convenient. There's no need for set-ups to heat large amounts of water or substrate. There are also no problems with over-pasteurization, and no concerns about the speed of cooling. And there is no problematic waste produced by the substrate preparation process. There is just the natural "tea" that is normally produced by soaking straw in water.

The procedure was designed for straw, but it should be possible to prepare other "drainable" substrates this way, too. These would include things like bagasse, dried grasses, and dried corn leaves. Materials of this kind are readily available in most parts of the world. I have also been told that cottonseed hulls can be prepared this way. So other non-porous nut hulls may work as well. (Wood chips are best prepared by a slightly different procedure - see below).

I have tested the protocol both with the elm oyster (*Hypsizygus ulmarius*) and with the almond mushroom (*Agaricus subrufescens*). Similar species such as traditional oyster mushrooms (Pleurotus species), Portobellos, white button mushrooms, and Royal Sun Agaricus (*Agaricus blazei*) should grow well on straw prepared this way. More of a question mark is shiitake. It is typically grown on straw with a nitrogen supplement, and I haven't used a supplement to grow the elm oyster and the almond mushroom.

What about the enzymes?

Here I have to admit that I previously argued that peroxide pasteurization of straw would not work. I reasoned that straw contains high levels of peroxide-decomposing enzymes in it (as do other similar substrates). These enzymes should destroy the peroxide in short order. They should also protect the numerous mold spores in the straw from the peroxide. But It turns out that straw nevertheless CAN be pasteurized with hydrogen peroxide. Yes, the enzymes in the straw do indeed destroy the peroxide in a relatively short time. But the peroxide can still have a beneficial effect even in the brief time it survives contact with the straw. We just have to raise the peroxide concentration (compared to what I previously employed for pellet fuel preparation). And we have to tweak the chemistry of the peroxide solution slightly. The peroxide itself does not linger to protect the straw from contamination, as it does in enzyme-free pellet fuel substrate. But the peroxide-treated straw seems to resist contamination, even after the peroxide is gone. And it seems to change into a more favorable substrate for the growth of mushroom mycelium.

The protocol

Despite this complicated preface, the protocol for preparing straw with peroxide is extremely simple. It goes like this:

1. Place your straw in a large soak vessel.
2. Fill the vessel with the appropriate cold solution (see below) to immerse the straw.
3. For chopped straw, soak about 4 hours at room temperature. For unchopped straw, soak for at least 28 hrs, or until the leachate takes on the color of a good tea.
4. Drain the straw thoroughly, until it is no longer drippy.
5. Remove the straw to your culture containers, mixing in spawn as you go.

Notes on straw preparation (keyed to the step numbers):

1. If the soak vessel has a heavy or tight fitting lid, this can help keep the straw submerged in the solution.

2. The most effective solution I have found so far uses hydrogen peroxide at a concentration of at least 0.15%. This is combined with 10 mls. of vinegar per liter of soaking solution, or about 2.5 tablespoons vinegar per gallon. Higher concentrations of vinegar did not work in mini-trials.

   Curiously enough, an alternative which has proved almost equally effective in mini-trials is peroxide with hydrated lime (calcium hydroxide, Masons' lime). But here you will use far less hydrated lime than you would if you were pasteurizing with hydrated lime alone. The latter approach uses so much hydrated lime that it creates disposal problems when you drain the straw. But you will now add just enough hydrated lime to raise the pH a bit while the peroxide reacts with the straw. You'll use just 1/2-2/3 tsp. hydrated lime per gallon of 0.15% peroxide solution, or 0.4 - 0.5 gms. per liter of solution. Higher concentrations of hydrated lime did not work in mini-trials.

   I recommend the hydrated lime alternative especially for materials that are naturally acidic. For instance, cottonseed hulls can be prepared this way, but not with the vinegar alternative (Michael Joy, personal communication).

Some commercially-available hydrated lime is made from dolomite. This has magnesium in it, which is not recommended for mushrooms. So avoid dolomitic lime if possible. The straw soak procedure, however, will still work with dolomitic hydrated lime.

Here's how to calculate how much stock peroxide solution you'll want. Your soaking solution needs to reach a concentration of 0.15%. So first divide 0.15% by the concentration of your stock peroxide solution. Then multiply the answer by the volume of water you will be using. For example, let's say you want to make 100 liters of 0.15% peroxide, and your stock solution is 6% peroxide. Then 0.15 divided by 6 gives you 0.025. Multiplying this by 100 liters gives you 2.5 liters. That's the amount of 6% peroxide you will need to add to 100 liters of water to get a 0.15% solution. (To be more precise, you would actually add 2.5 liters to 97.5 liters of water. That gives you a total volume of 100 liters. But either way will get you close enough.)

The solutions can be prepared with cold water from the tap. But the best bet is to use water that is not far below room temperature.

3. I recommend chopping the straw for best results. Chopping the straw promotes more efficient absorption of water. The smaller particle size also encourages faster mycelial growth upon inoculation.

   The wetting of the straw will proceed more quickly in warmer climates, more slowly in colder ones. Adjust your soak times accordingly.

4. How long you have to drain the straw depends on how much straw you are working with. But a couple of hours will probably be the minimum.

5. Straw can be mixed with spawn and loaded into plastic columns, for instance. Pasteurized gypsum, if added, can be mixed in at this stage as well.

I don't recommend adding nitrogen supplements, as most of the standard ones such as bran will invite contaminants. But if you must have a supplement, I would suggest using drainable materials resembling straw. One such material is alfalfa, which can be soaked in peroxide solution with the straw.

Table of Contents

Bulk Substrate II

Preparing raw wood chips with peroxide

Some mushroom species traditionally have been grown outdoors in beds of woodchips. The chips are usually prepared simply by watering over several days until they are moist. Growers have noted, however, that weed species often appear. Also, the inoculated species may end up fruiting away from the bed. So there is a need for a cleaner way to prepare the chips.

I find that raw wood chips can be prepared with peroxide, despite their content of peroxide-decomposing enzymes. But the procedure that works for straw results in wood chips that are rather slowly colonized. For better results, I recommend a different method:

1. Soak the chips in water overnight to get them wet.
2. Drain.
3. Coat the chips with peroxide at a 1% concentration or higher.
4. Inoculate with sawdust spawn.

The chips can be coated with peroxide by applying a fine mist spray while mixing. Although the peroxide concentration is high, relatively little peroxide gets used up this way.

The chips can be inoculated immediately if your spawn was peroxide-grown. Otherwise, you may want to allow some time for the peroxide to "cool" as it reacts with the enzymes in the chips.

The chips can also be given a nitrogen supplement such as Sylvan's CG60 provided the supplement is given the same treatment as the chips. I have not yet tested other supplements.

This procedure works well for the elm oyster mushroom. It should also work for King Stropharia (*Stropharia rugosa-annulata*), which backyard growers have often attempted to grow on chips prepared with plain water. But remember that after colonization of the chips, Stropharia needs a casing soil layer applied on top of the chips for fruiting to occur.

Bulk Substrate III

An "add-and-stir" method for peroxide-compatible substrates

This next procedure allows you to prepare wood-based mushroom substrate at room temperature, virtually in a single step. Unlike the previous methods for straw and wood chips, this procedure DOES require that you use a starting material essentially devoid of peroxide-decomposing enzymes. The added peroxide will remain in the substrate and protect against airborne contaminants. So there should be no need for air filtration or sterile facilities. The resulting substrate should allow contaminant-free growth of any wood decomposing mushroom species. Of course, you will still need to make an appropriate choice of additives, wood type, and growing conditions.

In the first volume of Growing Mushrooms the Easy Way, I presented one procedure for preparing wood pellet fuel. That procedure required adding boiling water to the pellets as the first step. This served both to pasteurize the pellets and to break them down into sawdust rapidly. The peroxide solution came into play only after the pellets had cooled. Then it served to kill heat resistant spores in the substrate and to protect the substrate from airborne contaminants. This procedure is easy enough for the home cultivator. But its requirement for two steps of liquid addition, as well as heating and cooling, makes it rather awkward to scale up for commercial cultivation. Also, the boiling water pasteurization doesn't work well with kiln-dried sawdust.

The new procedure avoids the awkwardness of the previous procedure by using ten times as much peroxide. At this level, the peroxide solution itself pasteurizes the substrate, and it does so at room temperature. That means there's no need for heating and cooling. It also means you can add the peroxide with all of the water in one step of liquid addition. What's more, you can add all your other additives right along with the peroxide solution: lime, gypsum, and peroxide-compatible nitrogen supplements. That gives you what is essentially an "add and stir" method of making ready-to-use mushroom substrate. It is not quite as easy as making pancakes from a mix - you'll need to wait for the peroxide to pasteurize the substrate. But it is undoubtedly one of the simplest methods of preparing sawdust substrate yet devised.

As a base substrate, you can use any peroxide-compatible wood product. You can use wood pellet fuel, composite logs, sawdust-based cat litter, and paper fiber pellets. I've even succeeded in using pelleted straw prepared this way for growing elm oysters, despite the presence of a low level of peroxide-decomposing enzymes in the straw. Just be sure the material you choose is otherwise conducive to the growth of the mushroom species you want to cultivate.

A few words on kiln-dried sawdust

In my area of the Pacific Northwest, this is the most commonly available kind of hardwood sawdust. It is the kind of sawdust that comes from the milling of kiln dried lumber. You will find it at mills and shops producing value-added wood products like flooring, panels, furniture, and the like. By contrast, raw sawdust comes from the milling of logs. Kiln-dried sawdust is usually cheaper than wood pellet fuel. Kiln-dried sawdust has very small amounts of peroxide-decomposing enzymes. There are so little that the enzymes are hard to detect, but enough so that the peroxide will be gone in a couple of days. This level of enzyme activity makes the sawdust workable for growing oyster mushrooms by the "add-and-stir" method. Oyster mushrooms are fast growing and relatively resistant to contaminants. But other species such as shiitake and Lions' Mane, which either grow more slowly or are more sensitive to contamination, are much less likely to succeed on kiln- dried substrate.

How can you tell if a sample of sawdust is actually kiln-dried? Drop some into a small quantity of 3% peroxide solution, and add a drop of detergent. If there is no more than a fine thin fizz produced after about ten minutes, your sample is kiln-dried, and it should work as a starting material for growing oyster mushrooms by the "add-and-stir" protocol.

The kiln-dried material can be too fluffy to pasteurize with a limited amount of boiling water, as is done in my earlier pellet fuel procedure in Volume I. But it is reasonably easy to coat the sawdust evenly with peroxide solution to pasteurize, as is done in the new "add-and-stir" procedure below.

The "add-and-stir" protocol

Here's the new protocol applied to preparing pellet fuel at room temperature. Kiln-dried sawdust can be prepared essentially the same way, but it will absorb more water, and take up more space in your container:

1. Clean and rinse a container (a boiling water rinse is not required).
2. Measure out your lime, peroxide-compatible nitrogen supplement, and gypsum if used. Have them at the ready (see Volume I for determining appropriate amounts).
3. Measure your pellet fuel into the container.
4. Measure into a separate container about 6.5 quarts (6.2 liters) of water for every 10 lbs. pellet fuel (but see the note below). The water needs to be at least "room temperature" (68 degrees F) or slightly warm to the touch. This helps the breakdown of pellets made from dense woods like oak. As in previous protocols, the water also needs to be free of visible particulates.
5. To the water, add peroxide to reach a concentration of about 0.45%.
6. Some types of pellet fuel, such as that made from oak, do not break down easily in water. For these, add a teaspoon (5mls.) of baking soda to every 6.5 quarts (6.2 liters) of peroxide solution as well.
7. After stirring the baking soda into the peroxide solution, pour the solution into the pellet fuel. Then add the other dry ingredients. Do it in this order so that the other dry ingredients don't get stuck on the bottom of the container.
8. Close the lid and let the pellets absorb most of the water (this may take 10-15 minutes).
9. Mix the substrate thoroughly by rolling the container.
10. Let the substrate sit in the closed container for at least 2 hours.
11. Mix the substrate thoroughly again. By this time, the substrate should be at least half in the form of sawdust and half as the round remnants of pellets.
12. Inoculate the substrate and divide into bags.

Notes on the "add-and-stir" protocol

As always, it is best to use woods favored by the mushroom species you want to grow. In general, avoid resinous woods like cedar and pine.

In Volume I, I suggested several processed enzyme-free materials as nitrogen supplements. In general, these are either expensive or difficult to find. But now I've discovered that it's possible to use some more common "natural" materials - at least for growing elm oyster mushrooms by the "Add-and-stir" method. One of the materials is steel-cut oats. They contain about 2.5% nitrogen. (Cracked wheat should also work. It contains about 2% nitrogen.) Although there are peroxide-decomposing enzymes in the oat particles, they haven't caused the cultures to spoil in mini-trials with elm oyster. Unfortunately, mini-trials with Lions Mane were not successful.

There's also a simple way to increase the effectiveness of these supplements: coat them with a small quantity of vegetable oil. Mushroom mycelium eagerly consumes the oil.

You will probably have to experiment a bit to find the right amount of water to add. This varies with the kind of material you are using as a substrate, and the kind of wood. For sawdust, you can use about an equal weight of water. For wood pellets, this may prove to be too much. You want to add enough water to break down the wood pellets to particles. But the material left at the bottom of the container (when you pour out the substrate into bags) should not be visibly wet. Pellets made from lighter woods will probably absorb more water per weight of pellets than those made from denser woods.

Some substrate materials, such as kiln dried sawdust, may resist wetting. In this situation, you can add a small amount of biodegradable dish detergent to speed up water absorption. For instance, I have used 1/4 tsp. detergent in 6.5 qts. water, or 2.5 mls per 6.2 liters.

The high peroxide concentration used in this protocol is most easily accomplished with a peroxide stock solution that is more concentrated than the usual drugstore product. I have used 1/3 cup (about 80 mls) of swimming pool peroxide for 6.5 quarts (about 6.2 liters) of water. This product was labeled 27%, but it actually tested at 34% by decomposition. You could also use food grade (35%) or similar solutions. Remember that these concentrated products are much more hazardous than the 3% solution. The liquid can cause burns, fires, or explosions, so it should be treated with considerable respect. Read the warning label and act accordingly.

How much stock peroxide solution will you need? Your final solution should reach a concentration of 0.45%. So first divide 0.45% by the concentration of your stock solution. Then multiply the answer by the volume of water you will be using. For example, let's say you want to make 20 liters of 0.45% peroxide from a stock solution that is 6% peroxide. Then 0.45 divided by 6 gives you 0.075. Multiplying by 20 liters gives you 1.5 liters. This is the amount of 6% peroxide you will need to add to 20 liters of water to get a 0.45% solution. (Actually, you would add 1.5 liters to 18.5 liters of water to get exactly a 0.45% solution. But either way will get you close enough.)

The substrate can be mixed the first time with non-pasteurized implements, if this is more convenient than rolling the container. After this first mixing, however, non-pasteurized implements should be kept out of the substrate. Only pasteurized (i.e. boiling-water rinsed) implements should be used.

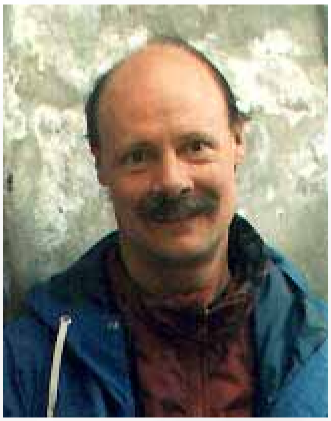
What about making spawn by the "add-and-stir" approach? I have succeeded in doing this with my elm oyster mushrooms. The fruiting cultures inoculated with it looked questionable at times, but they did complete their colonization and they did form mushrooms. To give this a try, just mix up some medium as for Eight Minute spawn above, but increase the peroxide concentration to 0.45%. If you are using jars, wet the cardboard disks inside the lids with 3% peroxide. Then let the spawn sit, closed up in its container, for at least two hours before inoculating.

Table of Contents

Conclusion of Volume II

The procedures I've spelled out in this supplement give a glimpse of the tremendous variety possible in mushroom growing techniques. At any given time, I usually have at least a few ideas for new tricks that I haven't had a chance to test. And I know from the correspondence I get that many of my readers have their own fascinating ideas as well. I hope this volume stimulates further creativity in this rapidly growing field.

About the Author



R. Rush Wayne

Rush Wayne holds a Masters degree in Biochemistry and Molecular Biology from Harvard University and a Ph.D. in Biochemistry from the University of California at Berkeley. He was first exposed to the elements of mushroom growing during his graduate work in the 1970's but did not begin growing mushrooms in earnest until he began to implement the innovations contained in this manual in 1993. Instructions for his peroxide method of growing mushrooms are now in the hands of mushroom growers in over 75 countries around the world.

Introduction to cultivating mushrooms

What is a mushroom?

Due to the lack of scientific knowledge fungi were classified as plants for a long time. Today's understanding of genetic and physiological facts show that fungi are more closely related to animals than plants. Unlike plants they neither are able to carry out photosynthesis nor can they produce the carbohydrates they need.

Mushrooms are dependent on organic carbohydrates, built up and provided by other creatures to feed themselves. In the life cycle of organic matter they operate as biodegradant destruents, who disintegrate organic material and dissolve soluble minerals.

Three distinguished groups

On reference to their different nutrient sources fungi can be distinguished into three groups:

Saprophytes decompose organic material like cow dung, wood waste or straw. These fungi are the most important recyclers within the ecological system. This group includes the majority of cultivated mushrooms. It must be mentioned that fungi - like most other live forms - grown in vitro react differently in comparison to their natural forms: With idealised mushroom substrate at hand, bounteous harvest can be reached. Mushroom substrate is a highly specific, nutrient-rich product consisting of selected organic and inorganic matter for the purpose of cultivating mushrooms.
Under natural conditions only a few mushroom heads arise out of a vast amount of mycelia. And they only appear during short periods of the year.

Mushrooms can also live as parasites. These fungi develop at the expenses of another living organism (=host). True parasites are dependent on their host, who provides shelter and nutrition, though they usually do not kill them. Worth mentioning: honey fungi (Armillaria spp.) are probably the largest living creatures on earth with individuals expanding to a surface area of several thousands of square meters, reaching up to 800 meters in depth.

Some fungi live as Symbionts in a mutual beneficial relationship. If a fungus interacts with the roots of a plant, mycorrhiza is formed and establishes a bidirectional flow of nutrients. The fungus provides inorganic nutrients to the plant since it dissolves inorganic matter a lot easier. In exchange the plant affords carbohydrate assembled in photosynthesis. Furthermore the mushroom mycelium retains a great amount of water which is disposed to mycorrhizal plants in periods of dry weather.

Table of Contents

Production of spore prints

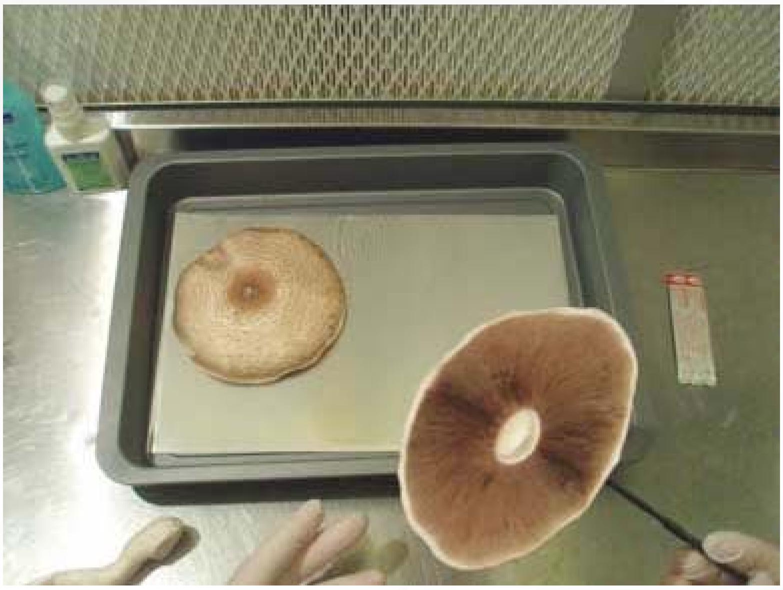
Spores are the "seeds" of mushrooms. They are microscopic and are mainly produced at the under part of the cap. After its fully-fledged they are released. To collect the spores, the fully developed caps are placed on a carrier material. The obtained spore print can be used to start a new mushroom culture. Placing spores on convenient substrate (most common are malt-agar substrates in Petri dishes) induces mycelium growth.

Recommended Tools:

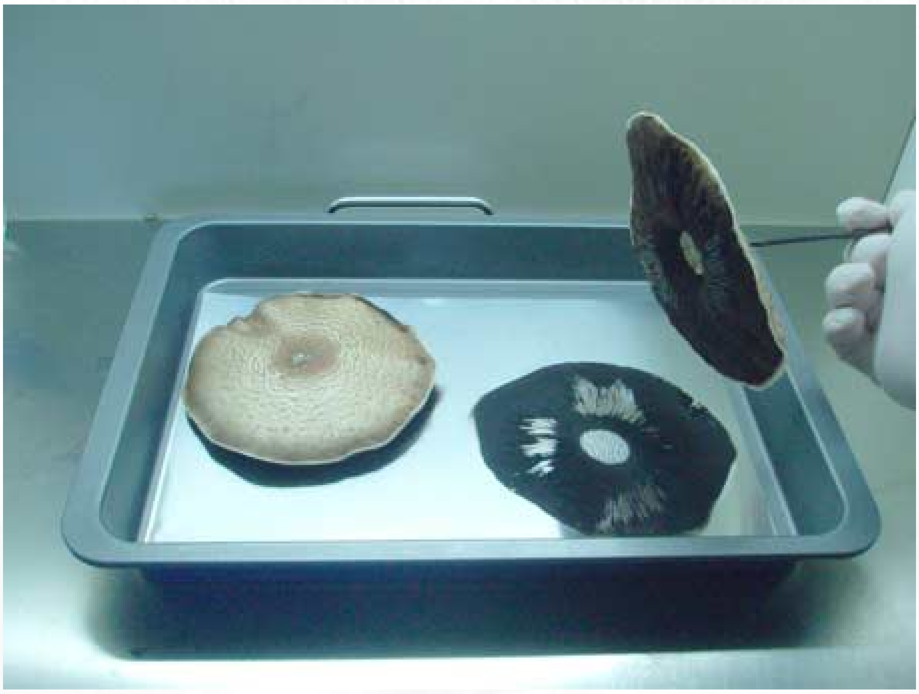
- Aluminium foil, paper (as large that you can place 1 mushroom cap on it)
- Bazillol - workspace desinfect
- Latex Gloves
- Facemask and hairnet
- Skalpell
- Cover (zb Tupperbox)
- Zipp-Lock Bags to pack the prints

Sterile working area: Glove Bag/Glove Box or sterile air flow (HEPA-filter, Laminar Flow Hood)

Proceed cautiously as sterile and clean as possible. The spores should not get in contact with contaminations while taking the print. Put on face mask, hairnet and gloves; clean the working area in front of the HEPA-filter or the Glove Box inside and disinfect the container and the aluminium foil. (The needed tools are already inside the Glove Box). Finally disinfect your gloves and allow drying off.



Cut off the designated mushroom cap carefully at the upper end of its stem; try not to damage the gills and pores. The disinfected aluminium foil collects the spores dropping out; transfer the cap with its lower surface briskly on to the foil. Cover them up in the disinfected container, for best result the caps should not dry out and stay clean while donating spores.



After 12 to 24 hours the spores should have been released, favourably they adhere to the foil by themselves. (Wear protective clothing, clean and disinfect working area and tools!) Remove the cap by impaling the upper surface on a scalpel. Do not touch the foil or spore print to avoid contamination. Besure the residual moisture is allowed to evaporate before packing the print. Sealed in an airtight zip-lock bag, spores stay viable for about one year. Store your spore prints at room temperature in a dark and clean place.

Table of Contents

Microscopic examination of spores

Recommended Tools:

- Sporeprint or
- Sporesyringe
- Microscop (40x - 1000x)
- Pipette or syringe
- Inoculation loop
- Water
- Object slide

General Procedure:

Form, colour and size of spores are almost distinctive trait for classification of mushrooms.

Take a clear object slide and put a drop of water on it. Now use the inoculation loop to stir a few spores into the water. Put the object slide under the microscope to view the spores.

An other method is to put a drop of sporesolution from a sporesyringe on the object slide. If you use a sporesyringe we recommend to shake the syringe well to disperse the spores well in the water.

It is important the microscope be firmly fixed on a flat stable surface!

Table of Contents

Preparation of Agar - Medium in Petri Dishes

The following formula makes 1 liter of "MEA" - malt extract agar medium, convenient for most species of cultivatable mushrooms. Especially for working with spores, antibacterial agar media is recommended. Ready to use formulas are offered, that only need to be mixed with water.

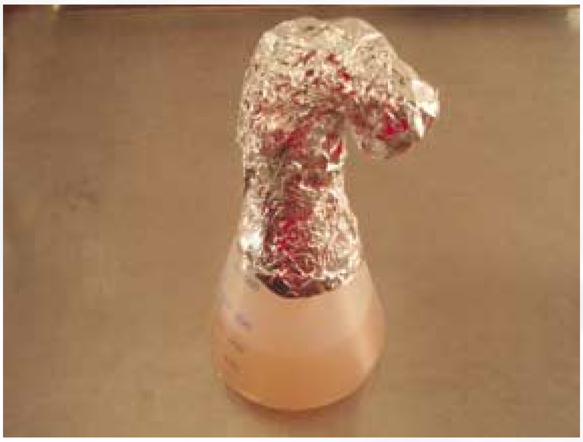
Recommended equipment:

- 20 g agar-agar
- 20 g malt extract
- 2 g dry yeast
- 1 g peptone
- 1 litre drinking water

- Erlenmeyer flask
- Sterile disposable Petri dishes or glass Petri dishes
- Measuring container
- Scale
- Parafilm
- Latex gloves
- Face mask and hairnet
- Disinfectant solutions for surfaces and hands
- Pressure cooker
- **Sterile working area: Glove Bag/Glove Box or**
- **Sterile air flow (HEPA-filter, Laminar Flow Hood)**

Mixing the substrate

Pour the ingredients into the Erlenmeyer flask along with hand-hot water, close the lid and shake well until mixed thoroughly. The maximum level of filling the flasks is reached at two-thirds of their volume. Remove the lid and wrap some aluminium around the flask's neck forming a tube which you bend down at its free end. This attached duct will ban condensate water to enter the unlocked flask during sterilisation.



Sterilisation of the agar medium

Agar medium should be sterilised for 45 minutes using a pressure cooker. Overlying a 2-3 centimetre water level at the bottom of the cooker a separating insert keeps the flasks above the water line. Assure yourself that there is no contact between water and the upright standing flasks, decant some water if necessary. (Mind the handling instructions given by manufacturers of your pressure cooker!)

Get the lid locked and put the cooker on a hotplate. Sterilise for 45 minutes, counting from the moment as the pressure gauge reaches its highest stage (for household pressure cookers). If you've got a professional pressure steriliser at your disposal sterilise at 121°C/ 259°F/ 15 psi/ 1.05 bar.

Attention: Do not exceed temperatures specified above for a longer span of time. By overheating the nutrients, the culture medium can degrade and the solutions colour darkens from yellowish to brownish. If so, the medium is useless. Substrates which are composed of other ingredients may have different colours.

After 45 minutes of sterilisation, let the cooker cool off in front of a HEPA-filter or in a clean place. During pressure equalisation air is sucked in; a clean and wet cloth over the cooker's cover filters the aspired air, if you do not use a HEPA-filter.

Pouring the Petri dishes

Wear protective clothing, disinfect working area and hands. Do not open the cooker before the pressure gauge indicates 0. Continue processing from now on because the agar medium is only in its liquid stage above a certain temperature. (If you work with glass Petri dishes, keep in mind, they have to be sterilised too.)

Pour about 25-30 ml warm agar-medium into a Petri dish with 90 mm in diameter, which gives 35-40 Petri dishes per 1 litre agar-medium. For cooling down leave them in a place of low microbiological contamination in front of a HEPA-filter or inside a Glove Box.

When the agar is hardened and cooled to room temperature, the Petri dishes are ready for inoculation. If you do not use all casted Petri dishes, you can seal up the remaining Petri dishes with Parafilm, wrap them in plastic foil or bag and keep them in a clean refrigerator for up to 4 weeks. (35.6-39.2°F / 2-4°C)

Table of Contents

Mycelium germination from spores

When growing mushrooms out of spores you obtain plenty of autonomous mycelia strands forming dikaryotic mycelium, a so called spore mass inoculation. This mycelium has sprung from various germinating spores, sprouting mushroom cultures comprise individuals, descending from different mycelia strands. (You can compare this mycelium to a fruit orchard - yielding heterogeneous fruits from different trees- not similar fruits from only one tree.) Multicultural mycelium is mainly used for selecting the fittest individuals from the new culture to continue work with them.

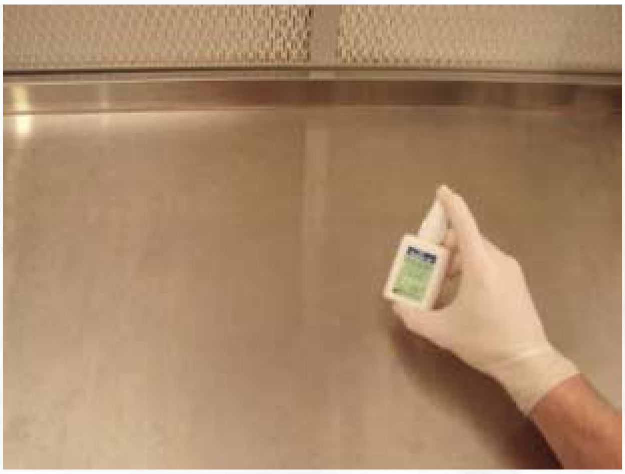
Recommended Tools:

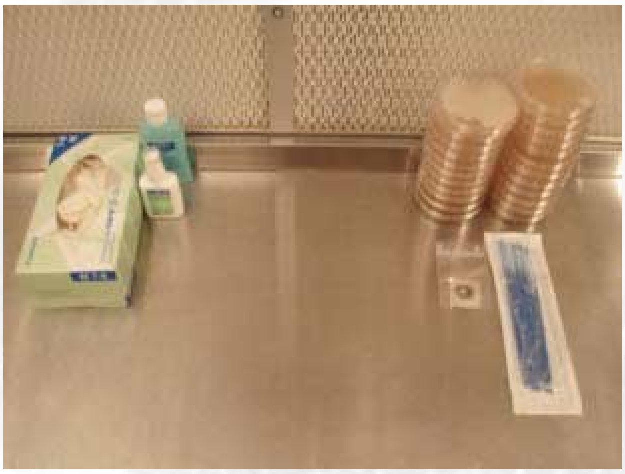
- Spores (Sporeprint or Sporesyringe)
- Agar medium in petri dishes

- Oneway Inoculation loop or Needelholder with inoculation loop
- Parafilm to seal the petris
- Spiritus Lamp (only for metal inoucluation loop)
- Facemask and Hairnet
- Latex gloves
- Workspace desinfection
- Handdesinfection
- **Glove Bag (sterile workspace)**

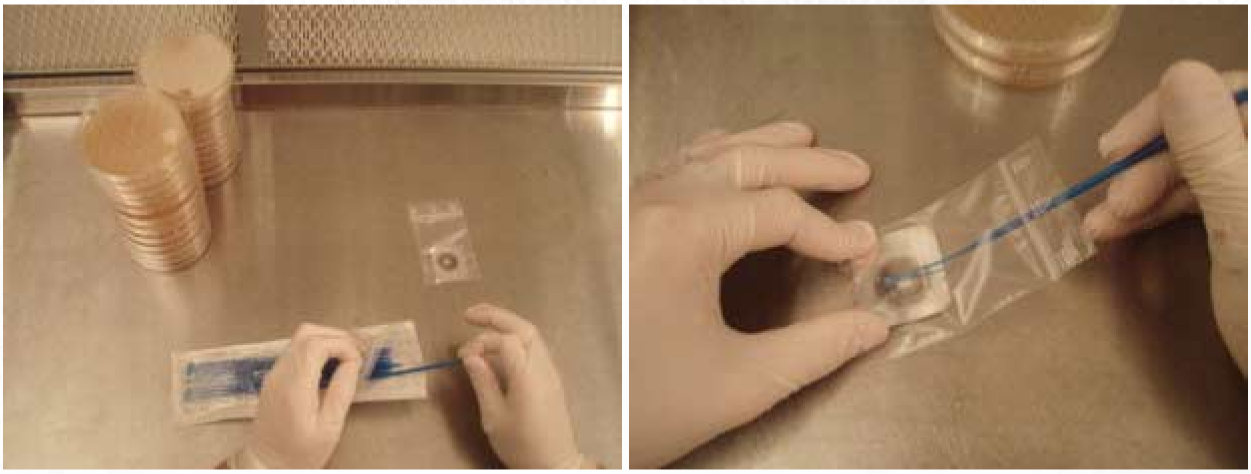
Inoculation of agar medium

To minimise the risk of contamination of agar medium by other organisms (e.g. bacteria, moulds, ...) we advise working in a Glove Box/Glove Bag or in front of a HEPA-filter. Clean the workspace, wash hands and forearms, put on a protective face mask, hairnet and gloves, then disinfect your worktop well. Disinfect hands again and allow drying before starting. Antibacterial agar has proven to be successful with spore prints gained from outdoor collected mushrooms, for those often carry bacterial contamination.



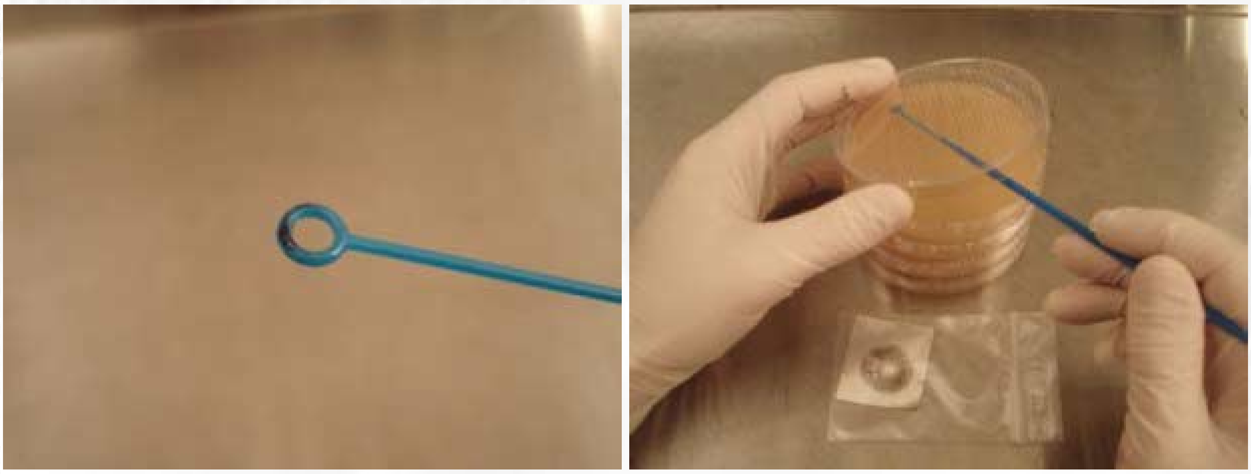


If working with a reusable inoculation loop, heat the inoculation loop red hot in the flame of a alcohol lamp and let it cool down in your hand. Do not touch the spore print, inoculation loop or agar medium. Now rub the spore print until the whole loop has gathered some spores. Open the Petri dish ajar, and import the spores to the agar drawing a "S" through the media. In case of inoculation with a spore syringe, 1-2 ml solution per Petri dish will suffice.



Do not take off the lid fully and work quickly to lessen contamination risks. Close the lid and seal it with Parafilm. It is advisable always to inoculate several Petri dishes with a spore print since they thrive and prosper varyingly.

Label the Petri dishes giving information about date, genus name, strain (strain means different type species within one genus - comparable with different kinds of apples) and consecutive number. A CD-marker, Edding-marker or permanent marker will stick to it.



Mycelium growth

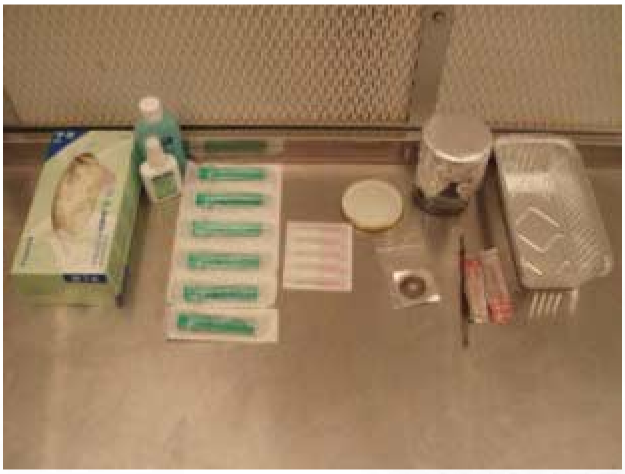
During spawn-run (development and growing of the mycelium) the sealed Petri dishes are stored in a dark and neat place. The appropriate temperature depends on the genus cultivated. Ensure that the incubator in which the mycelium is grown provides enough ventilation. After a few days up to one week the spores start germination. As soon as rhizomorph mycelium strands become visible, they are ready for selection. (Look up the instruction for "Selection of mycelium strands".)

Table of Contents

Production of spore syringes

Spore syringes contain spores dissolved in water and are being used to inoculate substrates. Hobby-mycologists tend to work with spore syringes because even if used in a not 100% sterile environment, the substrates seldom contaminates.

It's rather easy to produce small to medium amounts of substrates or grain spawn with spore syringes. If you inoculate substrates with a spore syringe, you get a "Multi-culture" (look up "Growing mycelium out of spores"), which mostly result in less crop yield, compared do usage of selected rhizomorph mycelium strains.



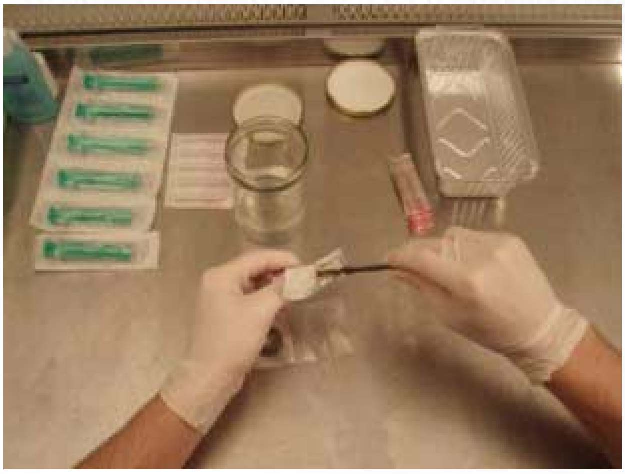
Recommended Tools:

- Spore print
- Glasses (sterilisable!!!)
- Scalpell with sterile blades
- Empty syringes and needles
- Latex Gloves
- Facemask and Hairnet
- Filter Disk
- Workspace desinfect - Bazillol
- Handdesinfect
- Water
- **Glove Bag (sterile workspace)**

We recommend using about 100 ml water and one spore print per glass. The lid of the glass needs a hole of about 1 cm in diameter; via this hole you will later fill the syringes. Fill the gasses with water (2/3 of the glass) and put the lid with the hole on during sterilisation. Wrap aluminium foil around the lid, sterilise the glasses and the lid without a hole (also wrap it in aluminium foil), for about 30 minutes.
We recommend using a pressure cooker for sterilization.

Counting the sterilisation time form the moment, the pressure gauge reaches its highest stage (for household pressure cookers). If you've got a professional pressure steriliser at your disposal sterilise at 121°C/ 250°F/ 15 psi/ 1.05 bar.

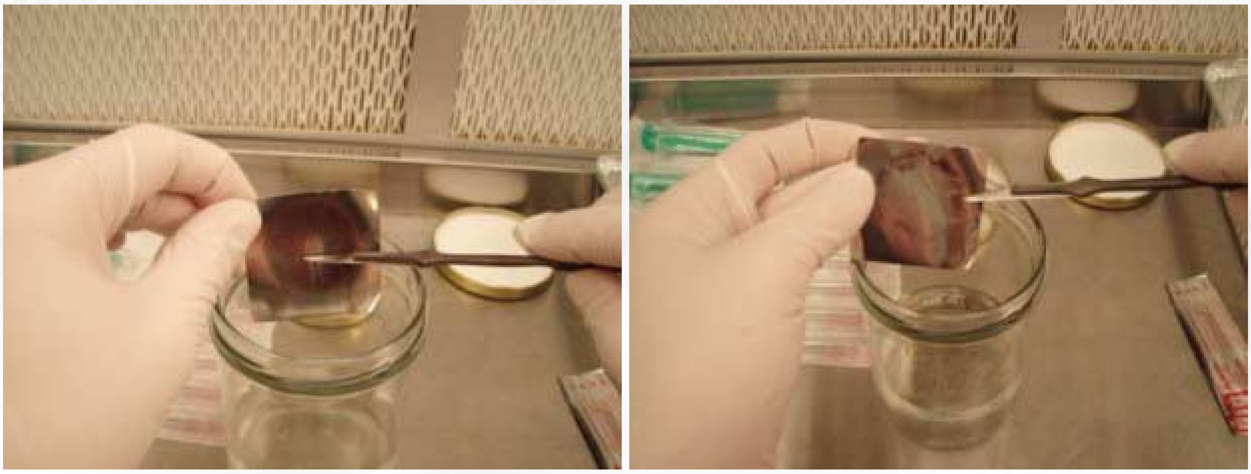
Leave the cooker to cool out in clean place or in front of HEPA-filter after sterilization. You can put a clean wet piece of cloth over the cooker during the cooling process to filter the air streaming into the cooker if working without a HEPA-filter.

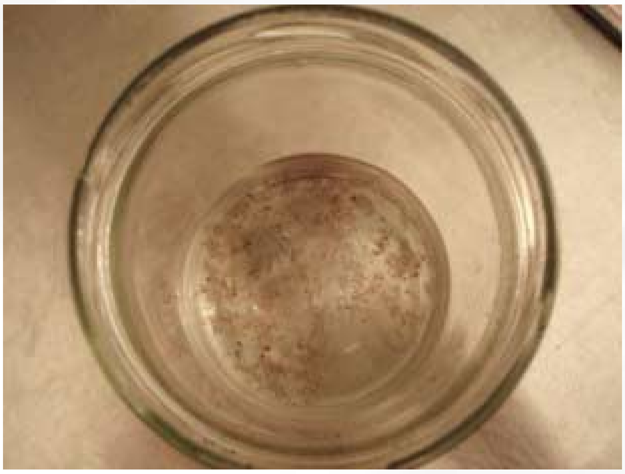


To keep contamination risk low, please work clean! Use a new, sterile skalpell blade for each spore print.

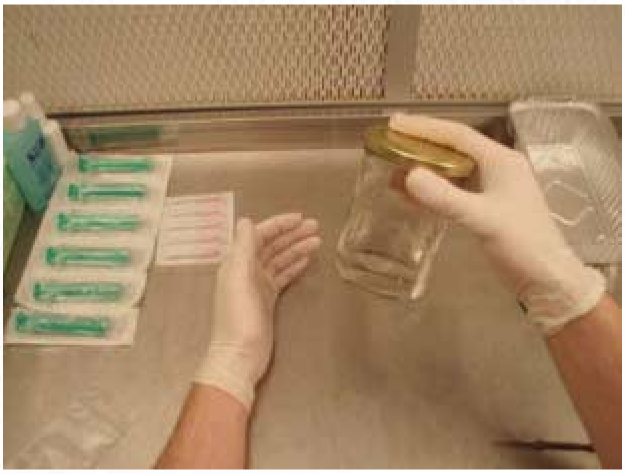
Open the lid as soon as the pressure has vanished. Wash and disinfect your hands and lower arms and use latex gloves. Store the glasses in a clean place (in front of a HEPA-filter or in a glove box). Proceed as soon as the glasses have cooled down to room temperature (less than 86°F or 30°C).

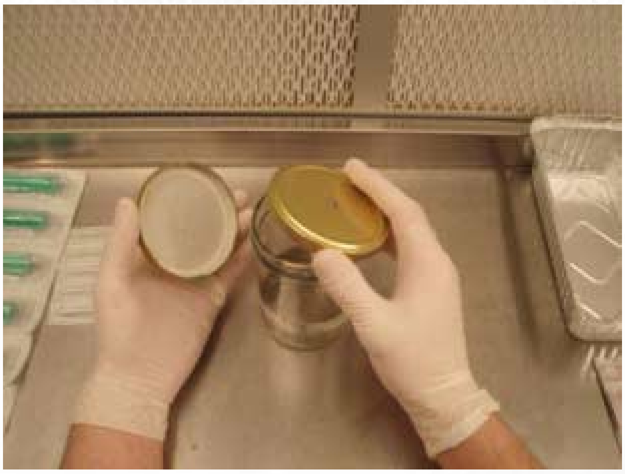
Before you start, please wash your hands, lower and upper arms with hot water and soap. Clean and disinfect your working space. Put on hairnet, face mask and latex gloves. Disinfect your gloves and wait till they're dry.

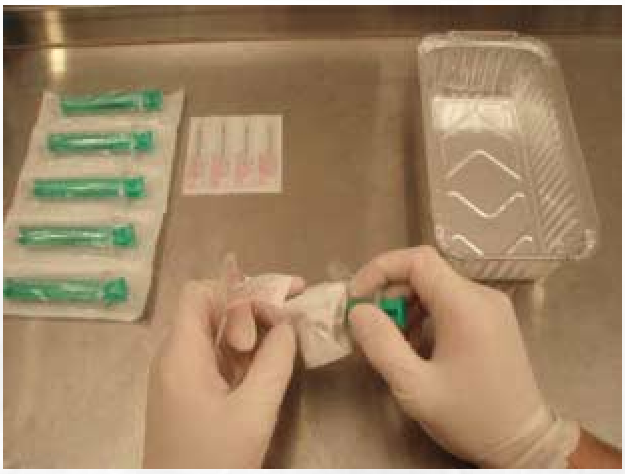


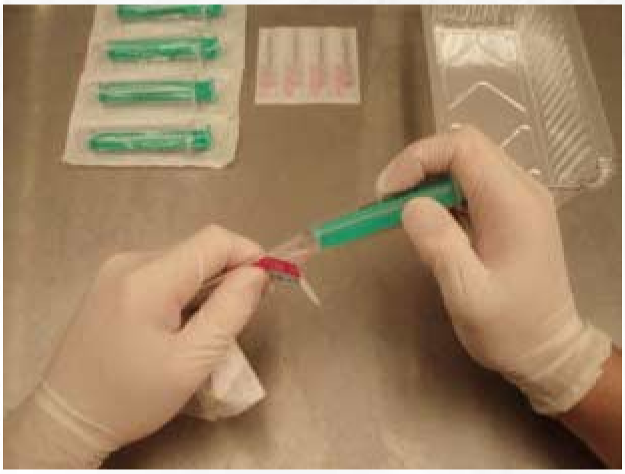


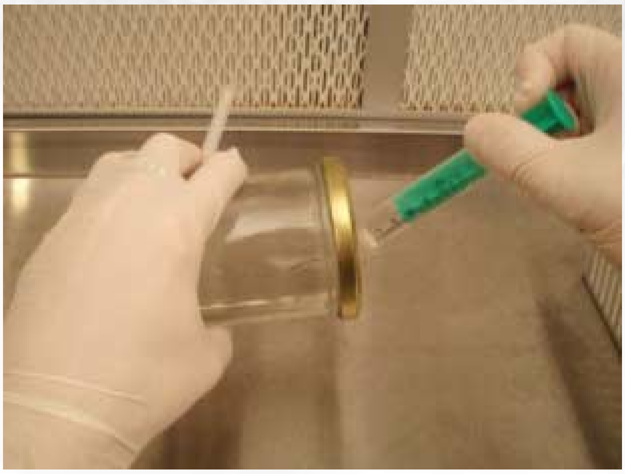
Use a scalpel to scrape the spores off the spore print into the water. Make sure not to touch the spores while holding the spore prints. After you have scraped the spores into the water, put on the lid (without hole) and shake the glass well. Change the lid to the one with the hole. Stick the syringes needle through the hole and fill the syringe. To avoid contamination, be careful not to touch the lid with the needle or needle with your hands.

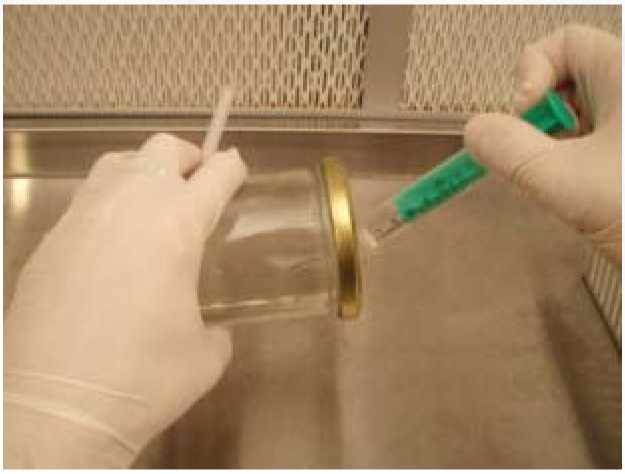












We recommend packing the syringes airtight using a zip-lock bag. Stored in a dark and cool place (max. 20°C) the spores will be viable for about one year (depending on mushroom species).

To test their ability to germinate, put a few ml (1 or 2 drops) on a Petri dish with agar medium. The mycelium will start to grow after a few days. (For detailed instructions kindly have a look on chapter: "Growing mycelium out of spores").

Table of Contents

Mushroom Cloning

Gaining new cultures out of a fresh mushroom involves asexual reproduction. A mycelium achieved through cloning is called "pure culture", it is genetically identical to the original mushroom. The successfully breeding of a mycelium out of spores on the other hand is the way of sexual reproduction the creation of a new organism with a new genetically code. When working with pure cultures, just one individual develops on the substrate, so there is no competition for nutrient elements. This will lead to a higher and well predictable yield with stable quality.

Recommended Tools:

- Hairnet and Facemask
- Latex Gloves
- Alcohol Lamp
- Scalpell with sterile blades
- Workspace desinfect
- Handdesinfect
- Petridishes with Agar-Medium
- Parafilm to seal the petris
- **Glove Bag (sterile workspace)**

Inoculating the nutrient medium with a mushroom clone

Only select the most vital and gratifying mushroom fruit bodies. If you are not able to make a clone immediately after picking, keep them neatly stored in the refrigerator for maximal 48 hours. Do not store a mushroom longer than absolutely necessary because it´s harder to gain germination of mycelium out of older fruit bodies and the risks of bacterial contamination increases.

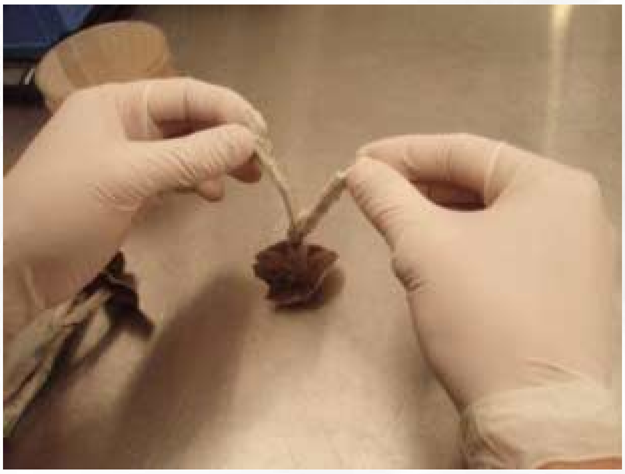
As in every laboratory working step during the life cycle of mushrooms, clean and sterile working is essential for success! Put on face mask, hairnet and gloves; clean the working area in front of the HEPA-filter or the Glove Box in-depth and disinfect working area and gloves. If you intend to clone more than one mushroom, disinfect the working space, change gloves and put on a fresh scalpel blade (or flame it until glowing red and let cool down) before carrying on with a new fruit body.

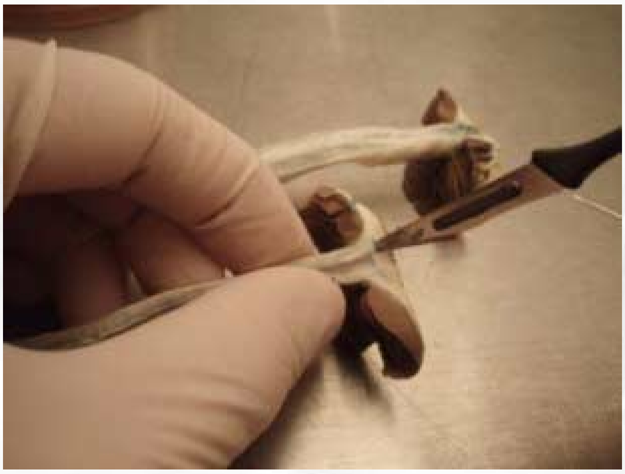
Fruiting bodies are basically composed of compacted mycelium, thus flesh intended to clone can be won from every part of the mushroom. Most suitable are interior parts of the upper stem and cap. Split the near-ground part of the stem half a centimetre deep and tear apart the mushroom without touching the inlying flesh with your fingers.

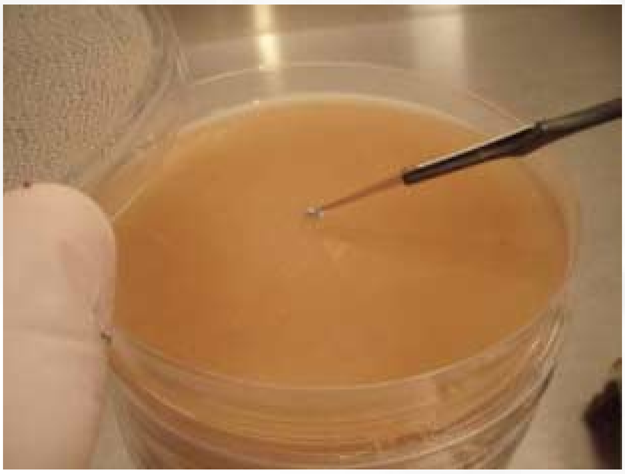
Flame-sterilise the scalpel until glowing red over the alcohol lamp, let cool off and put on a sterile blade. For tissue harvesting we recommend to graft tissue from the most internal parts of a mushroom which provides greatest cleanliness and the lowest contamination risk. A piece of fruit sized 3x3 mm will suffice. Impale the small piece of flesh on the scalpel and transfer it onto agar medium. Seal the inoculated Petri dishes with Parafilm and shelve them in a dark place to stimulate the mycelium growth. The adequate temperature depends on the genus cultivated. A few days up to one week later the mycelium starts germination.

It has proved itself to inoculate several Petri dishes with internal mushroom grafts of the individual you wish to clone since the results sometimes strongly vary. Even under best laboratory conditions you will have to face failure rates at 10%. Amateurs and freshmen should bargain for failure rates around 25% or even more. Do not get discouraged, with a little practice in cloning you will amend quickly.

Label the Petri dishes giving information about date, genus name, strain (strain means different type species within one genus - comparable with different kinds of apple) and consecutive number. A CD-marker, Edding-marker or permanent marker will stick to it.







Mycelium growth after cloning

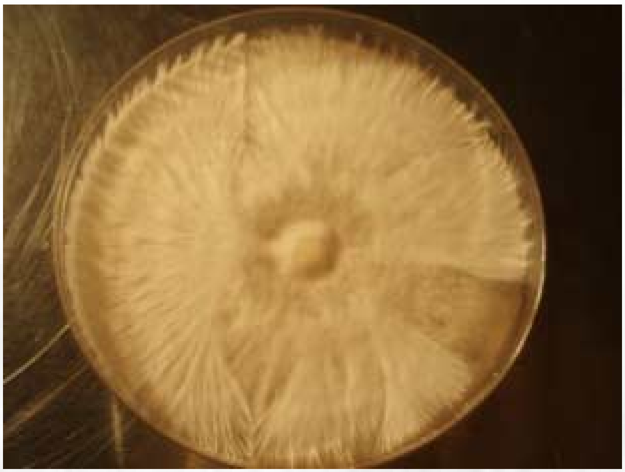
During the spawn-run (development and growing of the mycelium) the sealed Petri dishes are stored in a dark and neat place. The appropriate temperature depends on the genus being cultivated. Ensure that the incubator in which the mycelium is grown provides enough ventilation. After three to five days (depending on species) new mycelium filaments will start to grow out of the piece of flesh. As soon as rhizomorph mycelium strands become visible, they are ready for selection. (Look up the instruction for "Selection of mycelium strands".)

Table of Contents

Selection of Mycelium Strains

If you cultivate mushroom mycelium on agar medium there will appear different form of mycelium. The two main forms are: rhizomorph mycelium and fluffy mycelium (looks like cotton). For further cultivation and introduction of fruiting only the rhizomorph mycelium is suitable. The rhizomorph mycelium looks like the roots of plants. The primordia which later become fruit bodies are built from it. If you cultivate mushroom cultures on petri dishes, you have to select the fluffy mycelium from the rhizomorph. Only the rhizomoprh growing mycelium is used for further cultivation.

Rhizomorph and fluffy mycelium strains on one petri dish.
It was selceted for one time before.



Rhizomorph and fluffy mycelium strains on one petri dish.
It was selected for one time before.

Recommended Tools:

- Hairnet and Facemask
- Latex Gloves
- Alcohol Lamp
- Scalpell with sterile blades
- Workspace desinfect
- Handdesinfect
- Petridishes with Agar-Medium
- Parafilm to seal the petris
- **Glove Bag (sterile workspace)**

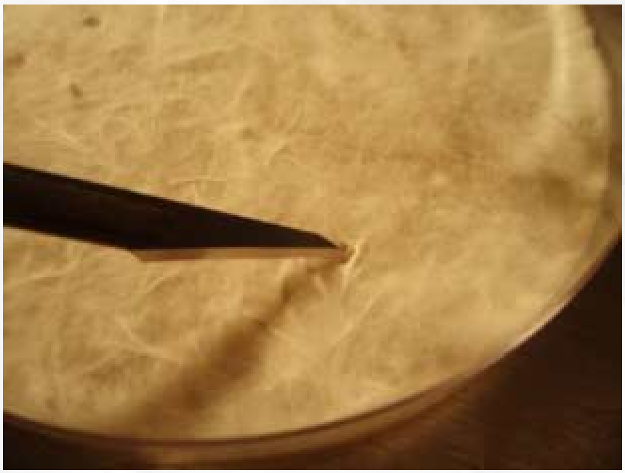
Transferring rhizomorph mycelium

As soon as an entire Petri dish is overgrown with mycelium it should be proceeded. If you wait too long the fluffy mycelium outreaches and overgrows the rhizomorph shaped form and the Petri dish becomes unusable. As in every laboratory working step during the life cycle of mushrooms, clean and sterile working is essential for success! Put on face mask, hairnet and gloves; clean the working area in front of the HEPA-filter or the Glove Box in-depth and disinfect working area and gloves.

This petri dish is ready for selection.

If you intend to clone more than one fruit body, scrap the used blade; disinfect the working space and change gloves. Flame-sterilise the anterior part of the scalpel over the alcohol lamp until it is glowing red, let cool down to room temperature and put on a fresh blade before carrying on. Do not get the mycelium in contact with hot tools!
Please be cautious about flame sterilising. Alcohol-containing disinfectants and gloves easily catch fire!

Choose a rhizomorph growing mycelium strain from the Petri dish and slice it into pieces measuring 3x3 mm. Skewer one piece with the blade and transfer it to a fresh Petri dish containing agar medium. Seal the Petri dishes with Parafilm, handle them with care for the piece of mycelium should not slip out of place!



This petri dish is selected for the first time,

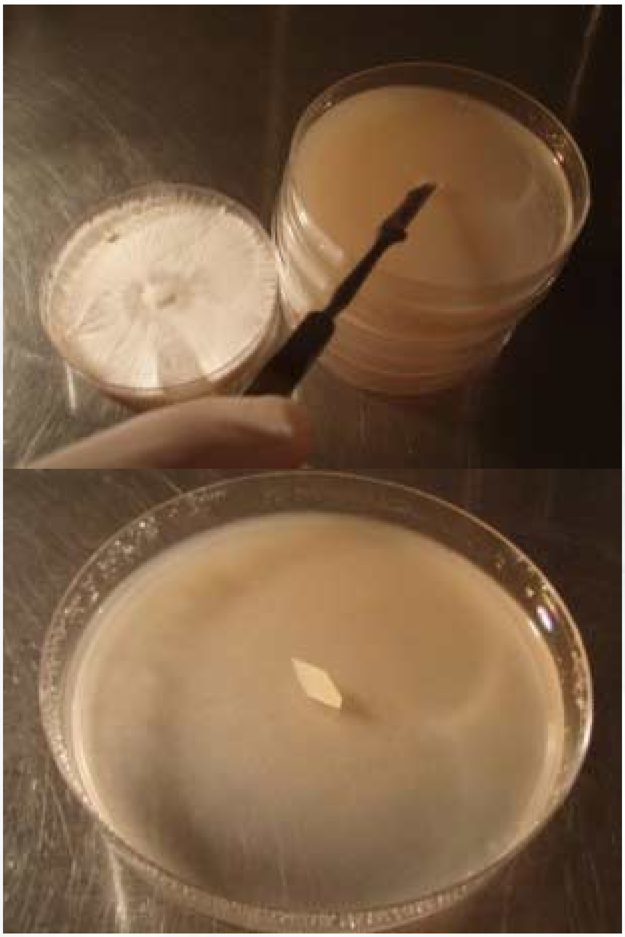
and this one is selcted for the second time.

Advice: It's easier to distinguish between rhizomorph and fluffy growing mycelium, if you hold the Petri dish in front of a lamp.

It has proved well to inoculate several Petri dishes with pieces of the same mycelium, since the results can strongly vary. Even under best laboratory conditions you will have to face failure rates of 10%. Newcomers should not lose courage if they have to cope with failure rates up to 25% or even beyond.

Usually it is necessary to select a strain several times to get Petri dishes with rhizomorph mycelium only. Moreover the selected mycelium is able to mutate, for example grow fluffy again, and become unfit for utilisation.

Label the Petri dishes giving information about date, genus name, strain (strain means different type species within one genus - comparable with different kinds of apple) and consecutive number. A CD marker, Edding marker or permanent marker will stick to it.



The mycelium pieces are placed on petri dishes filled with agar medium.

Mycelium growth after selection of strain

During the spawn-run (development and growing of the mycelium) the sealed Petri dishes are stored in a dark and neat place. The appropriate temperature depends on the genus being cultivated. Ensure that the incubator in which the mycelium is grown gives enough ventilation. After three to five days new mycelium filaments will start to grow out of the piece you transferred. As soon as you have gained a Petri dish almost completely overgrown with rhizomorph mycelium, it is ready for inoculating grain spawn.

The mycelium have to be selected as long as it grows uniformly rhizomorph.

Table of Contents

Sterilising rye substrate for grain spawn

In mushroom cultivation, cereal substrate is being used to produce grain spawn. This production stage is mainly used to multiply mycelium mass, you get from the agar plate, for inoculation of fruiting substrate.

Recommended equipment:

- Rye grain
- Vermiculite medium
- Gypsum
- Autoclave Bags Unicorn type 3 T or
- Glasses with lids with a hole (1 cm in diameter) and filter disk
- Scale
- Bag sealer or strong adhesive tape
- Sieve
- Container for mixing
- Pressure cooker

Preparing the rye substrate

Soak the rye in 167°F/ 75°C warm water, allow the water level to be 4 - 5 cm higher and leave it overnight (12 - 18 hours). Put the soaked rye grain into a sieve and let it drain for around a quarter of an hour, then put it into the mixing container. Moisturise the vermiculite using the sieve, until entirely soggy, watch out not to soak it too much. Make sure that the vermiculite is even wet, but not as wet that water drops out of the sieve. Let it drain for a moment. Now mix the gypsum equally with the rye grain, then add the vermiculite and mix it again very well.

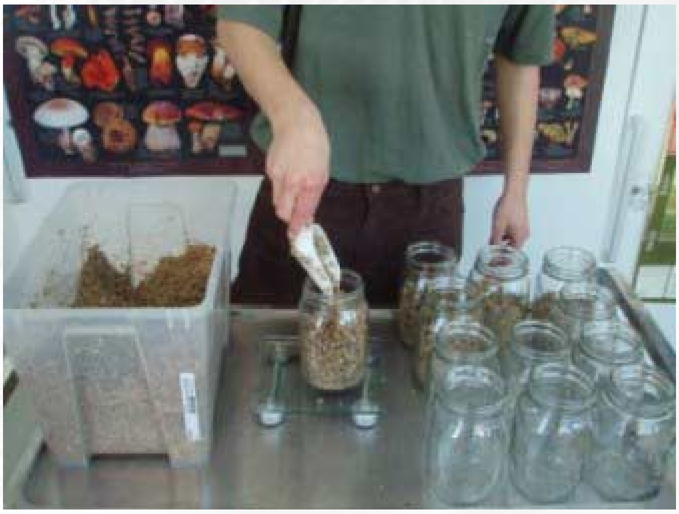
Mixing proportion of substrate

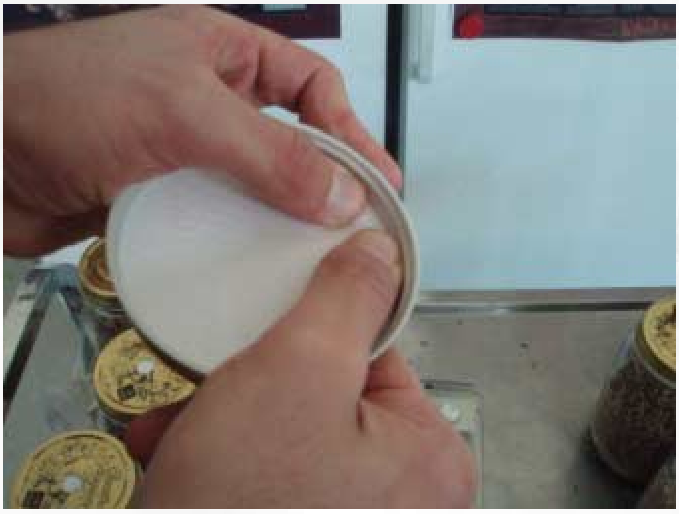
For 1 glass with volume of one litre we recommend to use 200 g (approx. 0.25 l) rye grain, 200 ml vermiculite medium and 1.5 g gypsum. This formula will result in 400 g rye grain substrate. Time needed to sterilise: 90 minutes.

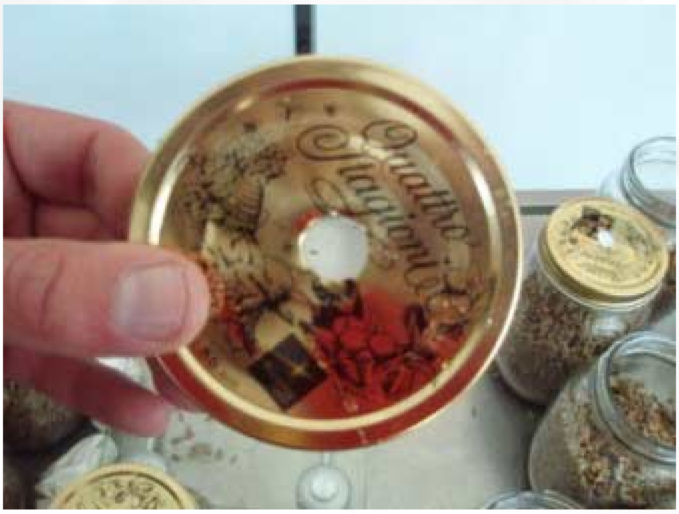
If you work with Bags, for grain substrates we recommend to use original Unicorn Bags Type 3 T. Use for each bag 1.3 kg rye grain, 1.4 litre vermiculite and 8 g gypsum. This formula will result in 2.7 kg rye grain substrate. Time needed to sterilise: 3 - 4 hours.

Filling glasses with substrate

Fill the glasses up to two-thirds of their volume. For a one litre glass that will be about 400 grams of rye - vermiculite - substrate. The lids should be perforated (pierce a hole 1 cm in diameter) to ensure that fresh air is given to the mycelium. The filter disk attached to the lid prevents contamination. Do not screw down the lids too firm during sterilisation to ensure pressure compensation (and prevent the glasses from breaking).







Filling bags with substrate

Roll down the autoclave bag about 10 cm and pour in 2.7 kg of the grain substrate mixture. Be careful not to spill any substrate on the upper regions of the bag (in case you did, clean the bag with a wet piece of cloth). Then wrap the bag twice.

Sterilising the substrate

A pressure cooker is used for the sterilising process. Overlying a 2-3 centimetre water level at the bottom of the cooker a separating insert keeps the bags above the water line. Assure yourself that there is no contact between water and the bags, decant some water if necessary. (Mind the handling instructions given by the manufacturer of your pressure cooker!) Now load the glasses or bags.

If the cooker is big enough you can make two levels of bags. Place the upper layer on a separating tray over the left spare zones of the lower layer. This ensures that the steam gets evenly distributed.

Get the lid locked and put the cooker on a hotplate. Counting the sterilisation time from the moment, the pressure gauge reaches its highest stage (for household pressure cookers). If you've got a professional pressure steriliser at your disposal sterilise at 121°C/ 250°F/ 15 psi/ 1.05 bar. Once the sterilisation time has passed the cooker must cool down in a clean place, preferably in front of a HEPA - filter (sterile air flow). If working without laminar flow hood put a clean wet piece of cloth over the cooker during the cooling process to filter the air streaming into the pot while pressure equalisation.

After the cooker is fully depressurised, open the lid. If you work with glasses close the lid of the glasses fast and tight to minimise contamination risk. The glasses/ bags should cool down to room temperature in front of a HEPA-filter or in a Glove Box.

As soon as the substrate has cooled down bellow 30 ° C / 86 ° F, it is ready for inoculation. If your are up to continue at a later date close the bags / glasses tightly, store the substrates in the refrigerator (35.6-39.2°F, 2-4°C) and use them within 4 weeks.

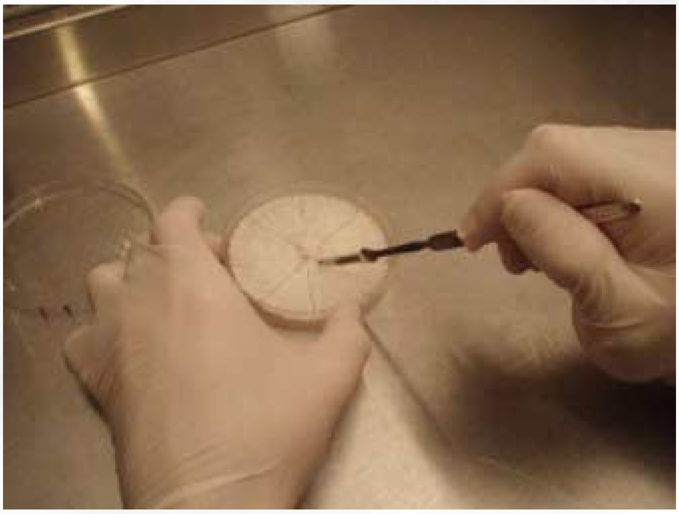
Ready sterilized substrates!

Table of Contents

Inoculation of grain spawn with mycelium on agar medium

Recommended Tools:

- Petri dish (at least 3/4 colonised, not mutated)
- Sterilised rye substrate
- Scalpel with sterile blade
- Bag sealer or strong adhesive tape
- Latex gloves
- Face mask and hairnet
- Disinfectants for workspace and hands
- Sterile working area: Glove Bag/Glove Box or
- Sterile air flow (HEPA-filter, Laminar Flow Hood)

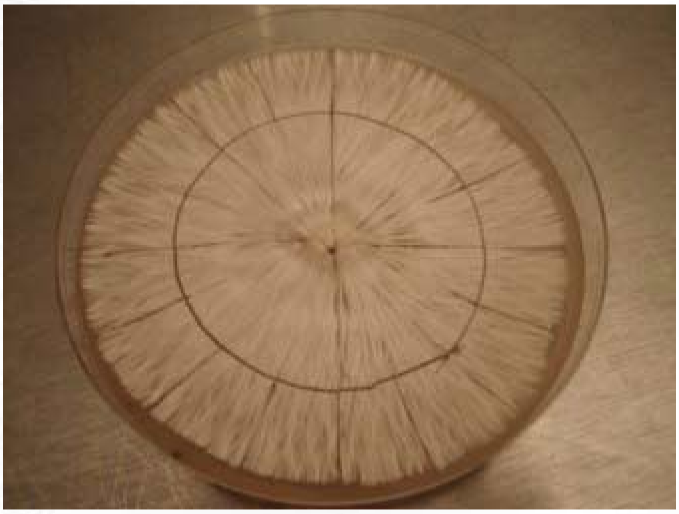


Inoculation

Perform this working step as aseptic as possible to prevent the grain from contamination by bacteria or mould. Clean your worktop, wash hands and forearms, put on a protective face mask, hairnet and gloves and disinfect your worktop well.

Use the mycelium of 1 Petri dish for inoculating 1 glass of sterilised grain (about 400 grams substrate), for substrate in bags take more petri dishes. Avoid inoculation of 1 grain substrate with different mycelia strains; use only copies of one clone per glass / bag.

Remove the Parafilm from a Petri dish only inside the Glove Box or only in front of a HEPA-filter. Take the scalpel and carve eight lines in star like array and a circle at half the diameter into the mycelium. Thereby you got 16 small pieces.



Unscrew the glasses or open the autoclave bags on their top. Spear the mycelium slice with the scalpel and transfer them carefully to the sterilised substrate. Close the glass / bag tight after this is done. Now distribute the mycelium pieces evenly by shaking the glass or bag, to achieve fast and equal colonisation. In case that mycelium pieces stick on the wall of the glass or bag, the can be released by knocking soft on the outside, to get again contact with the substrate.

Mycelium growth after inoculation

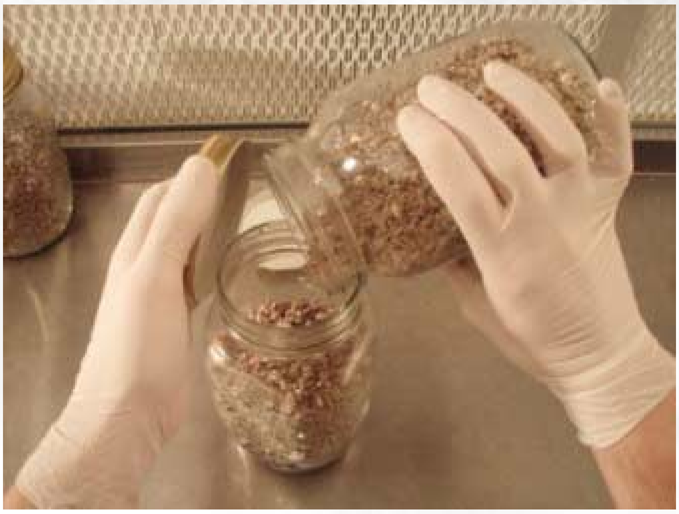
Store the inoculated substrate in a dark and clean place at convenient temperature for spawn run of this mushroom species. Ensure that the incubator in which the mycelium is places provides enough ventilation.

After a few days mycelium strands become visible growing out of the small agar pieces and colonise the grain. One or two weeks after inoculation the glasses and bags should be given a good shake to redistribute the already colonised matter amongst the unsettled material. This will accelerate the colonisation of the grain. Under convenient conditions rye grain should be fully colonised about 3 to 4 weeks after inoculation.

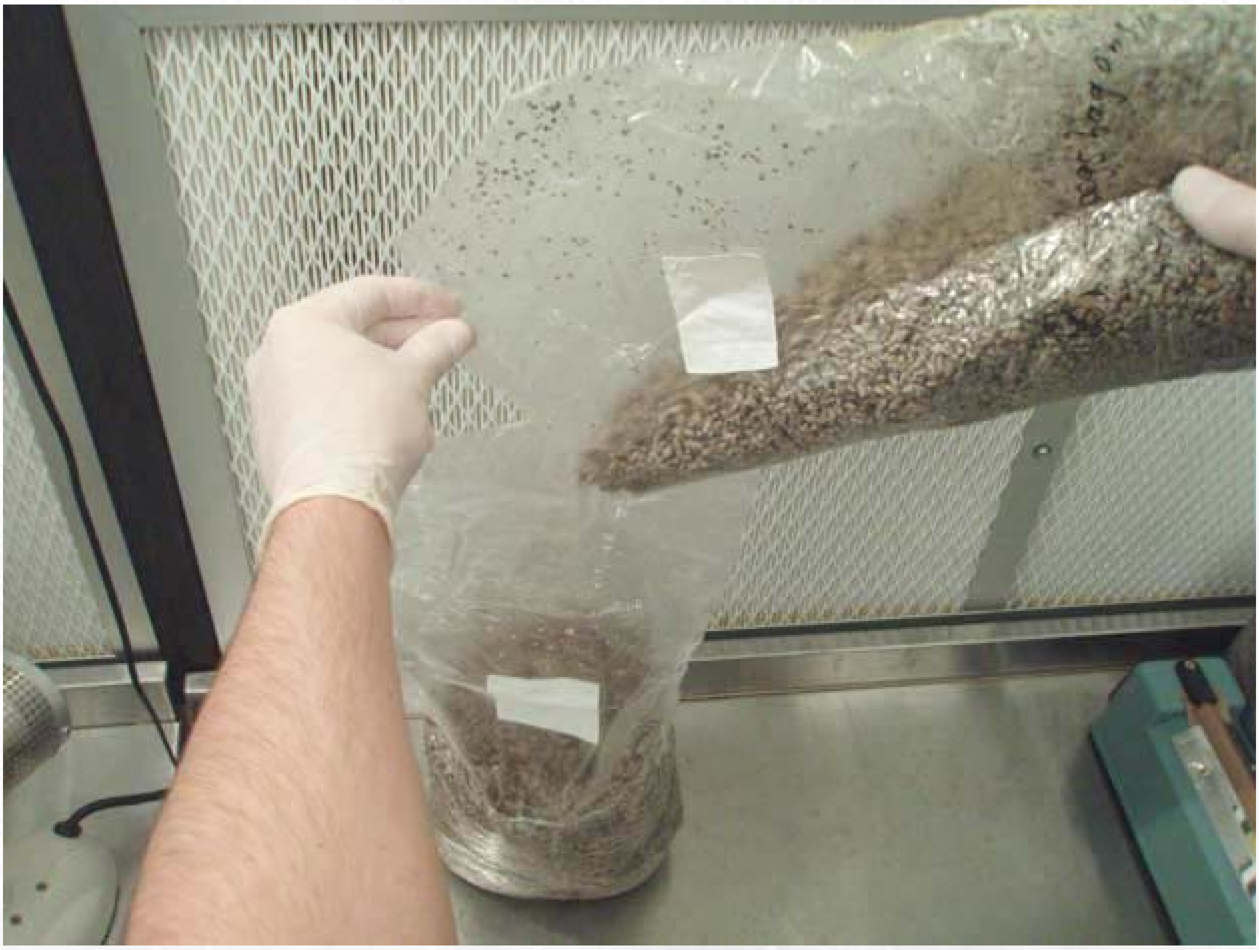
As soon as all rye grains are overgrown with white mycelium, the grain spawn is ready to be used for inoculation of the fruiting substrate (e.g. compost, straw, wood - depending on the mushroom species). Use 2 to 10 % of grain spawn for inoculation of fruiting substrate, according to mushroom species and type of substrate.

Reproduction of grain spawn

To produce more inoculation material you can use grain spawn to inoculate sterilised rye grain substrate. For optimum result use 10% of ready colonised grain spawn, based on the weight of the fresh rye substrate. Please make sure to perform this step under sterile conditions to prevent contamination.



Unscrew the glasses or open the autoclave bags on their top. Separate the grain kernels of the colonised spawn by shaking and plumping them repeatedly. The fresh rye substrate can now be inoculated with grain spawn. Close the glass / bag tightly after this is done. Now distribute the colonised grain evenly into the fresh substrate, by shaking the glass / bag, to achieve fast and equal colonisation.



For mycelium growth stage, store the inoculated substrate in a dark and clean place at convenient temperature (spawn run) for this mushroom species. Ensure that the incubator in which the mycelium is grown gives enough ventilation.

Table of Contents

Sterilisation of wood substrate

Most fungi won't develop fruiting bodies on rye grain substrate, that's why an adequate fruiting substrate must be inoculated with the grain spawn. In this instruction we want to introduce a standard substrate, which is suitable for a wide range of wood habitant mushrooms.

Recommended equipment:

- Woodchips
- Saw dust large
- Gypsum
- Rye bran
- Water
- Autoclave Bags Unicorn type 14#
- Scale
- Bag sealer or strong adhesive tape
- Sieve
- Container for mixing
- Pressure cooker

Preparing the substrate

Let the wood chips soak in cold water overnight (12-18h).Use as much water until all the chips are floating. Put the soaked wood chips in to a sieve and let it drain for around a quarter of an hour. In the meantime put all dry ingredients (sawdust, rye brain and gypsum) into the mixing container and mix it very well. After the dry ingredients are mixed, add the soaked wood chips and mix the substrate again. To conclude, add the water and mix it again very well.

Mixing proportion

For filling of 1 autoclave bag, (please use the original unicorn bags type 14# for wooden substrates) you'll need 368 g wood chips, 735 g saw dust large, 31 g gypsum, 200 g rye bran and 950 ml water. This will produce approximately 2,5 kg substrate. Sterilisation time: about 3 - 4 hours.

Filling bags with wood substrate

Roll down the autoclave bag about 10 cm and pour in 2.5 kg of the wood substrate mixture. Be careful not to spill any substrate on the upper regions of the bag (in case you did, clean the bag with a wet piece of cloth). Then wrap the bag twice.

Sterilising the wood substrate

A pressure cooker is used for the sterilising process. Overlying a 2-3 centimeter water level at the bottom of the cooker a separating insert keeps the bags above the water line. Assure yourself that there is no contact between water and the bags, decant some water if necessary. (Mind the handling instructions given by the manufacturer of your pressure cooker!) Now load the bags. If the cooker is big enough you can make two levels of bags. Place the upper layer on a separating tray over the left spare zones of the lower layer. This ensures that the steam gets evenly distributed.

Get the lid locked and put the cooker on a hotplate. Counting the sterilisation time from the moment, the pressure gauge reaches its highest stage (for household pressure cookers). If you've got a professional pressure steriliser at your disposal sterilise at 121°C/ 250°F/ 15 psi/ 1.05 bar.

Once the sterilisation time has passed the cooker must cool down in a clean place, preferably in front of a HEPA - filter (sterile air flow). If working without laminar flow hood put a clean wet piece of cloth over the cooker during the cooling process to filter the air streaming into the pot while pressure equalisation.

After the cooker is fully depressurised, open the lid. If you work with glasses close the lid of the glasses fast and tight to minimise contamination risk. The bags should cool down to room temperature in front of a HEPA-filter or in a Glove Box. As soon as the substrate has cooled down bellow 30 ° C / 86 ° F, it is ready for inoculation. If your are up to continue at a later date close the bags tightly, store the substrates in the refrigerator (35.6-39.2°F, 2-4°C) and use them within 4 weeks.

Table of Contents

Inoculating wood substrates with grain spawn

Most fungi won't develop fruiting bodies on rye grain substrate, that's why an adequate fruiting substrate must be inoculated with the grain spawn. This method is suitable for most wood habitant mushroom species.

Recommended equipment:

- Grain spawn, ready colonised
- Sterilised wood substrate
- Bag sealer or strong adhesive tape
- Latex gloves
- Face mask and hairnet
- Disinfectants for workspace and hands
- Sterile working area: Glove Bag/Glove Box or
- Sterile air flow (HEPA-filter, Laminar Flow Hood)

Inoculation of wood substrate

Perform this working step under aseptic conditions to prevent the grain from contamination. Clean your worktop, wash hands and forearms, put on a protective face mask, hairnet and gloves and disinfect your worktop well.

Open the sterilised wood substrate bag. Shake Separate the grains of the colonised spawn by shaking and plumping them repeatedly. Use 2 to 8 % (of the weight) of grain spawn for inoculation of wood substrate.

Add about 50 - 200 g of grain spawn per 1 bag containing 2,5 kg of wood substrate.
Close the inoculated substrate bag using a bag sealer or strong adhesive tape. Now distribute the colonised grain evenly into the fresh substrate, by shaking the bag, to achieve fast and equal colonisation.

Mycelium growth on wood substrate

For mycelium growth stage, store the inoculated substrate in a dark and clean place at convenient temperature (spawn run) of this mushroom species. Ensure that the incubator in which the mycelium is grown provides enough ventilation. After about 2 - 3 weeks the mycelium should have grown through the bag and the substrate should be overgrown by white mycelium. (Please note that some different species of fungi could have different mycelia colours.) Now the mycelium is ready for the fruiting phase.

Table of Contents

Laying of a mushroom bed

Preparing a mushroom bed with wood inhabitant mushrooms is a very easy thing! The best time to start is spring, as soon as the nights are frost-free. We recommend the use of spawn on wood basis (spawn describes a substrate, which is fully colonised by mushroom mycelia, used for inoculation of the fruiting substrate). The usage of grain based spawn may attract mice, rats or other vermin. Just mix the spawn with an convenient base material and keep it moist.

Depending on the species of mushroom and weather conditions the mycelia often develop their first fruiting bodies only a few months after the inoculation. The mushroom fruits until all nutrients have been consumed. With little luck, the mushroom will settle permanently in your garden.

Recommended equipment:

- Completely colonised wood substrate (spawn)
- Wood chips
- (for 1 autoclave bag with 2,5 kg spawn we recommend 15 kg wood chips)
- Covering material (bark mulch approximately 25 litres, straw or soil)
- Corrugated card board
- Spade or shovel
- Water (garden hose)

Bed preparation

Mushrooms breeding in your garden need a shadowy place, preferably either near trees or underneath bushes. If you want to lay several beds side by side, leave enough space between the beds. With proper nurture they will expand and develop fruits for several years.

With one spawn bag (2,5 kg capacity) a mushroom bed of 80 x 80 cm can be inoculated. Excavate about 10 cm of soil and spread out cardboard as a bottom layer of your bed. Now disperse one half of the wood chips evenly on the bed and irrigate them for about 10 minutes using a hosepipe.

Inoculating the bed

The spawn bag needs to be properly shaken because mycelium populated wood substrate tends to be closely clotted. By fluffing and rubbing of the bag with the whole palm of your hand, the substrate can be separated. Make sure you separate the substrate thoroughly to ensure a consistent and quick colonisation of the wood chips.

Now spread out the spawn over the watered wood chip layer as evenly as possible and cover it with the remaining wood chips. Afterwards the mushroom bed needs to be watered again for about 10 minutes. To prevent the bed from drying out we recommend a 5 cm thick cover layer of bark mulch or straw. This cover layer needs to be moisturised as well.

Some mushrooms even allow you to use a cover layer made out of soil. We recommend using mushroom casing soil. Fluff up the soil in the bag, evenly spread out a 5 cm thick layer over the bed and water the bed for a few minutes.

Further care

Check the moisture of the mushroom bed periodical. If the bed isn't moist under 3 cm depth or more, please water it again. During the harvesting season we recommend to harvest the fruiting bodies daily. The simplest method to do this is twisting the fruiting bodies on their base. Take care to remove the whole shaft to prevent bacterial contaminations.

Wintering and feeding

To ensure your mushroom bed survives the winter, we recommend spreading out a 5 cm thick layer of wood chips before the first frost. This new layer offers your mushroom bed fresh nutrients. In the next spring, as soon as the nights are frost-free again, the mushroom bed should be controlled for moisture and be watered in case it dries out.

Fighting snails

Snails love mushrooms! To prevent these voracious creatures from destroying the whole crop, we recommend building a snail fence around the mushroom bed. Don't use slug and snail bait or other chemical pest control substances, the poison might end up in the fruiting bodies!

Table of Contents

Inoculation of wood logs with spawn dowels

The inoculation of wood logs or stumps with spawn dowels can be done throughout the whole year, if the logs / stumps are stored frost-free during spawn run, until they are fully colonised. Depending on the species, the mushroom fruits for several seasons untill all the nutrients of the wood have been consumed.

Recommended equipment:

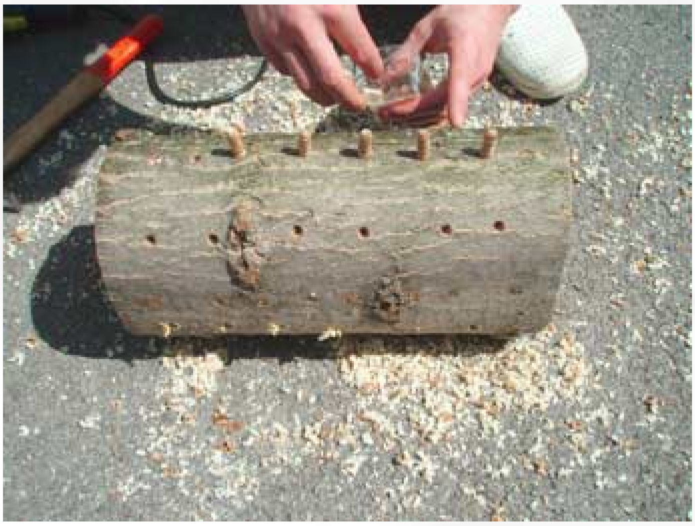
- Wood logs or stumps
- Wood saw
- Tub for soaking
- Drilling machine and 9 mm (0,35 inch) drill
- Spawn dowels (wood dowels, fully colonised with mycelium)
- Jute bag
- Sealing wax
- Hammer

Preparations of log

The quality of the wood is crucial for successful cultivation. After you have cut the wood, make sure to store it in a dry place for 2 -3 weeks, then prepare it as follows:

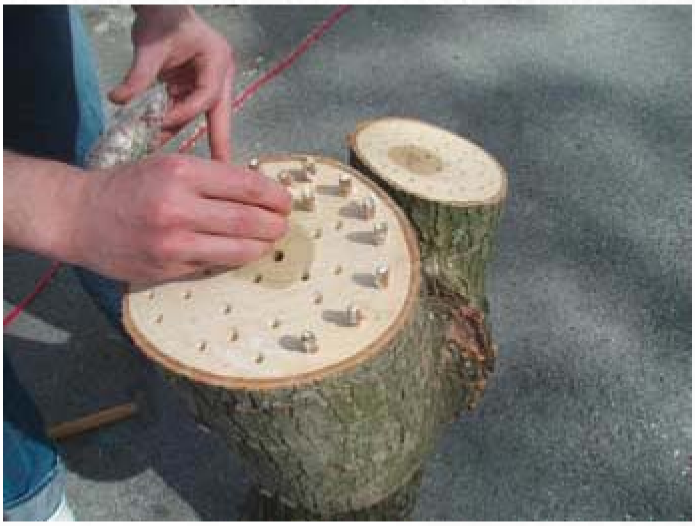
Soak the entire log for 3 days in a tub and leave it to dry on a canvas outdoors for one day. The primary choices of material are wood logs with bark, with 20 - 35 cm (7 - 14 inch) in diameter and 90 - 120 cm (35 - 47 inch) long.

After it's deliverance the spawn dowels should be left in rest 2 to 3 days at room temperature (maximum 29 ° C / 84 ° F) to give the mycelium time to recuperate from it's journey. If you don't plan to use the spawn dowels immediately after the recuperation, please store in the fridge at 2 - 4°C/ 36 - 39°F and use it within a few weeks time.



Inoculating the logs

Cut off about 2 cm on each end of the trunk directly before inoculation to prevent unwanted fungal growth and contamination and throw the pieces away. Now drill about 50 holes of 3 - 4 cm (1,2 - 1,6 inch) depth all around the log evenly. Take care to work slowly, if the wood heats up too much it might affect it's quality! Now place the dowels into the holes carefully. Take care not to injure the mycelium. We recommend to inoculate the cut surfaces too, to reach even better results.



For logs we recommend to use about 50 spawn dowels, for stumps 30 - 50 spawn dowels. As soon as the whole log is inoculated, close the holes with sealing wax. The simplest method is to apply warm, liquid wax with a paint-brush and immerse the cut ends.

Mycelium growth at log

For mycelium development / spawn run, wrap the trunks in moist jute bags and put them in a shadowy place in your garden or in a well ventilated cellar for about 10 weeks. The jute bags need to stay moist. The spawn run phase is over as soon as white mycelium can be seen besides the holes. (Recommended temperature: spawn run - depending on species)

Setup in the garden and further care

As soon as the logs are fully colonised, dig a hole of 15 cm (6 inch) depth in a shady place in your garden and place the log in an upright position. For cultivation on a shady balcony or terrace use a flower pot filled with sand or pebbles. Keep the wood and the soil around it moist and water them on a periodical. The fruiting bodies develop during the season, providing the natural weather/fruiting conditions - depending on the species.

Wintering of log

To protect the logs against frost just wrap them in jute bags during winter. In spring time, bags are removed and the logs are sprayed with water.

Fighting snails at log

Snails love mushrooms! To prevent these voracious creatures from destroying the whole crop, we recommend building a snail fence around the log. Don't use slug and snail bait or other chemical pest control substances, the poison might end up in the fruiting bodies!

Special tips for Lentinula edodes (Shiitake)

Shiitake doesn't need contact with soil. The logs also can also be placed and fixed at a fence. We recommend using wood logs (with bark) of about 70 - 120 cm (27 - 47 inch) length and a diameter of about 15 - 20 cm (6 - 8 inch).

To start the fruit cropping prepare the logs as following: Dunk them in cold water for approx. 24 h (the log should be complete covered with water). The best yield can be made if the water has a ph value of 5 (to adjust the ph value use 0,1 % N hydrochloride). After dunking, pitch the log for 3 times on a stone plate. Now it takes 10-14 days fort he pins (mini mushrooms) to appear. After harvesting, let the log rest for 6 weeks then you can dunk and pitch it again!

Table of Contents

Mushroom cultivation on a bale of straw

Several mushroom species are straw inhabitant. You can use wheat, rye or barley straw. One of the most successful ways for these species is the cultivation on bales of straw in the garden.

Only use dry and healthy bales of straw, because the quality of the fruiting substrate always has a big influence on the crop yield. The colour of the straw (golden yellow) and the almost tear-proof blades indicate the health of the straw. Furthermore it should smell fresh, if it doesn't, don't use it, a musty smell either comes from mould or other fungi which are already populating the bale. Musty bales are not suitable for mushroom cultivation!

Recommended equipment:

- Bale of straw (27cm x 20cm x 40cm)
- Tub for soaking
- Grain or wood spawn (completely colonised)
- Jute Hessian Cloth (200 x 100 cm)
- String (2 m)
- Water

Preparations of a bale

Soak the bale in water overnight (12 -16 h) before inoculation. Take care that the whole bale is covered with water. Immediately before the inoculation take the bale out of the water and drain the spare water for half an hour.

Inoculation of a bale

Please wash your hands and arms thoroughly before you touch the spawn. For one bale of straw (27cm x 20cm x 40cm) we recommend the use 1 liter spawn. To assure a consistent population form one 5 -10 cm (2 - 4 inch) deep hole on each side. Use a clean stick to drill the holes. Divide the 1 liter spawn evenly on the 6 holes.

To keep the spawn in the bale and ensure that it grows through it, close the inoculated holes with straw from the outside. Now wrap the bale in the jute fleece and tie the string around it.

Mycelium growth on a bale - Spawn run

For spawn run store the bale in a shady place in the garden. Depending on the species, temperature and humidity, it will take 2 - 4 weeks till the bale is fully colonised with mushroom mycelium.

Control the humidity in the bale periodically. Humidify the bale again, if more than 3 cm of the outmost layer are dry. Please apply only small doses of water, because the spawn could die if the bale gets too wet. Depending on the weather it will be sufficient to use 2 - 3 litre per bale 1 to 3 times a week. Control the humidity inside the bales with your hand. Do this on a regular basis and adjust it with small amounts of water to prevent the spawn from drowning.

Fruiting of a bale

As soon as the bale is completely colonised, you can initiate the fruiting by increased air supply. Just remove the jute fleece on one broad side of the bale. If the weather conditions are right, the first pinheads should show up after 2 - 4 weeks.

The mycelium will fruit in several flushes until all the nutrients in the bale have been consumed. Afterwards you can still use the bale as a commodity for composting. Take care to harvest all the fruiting bodies. Please check the humidity in the bales during the harvest periods and also adjust the humidity if necessary.

Fighting snails at bale

Snails love mushrooms! To prevent these voracious creatures from destroying the whole crop, we recommend building a snail fence around the bale. Don't use slug and snail bait or other chemical pest control substances, the poison might end up in the fruiting bodies!

Table of Contents

"PF-technique"

The PF-technique aka BRF-Tech (Brown Rice Flour technique) is a method developed by hobby mushroom cultivators for growing mushrooms in the simplest way. Over the last centuries many different versions of this method have developed. The following instruction is based on our experience.

Mushrooms need a convenient substrate to develop fruits. The substrate has to be produced under sterile conditions to avoid contamination through mould or bacteria. Contamination destroys not only the fungi but also the substrate. The substrate is inoculated with spores. In the next phase, the so called spawn run, the mycelium grows on the substrate. As soon as the substrate is fully colonised with mycelium, it is ready for the fruiting phase.

Recommended materials:

- Micro-Boxes or PF-glasses
- Measuring cup
- Vermiculit
- brown rice flour
- Sporesyringe (ATTENTION, not every mushroom species is suitable for cultivation on PF-substrate.)
- Fruiting chamber
- Pressure cooker
- Container for mixing
- Water

Mixing the PF substrate

Blend one litre (about 700g) of rice flour with three litres of vermiculite medium, then add one litre of water and mix again. That should result in five litres of PF-substrate for 10 micro-boxes with 500 ml each.

Filling the substrate

Use your hands to fill the substrate into the boxes or glasses. Use your fingers to push the substrate into form to eliminate any hollow spaces, but don't press too much. Fill the boxes or glasses up till 1,5 cm under the edge of the box remains free, and smoothen the surface of the substrate. Clean the edge of the box or glass with a wet piece of cloth, and fill the rest with dry vermiculite. The dry vermiculite acts as a filter to prevent growth of contamination from the outside into the substrate. Close the boxes/glasses. If you are using micro-boxes remember to make sure the lid is lying loose on the box to ensure pressure balance. If you using glasses pierce the lid four times (make holes of about 2 - 3 mm / 0,1 inch in diameter), these will later be used to inoculate the substrate.

Sterilise the substrate

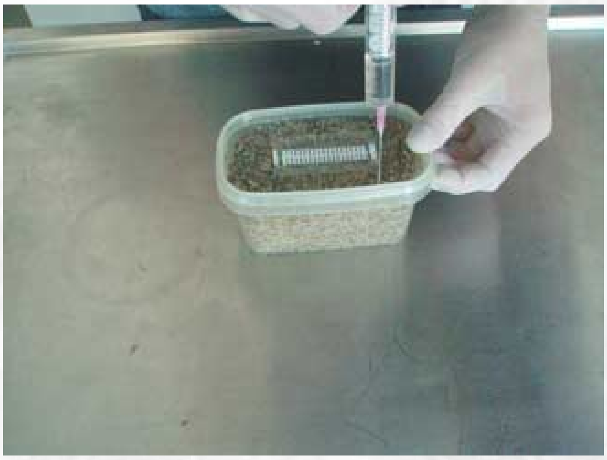
A pressure cooker is used for the sterilising process. Overlying a 2-3 centimetre water level at the bottom of the cooker with a separating insert keeps the boxes / glasses above the water line. Assure yourself that there is no contact between the water and the boxes / glasses, decant some water if necessary. (Mind the handling instructions given by manufacturers of your pressure cooker!) Now fill in the glasses or boxes. If the cooker is big enough you can make two levels. Place the upper layer on a separating tray over the left spare zones of the lower layer. This ensures that the steam gets evenly distributed.

Get the lid locked and put the cooker on a hotplate. Start counting the sterilisation time as, the pressure gauge

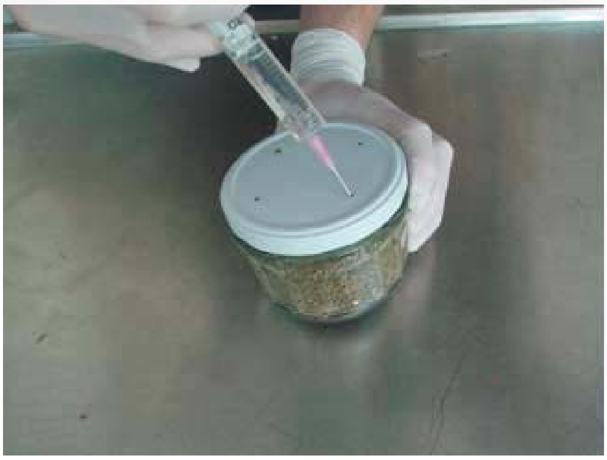
reaches its highest stage (for household pressure cookers). If you've got a professional pressure steriliser at your disposal sterilise at 121°C/ 250°F/ 15 psi/ 1.05 bar.
Once the sterilisation time has passed the cooker must cool down in a clean place, preferably in front of a HEPA - filter (sterile air flow). If working without laminar flow hood put a clean wet piece of cloth over the cooker during the cooling process to filter the air streaming into the pot while pressure equalisation.
After the steriliser is fully depressurised, open the lid. The glasses/ boxes should cool down to room temperature in front of a HEPA-filter or in a Glove Box. As soon as the substrate has cooled down bellow 30 ° C / 86 ° F, it is ready for inoculation. If your intend to continue later close the boxes / glasses tightly, store the substrates in the neatly clean refrigerator (35.6-39.2°F, 2-4°C) and use them within 4 weeks.

Inoculation of the substrate

Perform this working step as aseptic as possible to prevent the substrate from contamination by bacteria or moulds. Clean the worktop, wash your hands and forearms, put on a protective face mask, hairnet and gloves and disinfect your worktop well.



Give the spore syringe a good shake to ensure that the spores are well spread throughout the water. If using micro-boxes you can pierce the lid with the syringe (please disinfect the spot you choose to pierce). The substrate glasses will be inoculated through the four holes in the lid. If you use ready sterilised PF-substrates please remove the tape from the holes on the lid before inoculating the substrate and leave the holes open afterwards, to ensure sufficient air exchange!
Remove the protective cover from the cannula just before inoculation. You mustn't touch the sterile needle. Stick the needle through the holes of your box or glass towards the wall and inoculate the substrate, spreading the liquid along the wall of the box. Use 1 - 4ml of the spore-water mixture per each box/glass (filled with 500ml substrate), portioned in all 4 holes.



Should the needle touch anything unsterile, you will have to sterilise it again. Therefore hold the nip of the needle into a flame (Bunsen burner or lighter) till the nip turns red and let it cool down again. (Do not overheat the needle as the stand is made of plastic which could melt!)

Mycelium growth PF

After all substrates have been inoculated, they should be stored in a warm (up to 30°C) and dark place. The substrate is ready for the next step as soon as the whole box / glass is grown through with white mycelium (this normally takes 2 - 3 weeks). Only the 1,5 cm layer of dry vermiculite stay free of mycelium.

Fruiting

Rub off the layer of dry vermiculite from the top of the boxes/glasses and take out the mycelium. Put the mushroom mycelia into a growing chamber or similar under the convenient environmental conditions for "the Primordia formation". As soon as the first small mushrooms (Primordia) appear change the temperature and humidity to the recommended fruiting conditions. According to the species, it takes about 1 or more weeks untill the Primordia appear, a few days later you can harvest your first own mushrooms.

Table of Contents

Inoculation of substrat bags with sporesyringes

This is a very simple method of mushroom cultivation and suitable for hobby-mycologists. Use a convenient substrat depending on the mushroom species you want to cultivate. Detailed information about the convenient substrate can be found in the product description of our spores. When you bring spores onto an appropriate nutrient medium, the spores start germination. As soon as the substrate is fully colonised by the mushroom, you can set up the bag for fruiting.

Recommended materials:

- Substratbag
- Spore Syringe
- Workspace Disinfection
- Kitchen paper
- Tape (cloth tape)

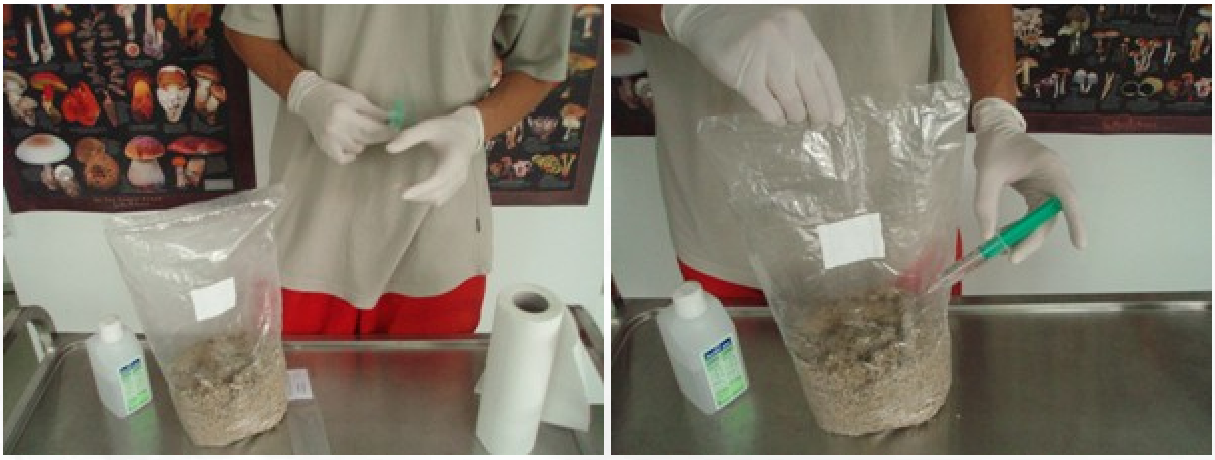
Disinfect the surface of bag

To avoid invasion of any contamination during inoculation, we recommend to disinfect the surface (just a few cm large - the place you want to put the needle in). Kindly spray disinfection (i.e. Bacillol) on the bag, let it react for about 20 - 30 seconds, then dry it with a clean ktichen paper or similar.

Inoculation bag with syringe

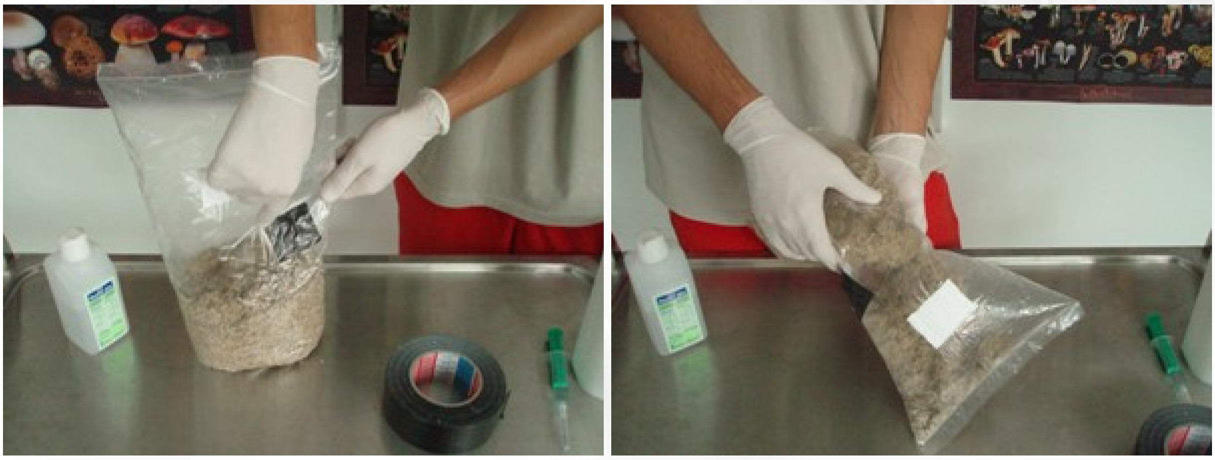
Shake the syringe to dispense the spores equally. Now put the needle into the bag (at the disinfected area) and push the the sporesolution into the bag. We recommend to use about 5 ml - thats 1/2 syringe - for small bags (2,5 l content). For larger bags (4,5 l content) we recommend to use 10 ml sporesolution - thats 1 spore syringe.

ATTENTION:
If the needle get in contact with any unsterile thing, you have to sterilize it. There for heat the forefront of the needle with a alcohol lamp (or with a lighter). The forefront of the needle should glow red. After that let the needle cool down for a few seconds.



Seal the inoculation area and distribute the spores

Close the inoculation area immediately with the tape. To distribute the spores equally in the substrate, shake the bag careful.



Spawn run in bag

For colonisation of the substrate, store the bag at the convenient spawn run - temperature (see in the product description in a dark place. After the substrat is fully colonised by the mushroom, you can put it into fruiting. If you work with rye grain substrate it is also possible to use the grain for inoculation of a different fruiting substrate.

TIP: If the substrat is not colonised even, kindly shake the bag after a few days.

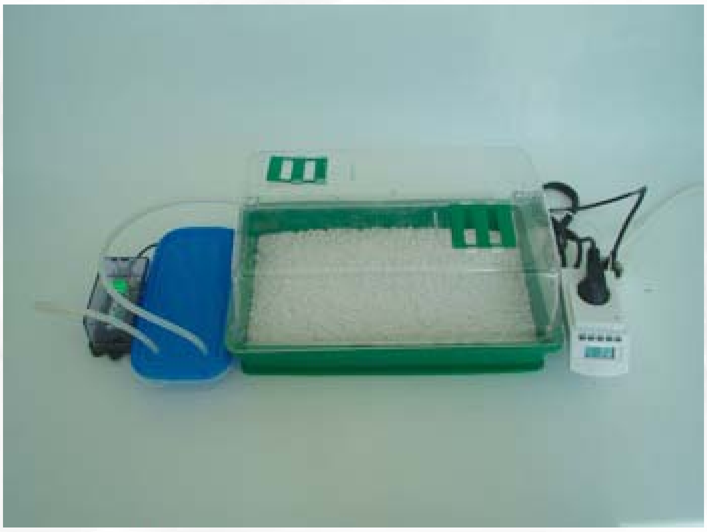
Instruction for indoor mushroom propagator

For successful growth mushrooms need suitable substrate, the right temperature and humidity, as well as oxygen and a little light. Our grow-kits are especially designed to provide these cultivation parameters in an easy to handle way.

It's easy to upgrade a customary greenhouse into a hobby-mushroom-grow-set. The main principle always stays the same, no matter how much space you cultivate, only the machinery used to regulate the climatic conditions gets more complex, the more space you occupy.

Recommended equipment:

- Greenhouse
- Digital temperature control
- Electric heat pad or heating cable
- Humidity/CO2 Apparel Set
- Perlit
- Spray bottle
- Disinfectant



Main principle

Throughout their different stages of development fungi need a variety of environmental conditions. During mycelium growth most mushrooms need relatively high temperatures (27 - 29°C), during fruiting they need high humidity.

The electric heat pad or the heating cable is used, to provide the right temperature. To set the suitable temperature for each mushroom species, the electric heat pad or cable will be triggered by the digital temperature control. The humidity will be the result of humidity or CO2 pump, which is also supplying oxygen, and the wet perlit on the floor of the greenhouse.

Use as Incubator

Inoculated substrates have to be kept in clean place, under suitable conditions, during mycelium growth. Installing the grow-set for mycelium growing stage:

Clean and dark spaces are ideal for setting up your grow-set (you may as well cover the greenhouse with opaque material). If the set is stored in a cupboard make sure it gets enough oxygen. Open the cupboard at least once a day.

Place the heating pad under the greenhouse. If possible put some heat isolating material beneath the pad. If you are using a heating cable make sure it is lying snake-wise on the floor of the greenhouse, try to spread it symmetrical over the floor.

Place the sensor for the temperature control system on the floor of the greenhouse. Plug the heat-pad or cable into the temperature control and plug the control into a socket.

Take one of the pumps silicon tubes and connect one end to the hole of the greenhouses lid and the other to the pump. Keep the pump running at all times, as it helps the ventilation during the "spawn run" phase. The knob above the connection point regulates the amount of air. If you are using a tube-micro filter, cut the pipe open and install it in the middle section.

Adjust the system to the necessary conditions for mycelium growth of your fungi genus. Try to keep the greenhouse as dark as possible during this phase (except for your daily control).

Use as fruiting chamber

As soon as the whole substrate is grown through with mycelium, the environmental conditions have to be changed to initiate the fruiting phase. The basic structure of the greenhouse stays the same as in the growth phase, the Humidity/CO2 pump as well as perlit will also be needed.

Moisten the perlit in a sieve or a plastic bag and spread it symmetrically on the floor of the hothouse. The perlit has to stay wet during the whole fruiting phase. Evaporated water can be refilled using a spray bottle. Substrate grown through with mycelium - blank or in opened bags - can be place directly on the perlit.

Installing the humidifier: First connect both of the silicone tubes to the hole in the lid of plastic box, one of them stuck about 1 cm through the hole, the other about 4-5 cm. The tube, stuck 4-5 cm through the hole, has to be connected to the ceramic diffuser. If you use an additional micro-filter connect it to the same tube as the ceramic diffuser.

Fill the plastic box with fresh tap water till ¾ of the volume are full and close the lid. Important: The ceramic diffuser has to be completely under water, the second tube must hang in the air above the water level.

The last step is to connect the tube, attached to the ceramic diffuser, to the air pump and stick the second pipe into the greenhouse. The button above the pumps connection regulates the amount of air, enabling us to control ventilation and humidity inside the hothouse. Change the water every 2-3 weeks. Adjust the system to the necessary conditions for mycelium growth of your fungi genus.

Adjust the system to the necessary conditions for fruiting of your fungi genus.

Cultivation of Psilocybe cubensis on cased sterilised grain

Making grain spawn

What is grain spawn?

Grain spawn is rye, (or other cereal grain) fully colonised by mushroom mycelium. It serves two purposes:
1) As a carrier of mycelium into spawn larger amounts of substrate
2) As a substrate by itself.

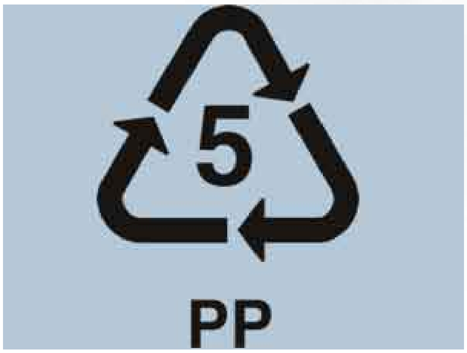
Not all species will fruit directly from grain spawn. *Psilocybe cubensis* is one of the species that can do this, Panaeolus species generally will not fruit directly on (cased) grain. The latter species requires a dung-based to fruit on, although the mycelium will grow fine on rye.
The mycelium of most saprophytic mushroom species can be grown on rye.

Some rye grain.

Containers

Glass jars

Real canning jars are best because they can withstand numerous sterilisation cycles without problems. A cheaper alternative is to find the cheapest brand of applesauce or vegetables in a local supermarket and to discard the contents (not in the store!). When these jars are cleaned and have their labels removed they can be used. However, since these jars are not intended to be sterilised often they are much more fragile, especially after 2-3 sterilisation cycles. Metal lids, or lids made from polypropylene (PP) can be pressure cooked.



This symbol is depicted on most polypropylene items.

Microboxes

These polypropylene containers provide an excellent alternative to glass jars. They come with a filter fitted in the lid and the lid seals hermetically to the bottom. They can be pressure cook and be re-used over and over again. Because they are made from polypropylene there's no risk of injury from glass shards as there is with glass jars.

Filter patch bags

These bags are specially made for the production of grain spawn. Made of polypropylene they have a filter patch sealed to one side of the bag. Traditionally these bags are sterilised open and sealed afterwards but we have some tips on how to sterilise them sealed, look here. The bags need to be sealed with a good impulse sealer. Cheap household sealers will not work because the width of the seal is too small.

A 1000ml microbox and 720ml jar

Filter patch bag and medium components

Closing the containers

Closing glass jars

For glass jars there are some options on how to close them. We prefer to use Tyvek or filter disks beneath the lids. Although it is possible to incubate the jars without some kind of filter, just with the lids loose, this is risky. Especially in somewhat drafty and/or dirty environments jars without a filter easily contaminate with airborne spores.
A hole should be drilled in the lids. In case of metal lids holes can be punched with a nail and hammer. The size and/or amount of the hole(s) depends on the type of filter that is used. If too much dehydration during incubation takes place more sheets of filter material should be used next time. Some experimentation may be necessary to find the optimum hole size and filter material.

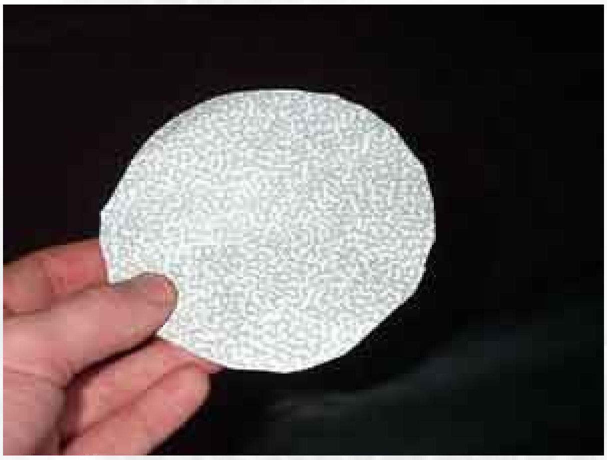
Lid with a hole.

The jars are filled with rye and water then the filter material is screwed tight under the lid. The lid can be screwed tight during sterilisation since the filter will allow steam to escape.

Rye and water

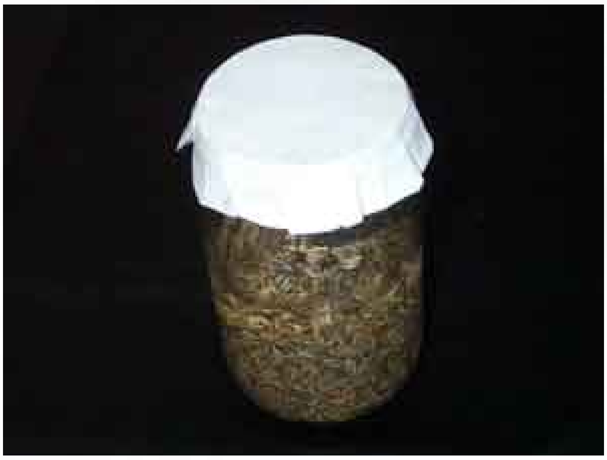
Rye and water combined in a jar

Filter disk

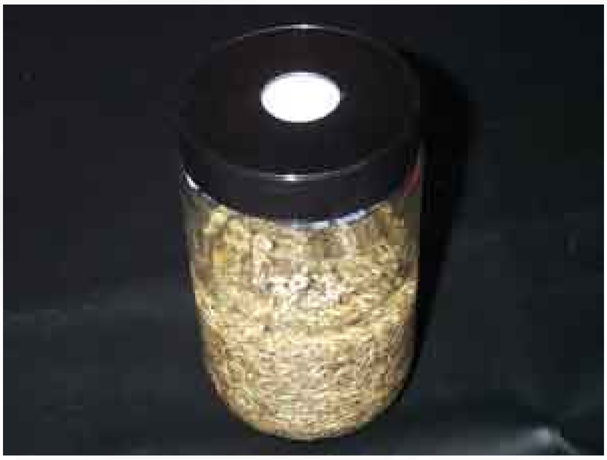


Tyvek filter

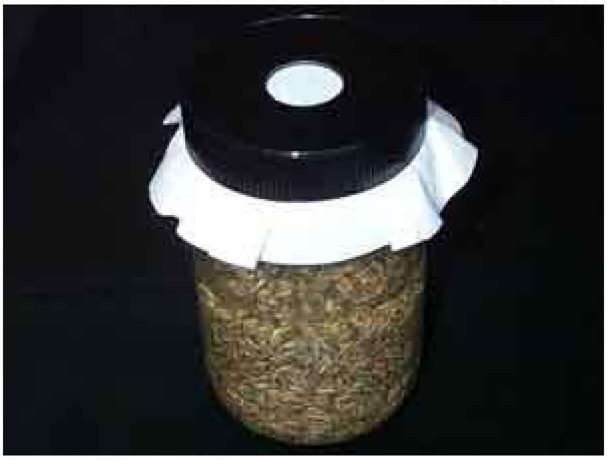
Lids on jars without a filter should never be screwed tight since the jars might explode/implode during sterilisation.
Jars are capped with a double layer of aluminum foil to keep the filter clean and dry for inoculation.



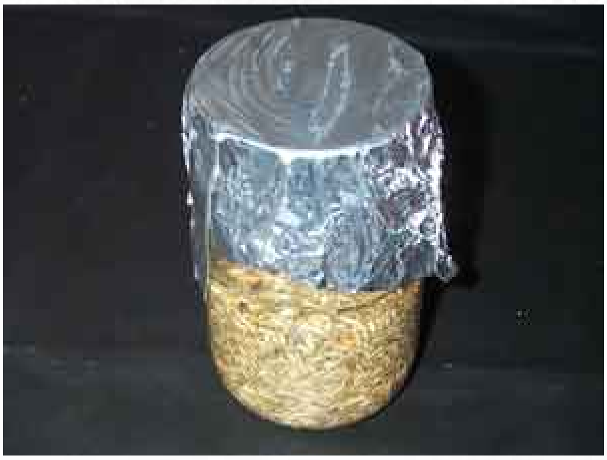
Jar with Tyvek filter



Tyvek jar with the lid on



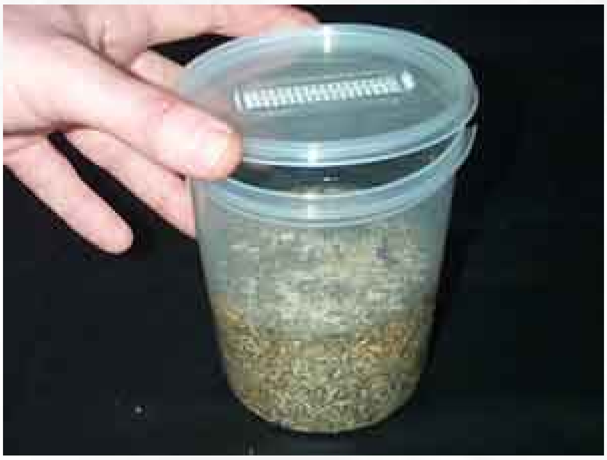
Jar with filter disk



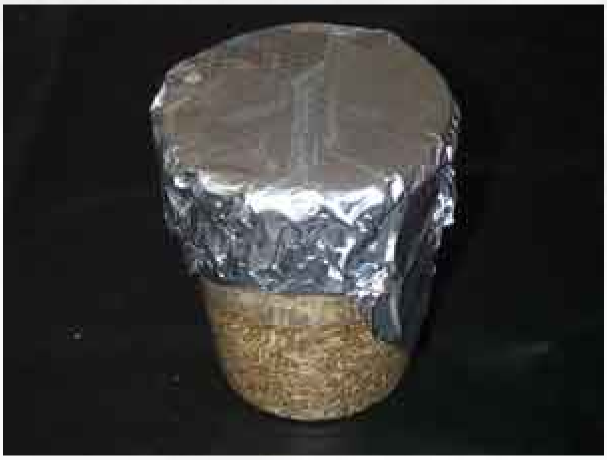
Jar capped with aluminum foil

Closing microboxes

These polypropylene containers come with a tight fitting lid. The lid contains a filter but this filter does not allow rapid venting of steam. Therefore microboxes should never be sterilised with the lid closed. Closed lids will result in deformation or other damage to the jars.
The container is filled with rye and grain then the lid is put on loosely or closed for 3/4. One 1/4 of the lid should always remain open.
The boxes are capped with a double layer of aluminum foil. As soon as the boxes come out off the cooker their lids should immediately be closed.



One edge should be left open

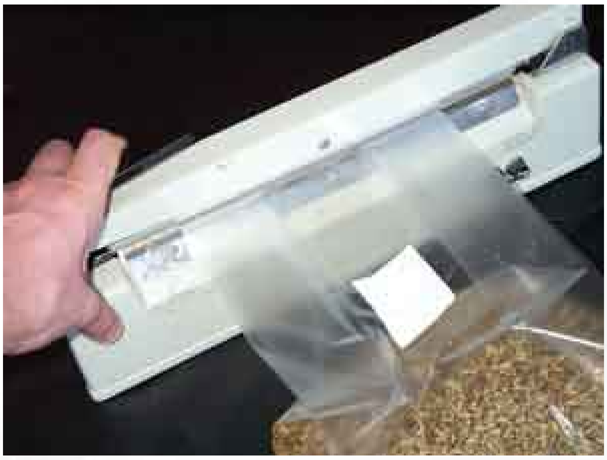


Microbox ready for sterilisation

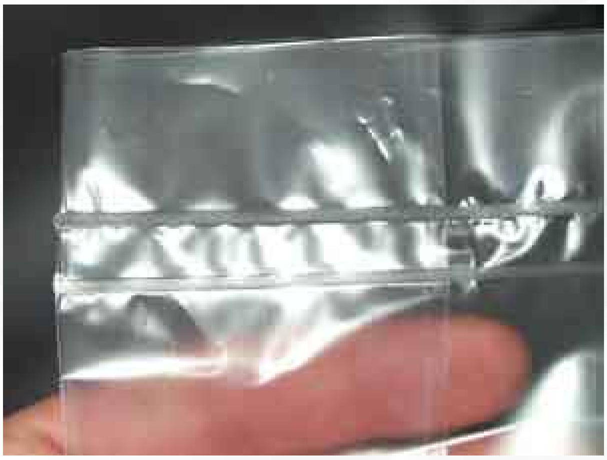
Closing filter patch bags

With some care bags can be sealed before they are sterilised. For more instructions look here. Sterilising open bags is possible but bags should be sealed the moment they come out of cooker or they should be left to cool down in a running flow cabinet.

Water and rye are combined



The bag is sealed with an impulse sealer



A good double seal

Bag ready for sterilisation

Substrate recipes

In general the more substrate is sterilised in a container the dryer it should be. Rye grain and water can be combined and subsequently sterilised. There's no need for pre-cooking the grain as is the case with birdseed. During the sterilisation cycle the rye grain will absorb the water but this will go a little uneven. The bottom kernels will be wetter than the top kernels so the jars need to be shaken while still hot to evenly distribute moisture throughout the substrate.

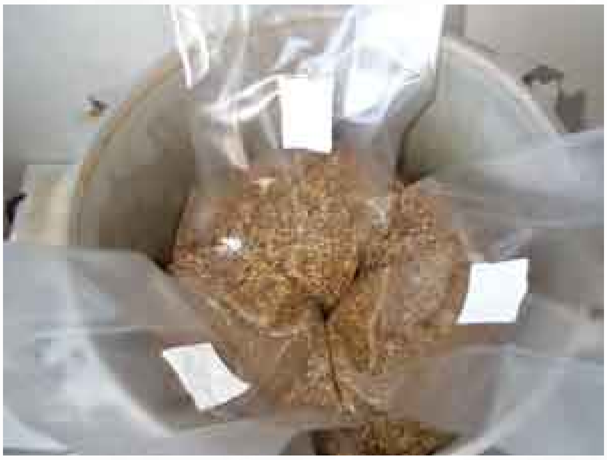
500 ml jar/microbox
125 g rye
160 ml water

1000 ml jar/microbox
250 g rye
280 ml water

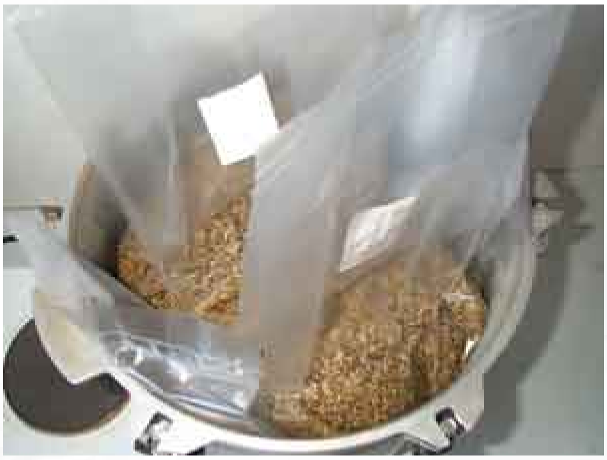
filter patch bag (4 liters effective)
1600 g rye
1350 ml water

Sterilisation

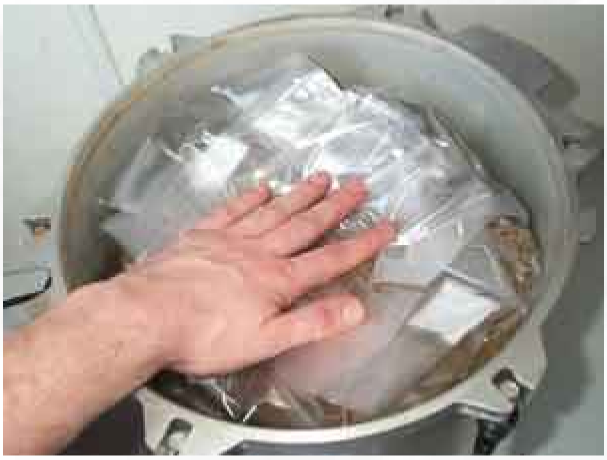
Jars and microboxes up to 1000 ml are sterilised for one hour at 121° Celsius. Bags require much longer; up to three full hours. More details about steam sterilisation in general and how to sterilise sealed bags can be found here.



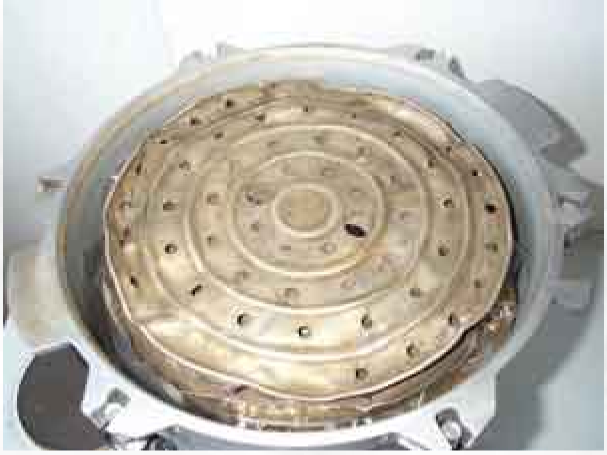
The first layer of bags



The second layer of bags



Flaps are folded down



The rack on top is very important

As soon as the microboxes come out of the cooker the lids should be closed completely, simply by pressing them downwards. When they have cooled down completely they can be inoculated.

The correct sterilisation pressure

Sterilised jar, rye has absorbed all water

Inoculation possibilities

Now that the substrate is sterilised and sitting comfortly in its container it's time inoculate. In theory one could keep the sterilised substrate indefinitely but in practice it's best to inoculate as soon as possible. As time goes by the substrate dries out and some contaminants may even be encountered after a few weeks of storage.

There are four practical means of inoculation:
1) Spores in a watery suspension (spore syringe)
2) Mycelium on agar (clone or multispore germination)
3) Mycelium on sterilised grain spawn
4) Mycelium in a watery suspension (liquid mycelium)

Spores in a watery suspension

A properly prepared or bought spore syringe can be used to inoculate sterilised rye. The hydrated spores easily germinate on the moist rye and form a mycelium. Often the first signs of germination can be observed after 3-10 days. Germination time depends on the strain and age of the spores. Well-hydrated spores germinate faster than those that have been just scraped off a spore print. When filter disks or Tyvek are readily available the syringe can be used to puncture the filter and to inject an amount of spore suspension. The amount of spore suspension used for one container depends on the availability of inoculant and the desired colonisation speed. More inoculant often results in somewhat faster growth. For jars and microboxes 1 ml of spore suspension would suffice. Of course, more spore suspension in combination with regular shaking of the jar would result in a (somewhat) faster development.
Bags are usually injected with 1-10 ml but they could very well be injected with up to 100 ml. Spore injection is an easy and efficient way for novice cultivators to inoculate small batches of spawn.

Mycelium on agar

Agar squares can be cut from a petri dish with a sterilised scalpel and these can be dropped into the jar. Since the jar has to be opened for this method to work an (improvised) inoculation hood is useful. One or more squares are dropped into the jar or microbox. These containers are are shaken and incubated.
This method will not work for bags since it's not practical to cut open a sealed bag to introduce the agar squares.

Mycelium on sterilised on grain spawn

In theory this would be the best and fastest way to propagate huge amounts of spawn but in practice it's not that easy. It's only possible to do these transfers in a totally sterile environment or huge amounts of contamination will be encountered. We found that this method has limited potential for home cultivators.

Mycelium in a watery suspension

This is the way to go if you have serious money to spend and have very good sterile techniques. It's possible to create huge amounts of liquid spawn from a single Petri dish by chopping it up in a laboratory blender and then diluting this broth The total amount of mycelium is of less importance than the amount of water it is delivered with. Although initial startup growth is slow, it will start in many points throughout the substrate.

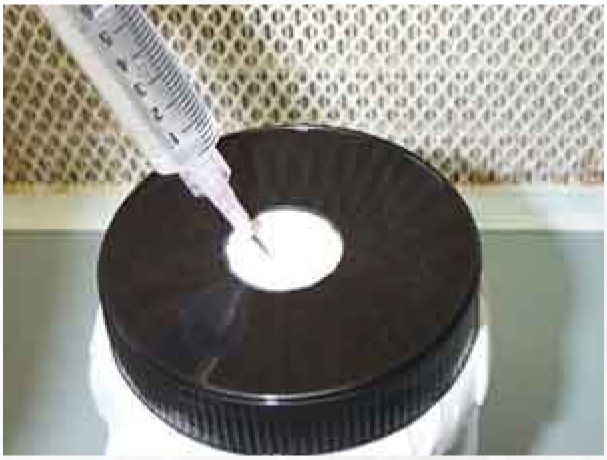
Inoculations in practice

In general the following goes: the longer the sterilised substrate is exposed to the outside air during inoculation, the cleaner the environment should be. When inoculating just a few jars by puncturing the lid with a syringe needle, a cleaned tabletop in the kitchen should be fine. When inoculating open bags with grain spawn a professional flow cabinet is indispensable. Airborne contaminants often settle on the top of the substrate, so when nasty fungi start to grow on top of the inoculated substrate the substrate was probably exposed to unclean air for too long.

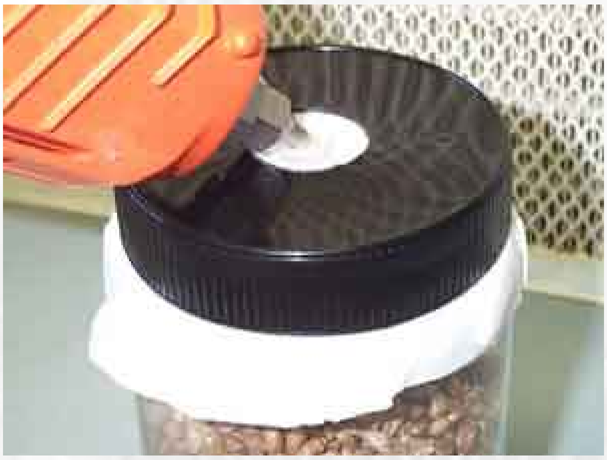
In theory one could get a 100% success rate in a flow cabinet but in practice even under the most hygienic conditions contaminations will be encountered. Contamination rates below 10% can usually be considered good.

Inoculation of jars and microboxes

The easiest method to inoculate jars and microboxes is with a syringe with spore-/mycelium-suspension. The needle of the syringe is heated until red hot and left to cool for 10-15 seconds. The aluminum foil of a jar is removed and excess moisture is wiped off with a clean tissue. The filter (Tyvek/filter disk) is punctured with the needle and some (1 ml) of suspension is injected into the substrate. The needle is withdrawn and the hole is immediately sealed with a drop of hot glue. Jars can then be shaken and incubated. Instead of glue, a piece of tape could also be used but we found that hot glue is the perfect way to seal jars. Even a small and cheap glue pistol will do the trick.

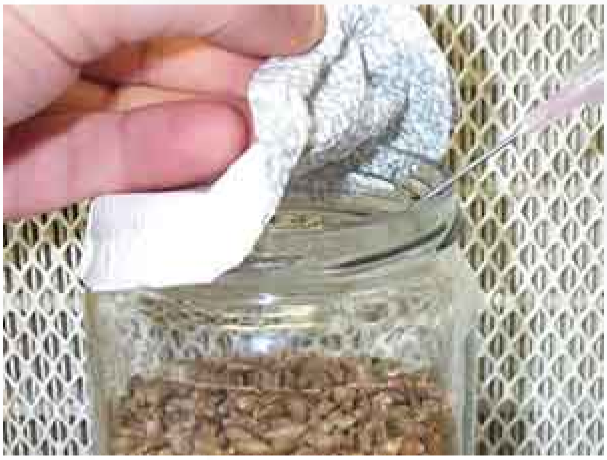


Puncturing the filter

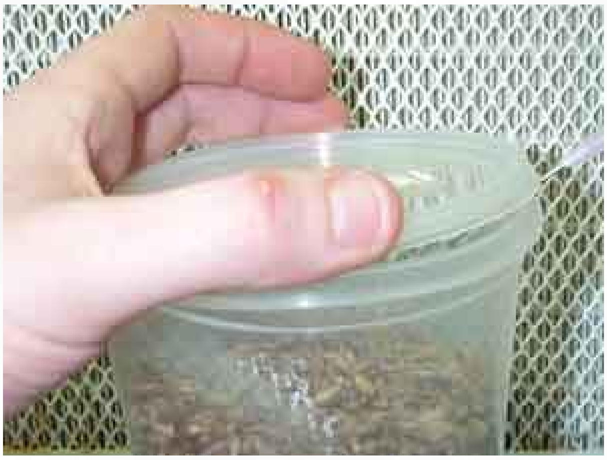


... and glueing it shut

When the lid or filter can not be punctured as is the case with microboxes, the lid should be opened just a crack and the needle can be introduced through there. The needle is withdrawn, the lid is closed and the microbox/jar is shaken and incubated. Since there is more air exposure with this method an (improvised) inoculation hood is desirable.

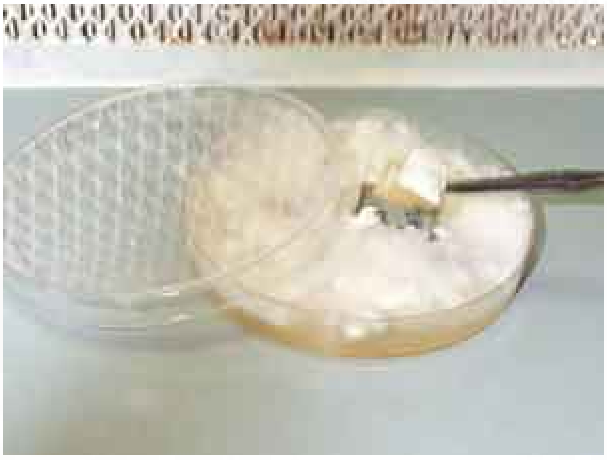


A jar inoculated with a spore syringe

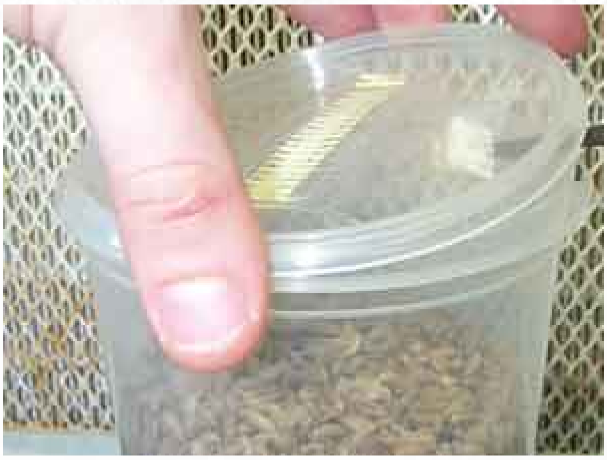


A microbox inoculated with a spore syringe

When inoculating with agar squares there's no choice but to open the lid just enough to introduce the agar. Again, an (improvised) hood is desirable for this kind of work.



Squares are cut from the agar

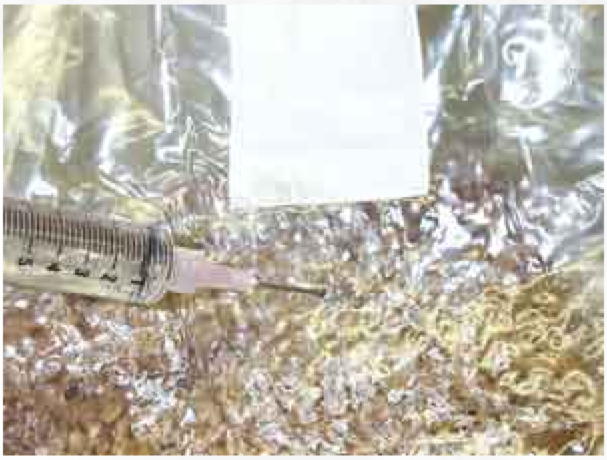


These squares are dropped on the substrate

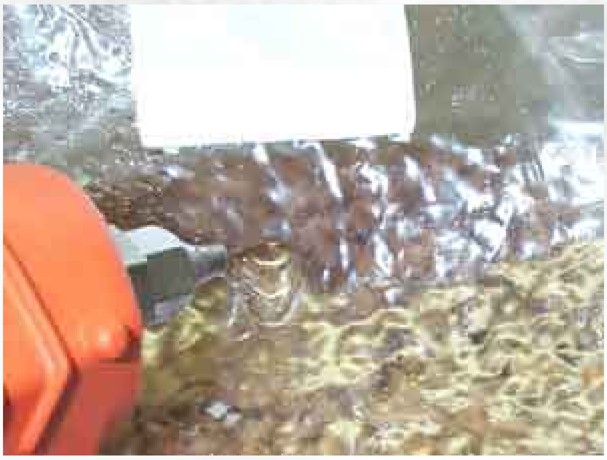
Inoculation of bags

When working with sealed bags the inoculant can only be introduced through means of injection. It's not practical or advisable to cut open a sterilised bag only to re-seal it after inoculation. Working with open bags is not advisable for those without a laboratory and a flow cabinet. Grain to grain transfers will not be discussed here.

The injection site on the bag is cleaned with an alcohol soaked tissue, then the (flamed) needle of the syringe is introduced. Some liquid is injected into the bag (1-200 ml) and the needle is withdrawn and the hole is sealed with a drop of hot glue. A spore syringe is fine for this.

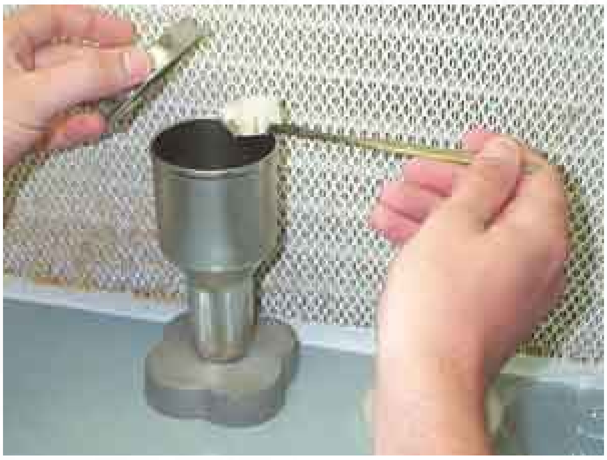


the bag is punctured with the needle

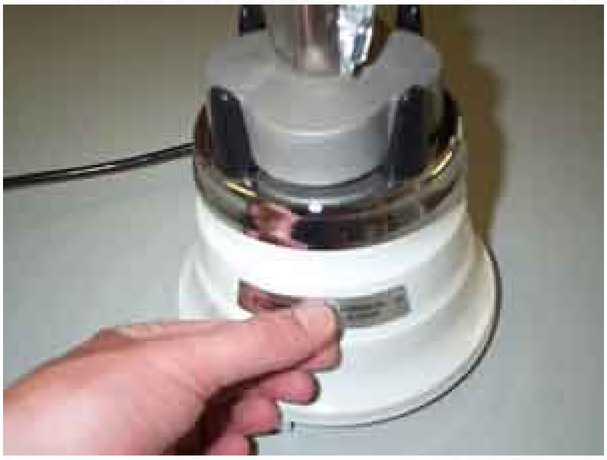


The hole is glued shut

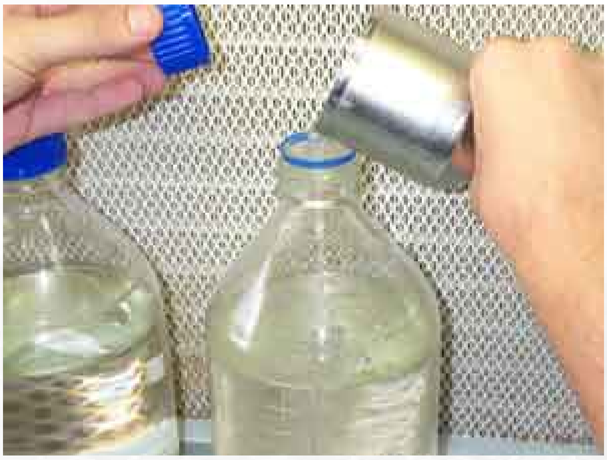
Below you will find a summary of the inoculation method MushMush employs. It involves chopping up an agar culture and using a peristaltic pump to deliver the diluted mycelium to the sealed bags. We understand that there are few people that might actually try this (the equipment is pretty expensive) but it might give you an idea of the possibilities.



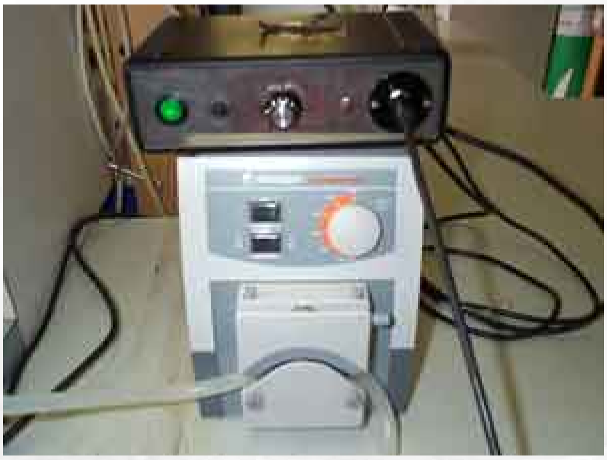
Colonised agar is transfered to a sterilised blender



Sterile water is added and the agar is chopped up

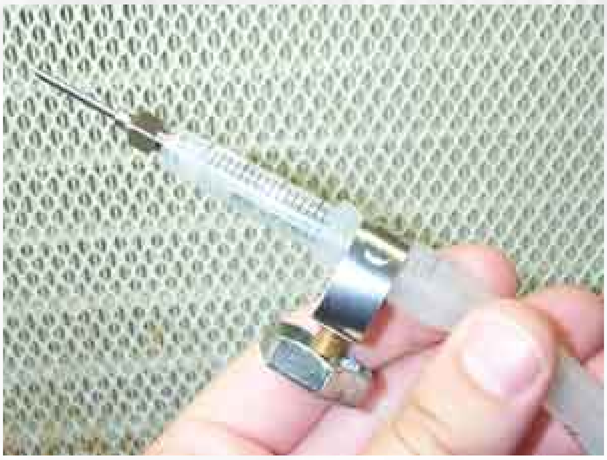


The blended agar is divided over two bottles with sterile water

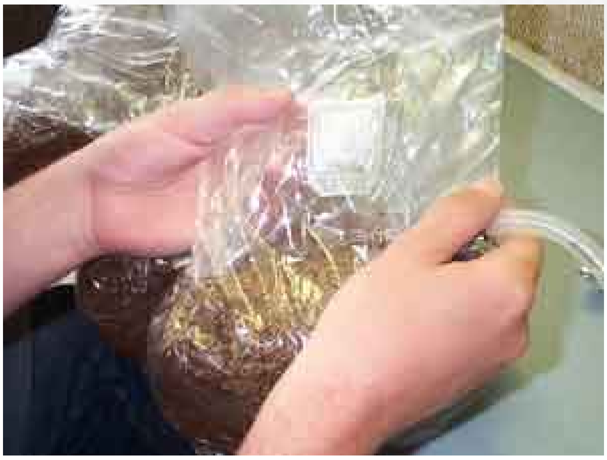


A peristaltic pump is used to dispens the mycelium suspension

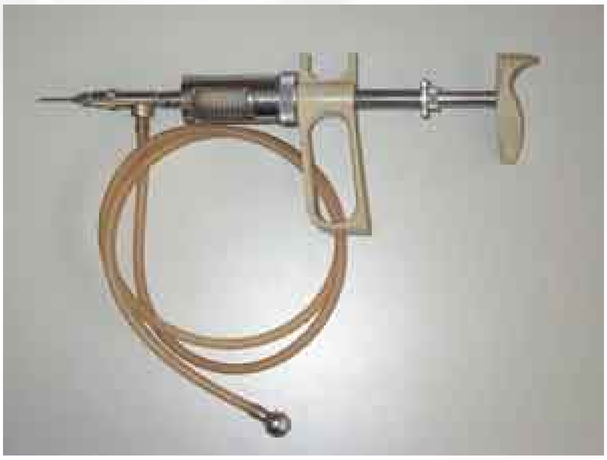
The pump is controlled with a foot pedal switch



A short thick needle is used to inject the liquid mycelium



The bag is punctured and the pedal is pressed



A cheaper solution is to use a self-filling syringe

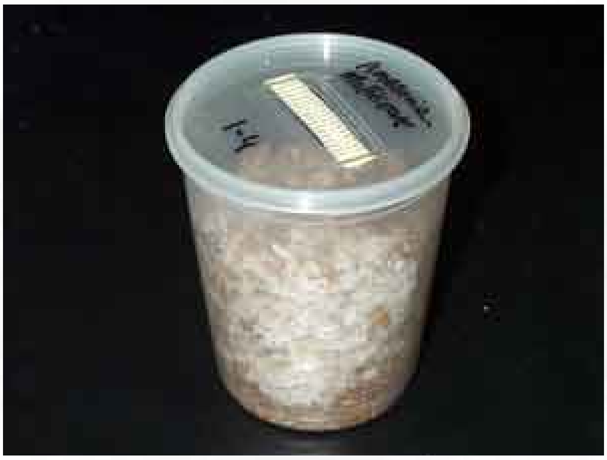
Incubation

The inoculated grain should be incubated at the temperature that is optimal for the species being cultivated. A temperature that is too low will result in slow germination/growth. A temperature that is too high will make the mycelium exude yellowish metabolites (sweat) that eventually sicken the spawn.

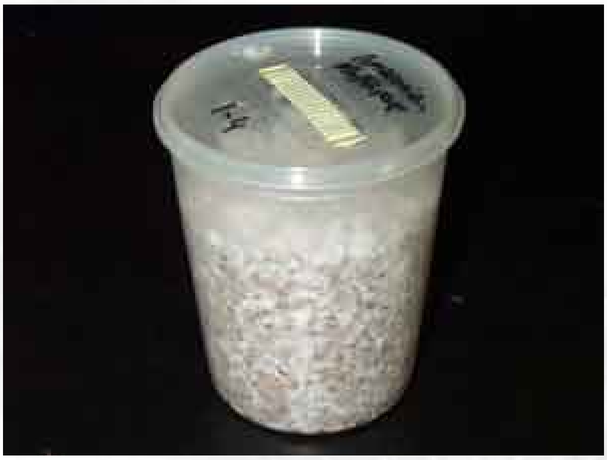
Since the growing mycelium produces heat a rise in temperature should be anticipated. A few jars will probably not heat up to critical temperatures but developing spawn bags might very well, especially in the summertime. Bags that stand at too high a temperature will often contaminate will thermophilic moulds (often black pin moulds). Take extreme care when handling contaminated substrate as some species of moulds and bacteria can cause serious diseases in humans.

To prevent condensation in the containers they should be kept at a temperature that is as constant as possible.

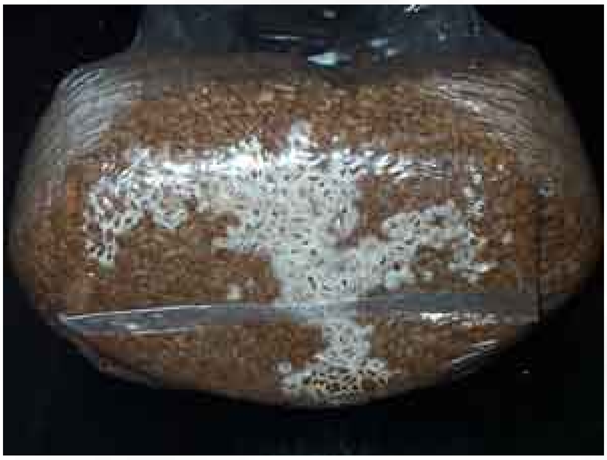
To speed up development jars and bags should be shaken regularly to distribute the colonised kernels throughout the substrate every few days. When the grain is completely covered with mycelium it's ready for further use.



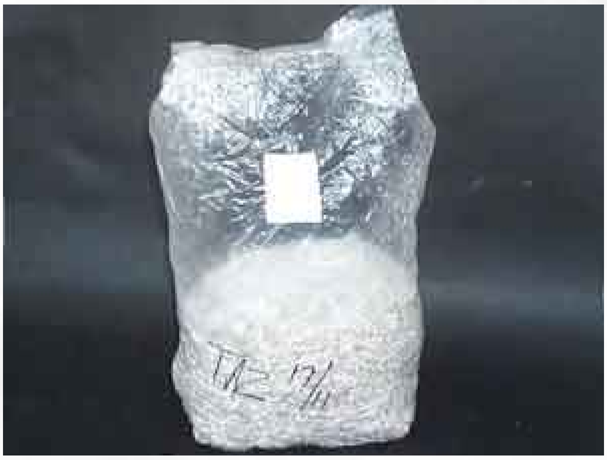
Microbox during colonisation



Microbox totally colonised



Bag during colonisation

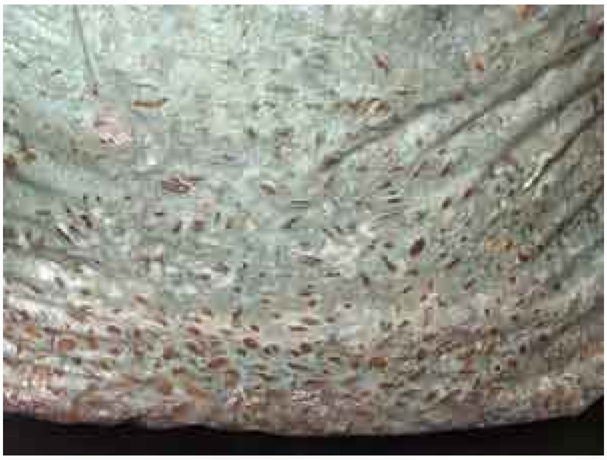


Bag totally colonised

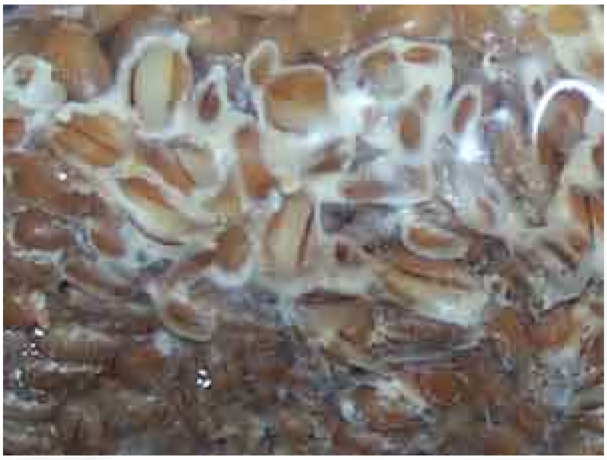
Contamination

Contaminated spawn will be encountered for sure. Contaminants show up in the form of fungi and bacteria. Fungi often grow whispy or powdery and come in an assortment of funky colours: blue, green, pink etc. Bacteria show as a slimy film on the grain kernels. When in doubt, take a smell at the the filter of the suspected container. A medicinal or musty odor often indicates fungi while a sour/sweet/rotten or alcoholic smell is a sure giveaway for bacterial contamination.

Perhaps needless to say, the contaminated spawn should be discarded. Bags can be thrown out as a whole. Jars should be cleaned out but only after they have been sterilised to kill the contaminants. Some contaminants can cause serious diseases in humans and the fact that you are reading this probably means that you are not experienced enough to distinguish harmless from dangerous contaminations. Never underestimate the health dangers associated with contaminants!



A bag contaminated with mould



A slimy bacterial contamination

Refrigeration

The spawn of most species can be refrigerated until ready for use. Although vitality declines most species can be stored for a few weeks at 4-7°C. *Panaeolus* mycelium however should never be refrigerated because it will loose it's vitality within a few days.

Cultivation on cased sterilised grain

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Ccultivation_of_psilocybe_cubensis_on_sterilised_rye_grain&old

Overview of the procedure

Mycelium of *Psilocybe cubensis* is grown on sterilised grain. The colonised grain is covered with a wet soil like mixture, this is called 'casing'. The mycelium will grow through the casing layer and will partly colonised the casing surface. Now the casings are exposed to fruiting conditions and the casing is kept moist. Mushrooms will form on the casing layer.

A bag of healthy spawn.

Testing the colonised grain

Before casing the colonised grain should be tested for contamination. This is done by shaking the spawn containers (bags or jars) 24 hours before putting on the casing layer. If the grain is contaminated with molds the whole bag or jar will turn green, blue or grey. Bacterially contaminated grain will not recover at all and will often smell very foul (sour, alcoholic or rancid).
If the spawn recovers nicely it's ready for use.

Casing

Once the grain is completely colonised it needs to be 'cased' before mushroom formation will take place. 'Casing' is the process of putting a wet soil like mixture on top of the colonised substrate. This is done for 4 important reasons.

1. Preventing the substrate from drying out
Mycelium is sensitive to dry air. Mycelium that is exposed to dry conditions for too long may form a leathery matted surface on which no mushrooms will grow. The moist casing layer prevents this and the mycelia will form a healthy network in the casing layer. The casing surface should be kept moist by regular waterings.

2. Storing and supplying water to the growing mushrooms
Developing mushrooms pull a lot of moisture from the casing layer. Since moisture in the casing soil can be replenished by watering it functions as a water reservoir for the growing mushrooms. A casing layer should be able to absorb water and to supply it to the mushrooms.

3. Providing a good microclimate for pinhead formation
With all small bumps and valleys the rough surface of a casing layer provides a good humid and protected environment for young mushrooms to form.

4. Supporting the growth of beneficial microorganisms
Although *Psilocybe cubensis* can fruit on a sterilized casing layer many species require certain bacteria to be present in the casing soil. This has consequences for the type of heat treatment that is chosen. A brief pasteurization will hinder most animal and fungal competitors in their growth while leaving most bacteria unhindered. Complete sterilization in a pressure cooker may only be used for species that do not require these soil bacteria.

Casing mixture recipe

The following recipes have proven themselves over the years as good all round casing mixtures:

- 10 parts of peat
- 5 parts of coarse vermiculite
- 2 parts of limestone

and

- 10 parts of wetted coco coir,
- 5 parts of coarse vermiculite,
- 1 part of limestone

(all ingredients by volume)

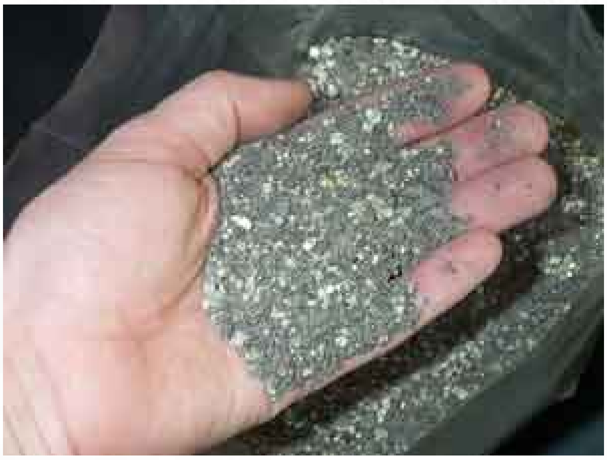
The exact ratio is not that important. As long as sufficient limestone is added the pH will rise to between 7-8. Many types of limestone are available differing in origin, composition and grit size. We prefer Marl (coral derived limestone) but most other types will do just fine. The coarser the particles the more is needed to to obtain a proper pH. Since peat is very acidic in nature it's wise to always add more limestone than to coco coir. It's nearly impossible to overdose on limestone.

The three ingredients for casing mixture

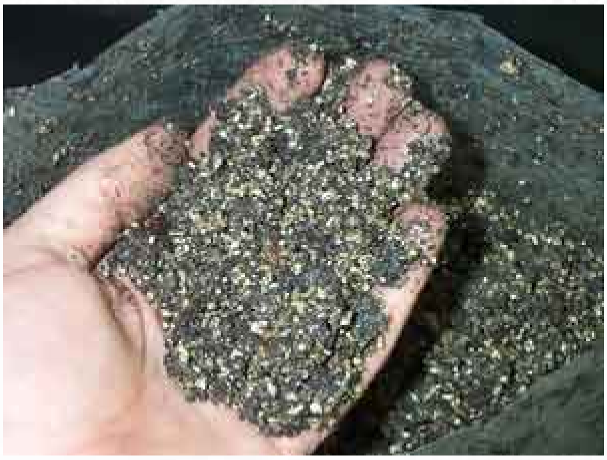
The ingredients are mixed in a bucket or bag in dry form and large particles such as undecomposed wood are removed. These particles might give contamination problems later on.

Once the ingredients are well mixed water is added. The object here is to get as much water into the mixture as possible without turning it into mud. It's wise to hold some dry ingredients apart in case the mixture gets too wet by accident. By adding some dry ingredients the excess water can be absorbed.

Proper wetness is achieved when a handful of mixture does not leak water when held loosely. The mixture however should release plenty of water when squeezed. It should feel wet, not soggy.



Casing mixture dry form



Casing mixture wet form

Alternative mixtures and considerations

The above recipes are not holy. We have achieved good results on many different types of casing mixtures. Some cultivators use plain vermiculite with great results but this is not advised for novice cultivators. Moisture content in plain vermiculite is very difficult to observe by eye (very wet and nearly dry vermiculite look the same). Vermiculite can be omitted in the above recipes but the mixture will be less rough in structure.

An important thing to mention is that the casing layer is not intended to supply the mycelium with nutrients. Any easily digestible compounds (whether sterilised or not) in the wet casing layer will surely contaminate. The conditions for the growth of competiting organisms are near optimal in the wet and warm casing layer. Additions such as flours, malt extract or sugars will not boost yields but only lead to contamination.

Heat treatment of the casing mixture

To free the casing mixture of any unwanted organisms (mainly fungal and animal competitors) it can be heat-treated. Although some cultivators get away without any heat treatment we feel that this is bad advice.

Untreated mixtures (except plain vermiculite) are much more likely to contaminate than pasteurised or sterilised mixtures.

There are two good methods for home cultivators:

Pasteurisation in a microwave oven

This method will not completely sterilise the mixture but will suffice for most cultivators. Most contamination problems associated with the casing layer involve fungi. Most of these fungi are killed are relatively low temperatures which are easily reached by microwaving.

The mixture is put in polypropylene bags or jars and some extra water is added to make up for evaporation. Care is taken to leave the lids a crack open or to open the bags to let the steam escape. Not doing this may result in an explosion!

The microwave is turned on at full power for approximately 30 minutes (for one 5 liter bag of soil). The bag is take out of the microwave with heat-insulating gloves, sealed with an impulse sealer or simply taped shut. When the soil has cooled down it's ready to use. Soil prepared in this manner is often a little on the dry side. Clean water may be added after sterilisation but before applying the mixture.

(semi-)Sterilisation in a pressure cooker

This method will, depending on the duration of the treatment, pasteurise, semi-sterilise or completely sterilise the casing mixture.

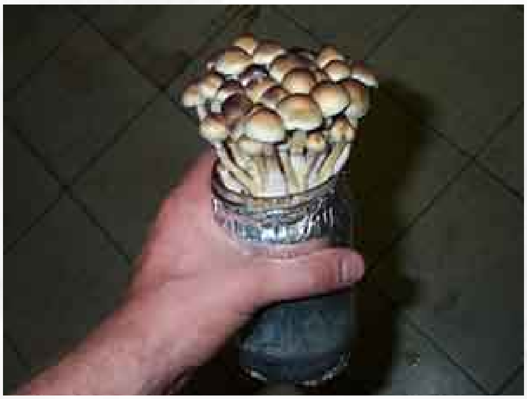
When a big pressure cooker is available this method may be faster then using a single microwave oven. The mixture is put in bags or jars and these are put in a pressure cooker. The contents is sterilised for the

appropriate amount of time and left to cool in a clean place. Here again great care is taken to leave jars always a crack open to prevent them from exploding/imploding. When the mixture has cooled down it's ready to use.
As a rule of thumb for the appropriate sterilisation duration we take half the time it would take to completely sterilise the same amount of rye grain. For a filled 20 liter cooker this means 1 hour at 121°C. This treatment does not completely sterilise the mixture but will give a very good resistant casing layer. For complete sterilisation use the duration for the same amount of grain.

Casing the colonised substrate

Casing jars

If the colonised substrate is in (wide-mouth) jars it can be left in the jars, however the volume/surface ratio is not optimal. Still substantial yields can be achieved with this method. The big advantage is that the complete casing process is very simple and leaves very little space for contamination.
Jars are cased with 1-2 cm of wet casing soil which is leveled by tapping the jar. The cap is replaced and the jar is incubated in the dark until the mycelium is poking up through the casing layer. Cased jars should be kept at the same temperature as the incubating spawn (25°C). At this stage the cap is removed and the jar is wrapped in aluminum foil. The foil is to prevent exposure to light of the colonised substrate. Not doing so will result in mushroom forming inside of the jar instead of on the casing soil.



A fruiting cased jar

Cased trays

When the colonised substrate is poured into trays which are cased a much better volume/surface ratio can be achieved. This results in more mushrooms in less time compared to cased jars.
First the grain is broken up by shaking. The broken up grain is divided into 1 liter trays and subsequently cased with 1-2 cm of casing mixture. The casing can be applied with a clean large spoon or with your hands wearing latex gloves.

Spawn before ...

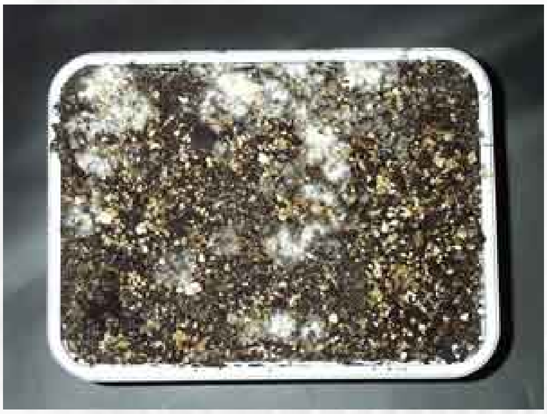
... and after shaking

The spawn is poured into the trays ...

... and is topped off with casing mixture

The cased trays are covered with aluminum foil and incubated in the dark until the mycelium is poking through. Cased trays should be kept at the same temperature as the incubating spawn (25°C). Now the foil is removed and the trays are exposed to fruiting conditions. Normally this is one week after casing.

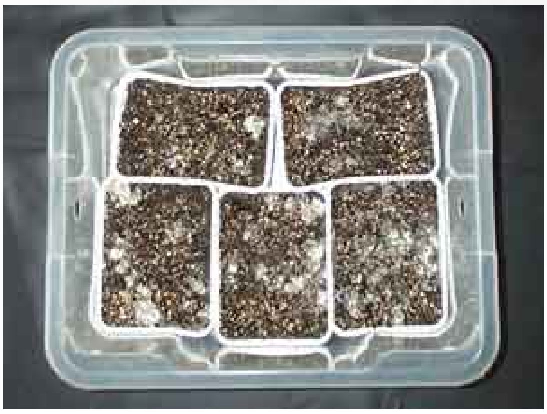
The cased trays are covered with aluminum foil



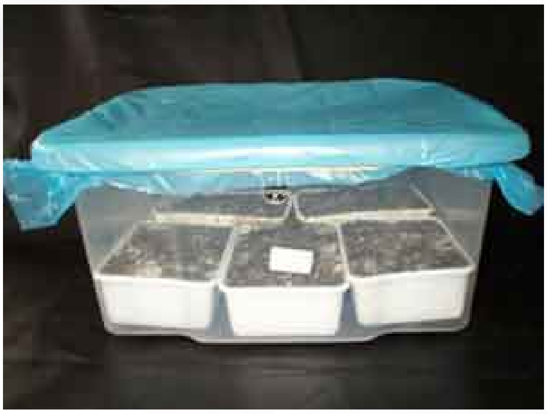
After a few days mycelium will be growing through the casing layer

Fruiting the cased substrate

Some cultivators use very elaborate set-ups with humidifiers, cool-mist devices and such. Psilocybe cubensis is an easy mushroom to fruit and we have never found these necessary.
A very space efficient fruiting container consists of a simple transparent plastic bins covered with polyethylene sheeting. There are stackable types available which allow one to grow in 10 bins or more on top of each other. Needless to say it can't get more space efficient than this. For air exchange some holes are drilled in the sides of the bins. These holes can be covered with mesh to keep out flies.



The fruiting container consists of a simple plastic bin



The bin is covered with plastic sheeting to maintain the proper humidity

After 10 days small mushrooms form

The casing soil is kept moist all the time

In our case five trays can be put in one bin and the evaporation of the casing surface is enough to maintain proper humidity inside the bin. The holes provide some air exchange. We always cold-shock the harder-to-fruit strains (we put them in the fridge for one night before putting them in the bins). For easy fruiting strains (i.e. Equador cubensis) this is not necessary.

As for as temperature is concerned: *Psilocybe cubensis* is an easy mushroom. From our experience trays and jars will fruit in the range between 19-30°C, Although a temperature of 25°C is most desirable. In other words: if the temperature is comfortable for you, it is too for the mushrooms!

The casings need some light. In the dark mushrooms will not form! Any kind of light will do (daylight, fluorescent, incandescent) but they should not be exposed to full sunlight for obvious reasons. If the casings receive (too) little light mushrooms will develop long and spindly.

The casings are misted each day and the casing is never allowed to dry out. Directly after a flush is picked watering is increased because the maturing mushrooms pull a lot of moisture from the casing soil. It's very difficult to give explicit directions on a watering regime. One has to develop a 'feeling' for it.
Depending on the strain the first pinheads will appear 6-15 days after putting the casings in the bins. The mushrooms will mature in 5-7 days after which they can be picked. We normally let the casings produce 3 flushes, but they may (when watered properly) produce as much as six flushes! The surface of the casing is kept clean by removing aborted mushrooms. If contaminations show up on the casing surface it's often better to throw the trays away.

A fruiting cased tray

A bin with 5 fruiting trays

Cased trays that fail to fruit

Casing completely colonises but fails to form mushrooms

When the environmental conditions aren't right for the strain being cultivated the mycelium will not form mushrooms but will continue to colonise the casing surface. If the situation is not corrected the trays soon become useless. The matted mycelial surface dies back and forms a crust that prevent the casing from absorbing moisture which results in drying out and eventually death.

In general this is caused by:
a) A lack of fresh air
b) A relative humidity that is too high
c) A temperature that is too high
d) A combination of the above.
Although some strains have more of a tendency to colonise the surface a fully colonised casing (no casing soil visible) is undesirable. To correct this situation the surface should scratched open with a clean fork to a depth of approximately 1 cm and environmental conditions should be adjusted to allow fruiting.

Mycelium doesn't colonise the casing surface at all

If the casing doesn't show any mycelium poking through within a few days the casing soil is probably too dry. Mycelium will grow wispy and thin in dry casing mixture. There is no objection to watering the trays before they are exposed to fruiting conditions but it's wise to wait at least one day after casing to allow the mycelium to recover.

Strange growth is showing up on the casing surface

Various molds may show up in the casing soil. Although mushrooms may still be formed on the contaminated casing it's wise to throw them out as they pose a risk to other trays nearby. A properly heat treated mixture that contains no nutrition will give very little problems with mold.
Green and blue molds can often be traced back to contaminated grain spawn. It's important to make sure that the spawn that is cased is absolutely clean. A simple test is to shake to spawn 24 hours before casing. If the mycelium recovers it's fine to use. If it does not or strange colors or structures (powder-like growth) appear the spawn is contaminated and should be thrown out.

Cultivation of Psilocybe cubensis on sterilized rye grain

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/rye.htm

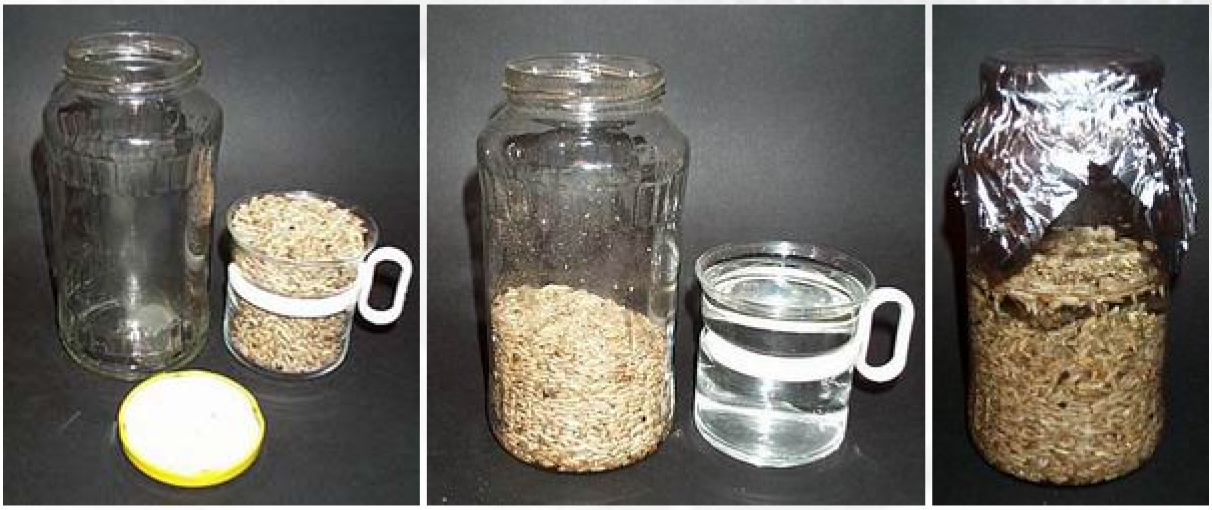
We cultivate *Psilocybe cubensis* on sterilized rye grain. This species can be grown on a wide variety of substrates such as rice, birdseed, pasteurized straw, compost and dung. We however think that, of all of these, rye grain is the most suitable for the small-scale cultivation of *Psilocybe cubensis* for research purpose because it's both cheap and easy to work with. Most other grain types have the disadvantage of having to be boiled or steeped before sterilization or else the kernels will clump together. Cultivating mushrooms on straw, compost or dung is possible but an art in itself.

Preparation of rye grain spawn

We prepare rye grain spawn by combining equal volumes (1 cup) of rye grain and water in a jar. In our case this comes down to (roughly):

- 175 grams of rye
- 230 ml of water

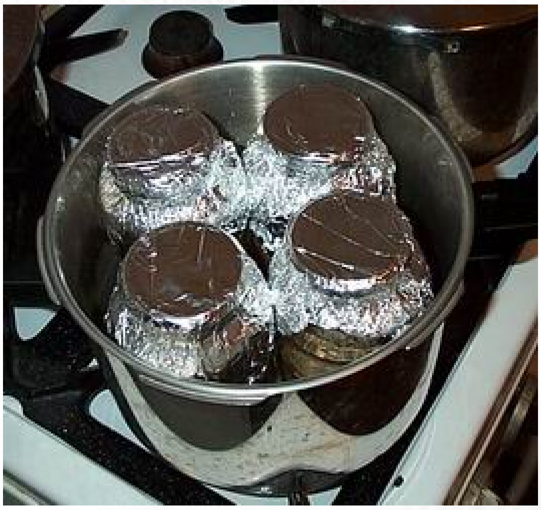
We use 720 ml jars with metal lids. After the water and rye have been filled into the jars, the lids are put on but NOT screwed tight! The lids MUST remain loose! Then a double layer of tinfoil is crumpled over the lid and top part of the jar. Now the jars are ready for sterilization. As an extra precaution some kind of filter (filter disc, Tyvek) can be inserted under the lid. For this method the lids must be punctured to facilitate air exchange.



Different ratios of rye and water have been suggested by literature. We recommend you do a test batch with different ratios of water and rye to see what works best for you. The 1:1 ration we use contains the maximum amount of water the we could use. When using larger volumes (big jars or bags) less water should be added or the bottom kernels will turn to brown goo. When using the colonized rye grain to directly fruit the grain can be somewhat wetter then when it's used to inoculate (non sterile) bulk substrate. Exploded kernels with their starchy inside exposed can flourish with bacterial bloom upon contact with non sterile materials.

Sterilization

The jars should be sterilized in a pressure cooker or autoclave, a normal pot will NOT suffice. First a layer of water is poured into the cooker. The jars are placed in the pressure cooker making sure that the lids are loose!



Now sterilize the jars for one hour according to the directions supplied with your pressure cooker. If you are using bigger jars then the sterilization time should be prolonged. (we sterilize 1.5 litre jars and spawnbags always for 2 full hours). Once the cooker is no longer under pressure the jars should be taken out and the grain in the jars should be shaken loose to mix the wet and dry kernels. The jars should then be allowed to cool in a clean place. Always check the jars for cracks before shaking! When the jars have cooled to room temperature inoculations can take place. As the jars are cooling down the lids should remain loose or else they will form a vacuum inside of the jar. When this vacuum is broken, dirty air is sucked inside and the jar will most likely contaminate.

Inoculation

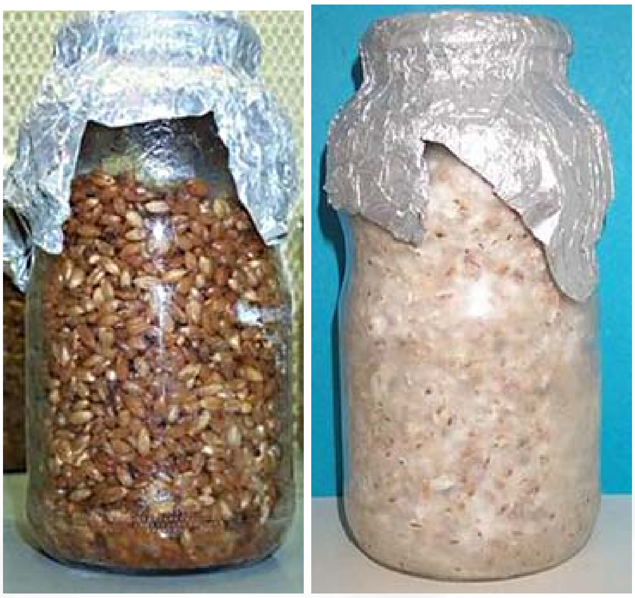
When the jars have cooled down completely they are ready to be inoculated. If you inoculate the jars while they are still hot the spores or mycelium might get killed. You can use a spore syringe, mycelium syringe, agar squares or whatever kind of inoculant you want. The most important thing to remember is to WORK CLEAN! When using syringes always flame the needle before commencing inoculations. When using agar squares always flame the scalpel! Be careful!

ALCOHOL, LYSOL AND MOST OTHER DESINFECATNTS ARE HIGHLY FLAMMABLE!!!

Even a simple hood made of a cardboard box prevents prevent drafts and subsequently contamination. Do not expose the sterilized grain to air longer then absolutely necessary. Open the lids of the jars just a crack and work swiftly. After inoculation the lids of the jars are closed and the jars are shaken. Then the lid is loosened again so the mycelium will be able to breathe.

Use your common sense and do not put yourself in risky situations. Again, most disinfectants are both toxic and flammable. When working in the presence of an open flame do not use any kind of other flammable materials. Also, do not overdose on disinfectants, most are seriously dangerous to your own health.

UV disinfectant lights are dangerous as they can cause damage to your eyes and cause skin cancer.

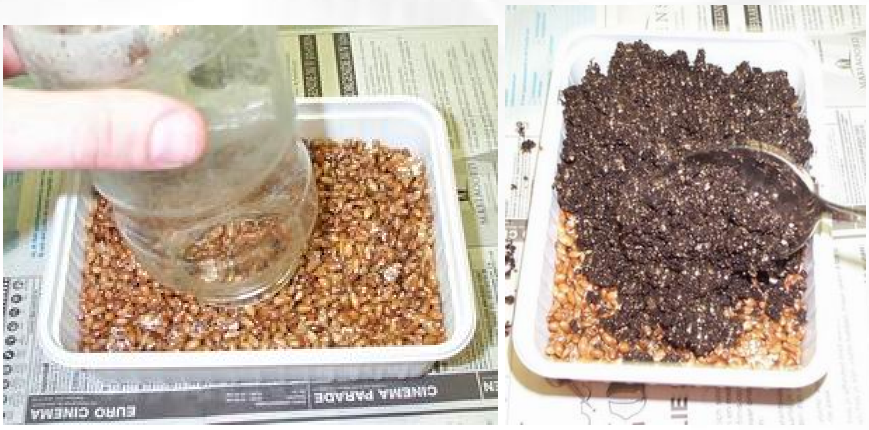


Colonization

After inoculation the jars are put in a clean and draft free location. Mycelial growth has its optimum at 30°C, but beware! Incubating jars generate heat themselves! The mycelium will grow in a wide range of temperatures. We normally put our jars at room temperature (20°C) or slightly higher. When mycelium starts to grow in only a few spots we shake the jars to redistribute the colonized kernels. This speeds up colonization dramatically. Depending on the temperature and the method of inoculation the grain can be completely colonized in 5-20 days.

Casing of rye

When the grain in the jars is completely colonized it needs to be cased. For this purpose we use 1-litre disposable plastic trays. The colonized grain kernels of one jar are shaken loose are poured into a tray. If there are lumps within the grain these can be broken up with the clean rim of the jar. The surface of the grain is leveled evenly. Using a big spoon and a fork the grain is now covered with a thin layer (1.5-2.0 cm) of casing soil. We always try to keep the casing surface even while at the same time keeping it rough (with small valleys and hills) The cased tray is then covered with tin foil and put in a clean location (20-25°C). Within a few days you will notice the mycelium growing through the casing soil. Depending on the strain (some strains fruit earlier and easier then others) the casings are now ready to be exposed to air and light to start the fruiting cycle.



Recipe and Preparation of the casing soil

We use the following recipe:

- 10 parts of peat
- 5 parts of vermiculite
- 2 parts of limestone (Marl)

The ingredients are mixed in dry form and while stirring water is added. The amount of water of course depends on the moisture content of the peat. The object is to get as much water in the casing soil as possible without turning it into mud. If the casing gets too wet just add a little more dry ingredients. This casing soil is then filled into oven bags (made of nylon), autoclave bags (PP) or jars and these are sterilized for one hour in the pressure cooker. When the soil has cooled down to room temperature it's ready to use.

Often an alternative method that utilizes the microwave oven can be used. The moistened casing soil is filled into heat resistant bags or jars and is sterilized for 20 minutes at maximum power in the microwave. Just add some extra water to make up for water loss from escaping steam.

Fruiting

Some cultivators use very elaborate set-ups with humidifiers, cool-mist devices and such. We have never found this necessary. The fruiting containers that we use consist of simple clear plastic bins that are covered with polyethylene sheeting. These bins are stackable and thus very space efficient. For air exchange some hole are melted in the sides of the bins. These holes can be covered with mesh to keep out flies.

Basically, five cased trays are put in one bin and the evaporation from the casing surface is enough to maintain the proper moisture inside the bin. The holes provide some air exchange. We always cold-shock the harder-to-fruit strains (we put them in the fridge for one night before putting them in the bins). For easy fruiting strains (i.e. Ecuador cubensis) this is not necessary.

The casings are misted each day and the casing is never allowed to dry out. Directly after a flush is picked watering is increased because the maturing mushrooms pull a lot of moisture from the casing soil. It's very difficult to give explicit directions on a watering regime. You will have to develop a 'feeling' for it.

Depending on the strain the first pinheads will appear 6-15 days after putting the casings in the bins. The mushrooms will mature in 5-7 days after which they can be picked. We normally let the casings produce 3 flushes, but they may (when watered properly) produce as much as six flushes! Keep the surface of the casing as clean as possible by removing dead pinheads (aborts) as these can lead to molds showing up on the casing surface.

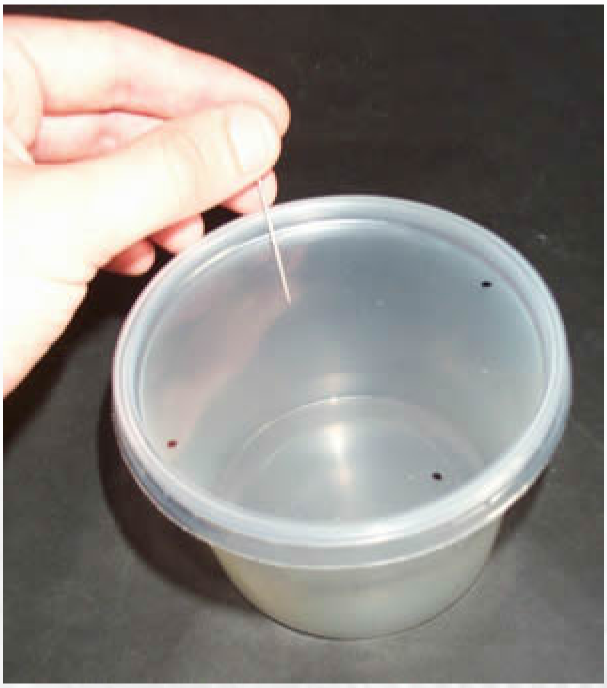
Cultivation on riceflour cakes (short version)

original source: http://mycotopia.net/archives/discus/messages/5/144749.html

This document gives instructions on the cultivation of Psilocybe cubensis on a sterilised substrate of riceflour, vermiculite and water.

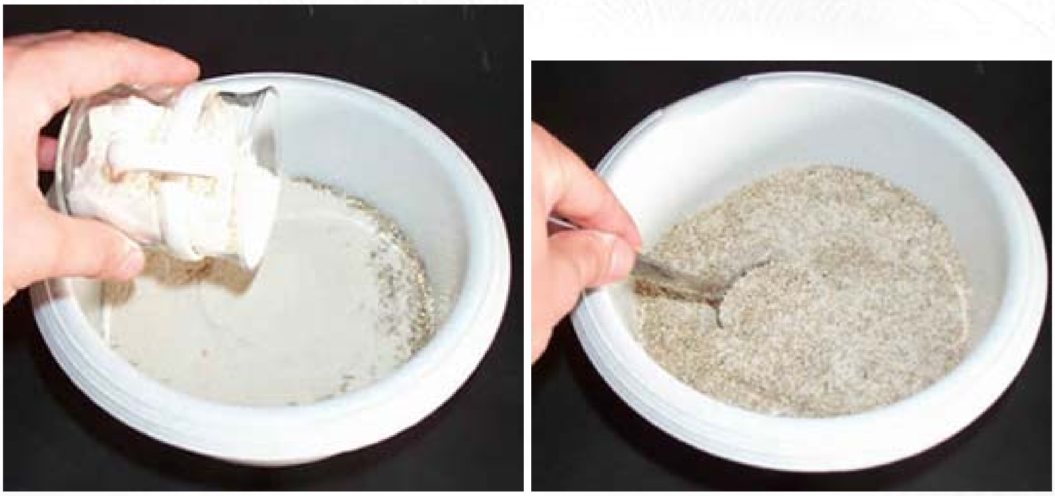
These polypropylene jars are used. They can withstand the heat of a pressure cooker. Of course glass jars can be used just as well.



Four holes are poked into the lid with a sharp pointy object (a syringe needle for instance). If you are using glass jars with metal lids you can use a nail and a hammer to punch four holes into the lid.

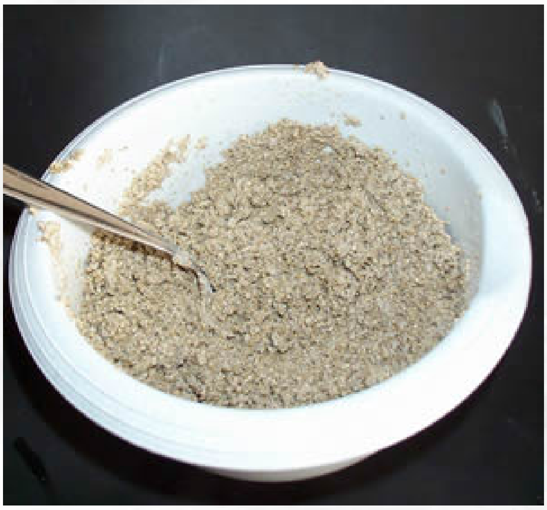
JOANNUSMOLEN
BIOCULINAIR
biologisch
VERS VAN DE MOLEN
rijstemeel

The two main ingredients: vermiculite and brown riceflour.

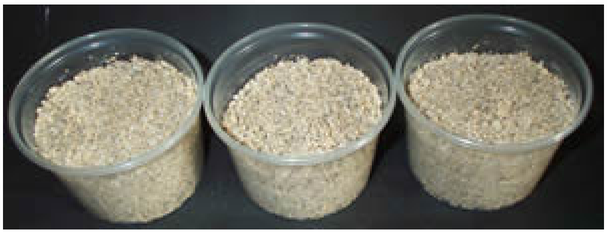


First the dry ingredients are mixed: 4 cups of vermiculite, 1.5 cups of riceflour.

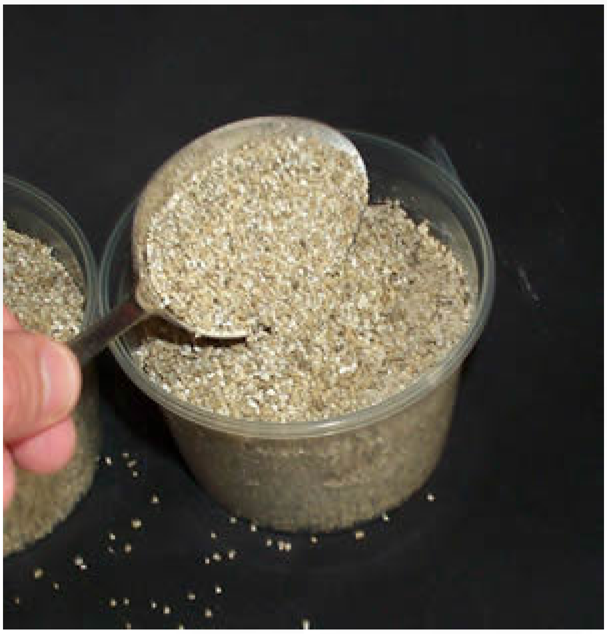
Two cups of water are added and everything is thoroughly mixed.



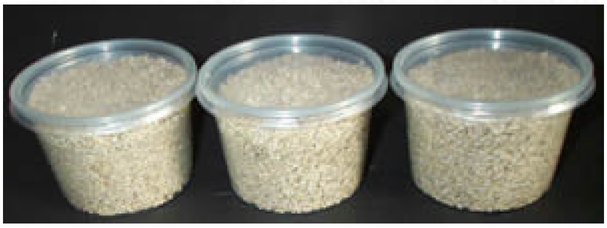
The resulting mixture will look like this.



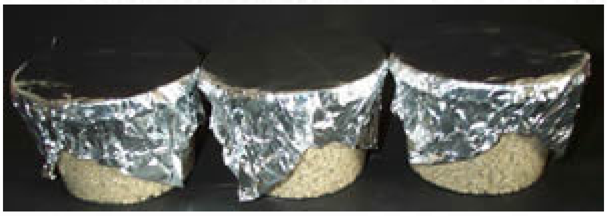
The jars are loosely filled with this mixture. The part of the jar above the substrate is cleaned with a paper towel.



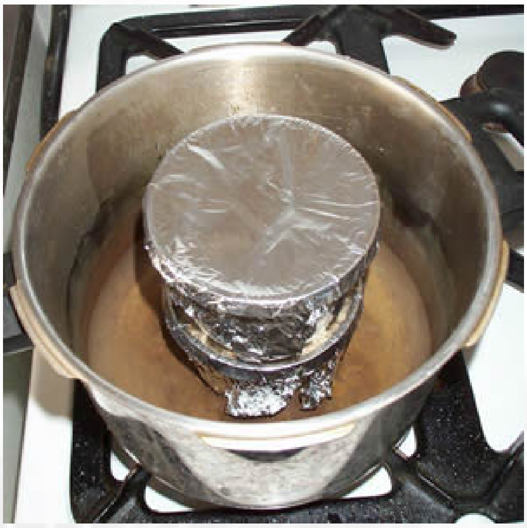
A layer of dry vermiculite is put on top of the mixture. This acts as an extra barrier for contaminants.



The lids are put on.



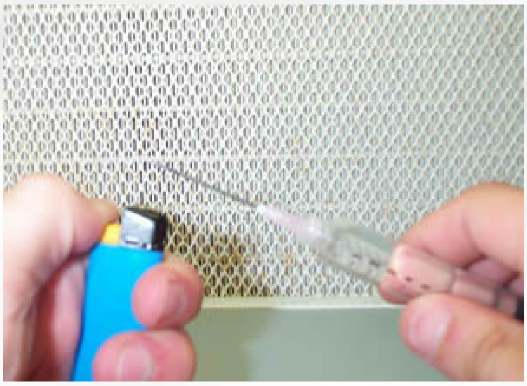
And a double layer of tinfoil is crumpled over the jars.



The jars are put in the pressure cooker...

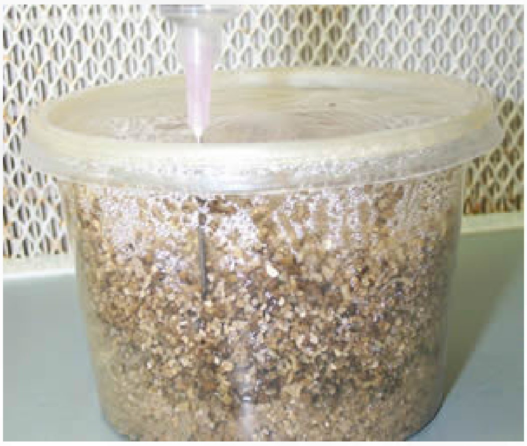
and sterilised for 1 hour.

The jars have cooled down.



The needle of the syringe is flamed...

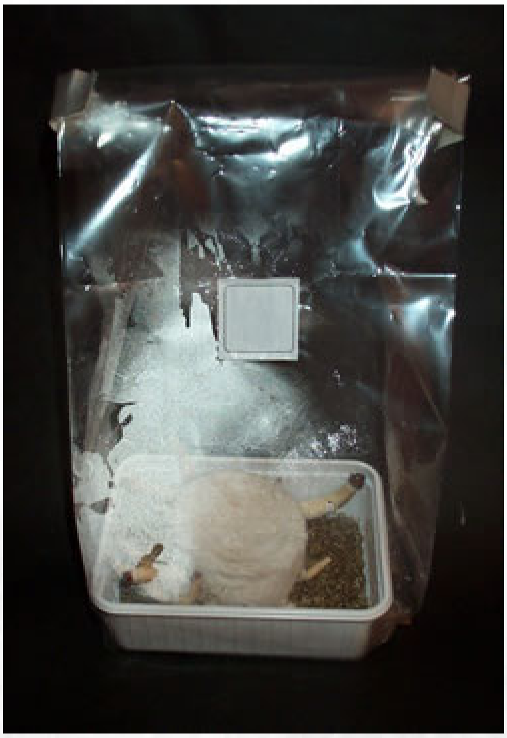
...and the tinfoil is removed.



The jar is inoculated through the four holes that were made in the lid. 1 cc should be enough for one jar. More sporewater can result in faster colonisation.

The tinfoil is replaced and the jars are put in a clean warm environment. The jars will colonise completely in 15-30 days (depending on strain, substrate, temperature and volume of sporewater used.

When the substrate is completely colonised the cake is taken out of the jar and put in the terrarium. We found that a plastic tray with wetted vermiculite inside an filter patch bag works perfectly for single cakes. Depending on temperature and strain mushrooms will appear in 5-20 days.



Harvest time!

Cultivation of Psilocybe cubensis on riceflour cakes

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Ccultivation_of_psilocybe_cubensis_on_riceflour_cakes&old

Introduction

The methods described here are generally known as the "PF-tek", although we made some useful adaptions here and there. The cultivation of Psilocybe cubensis on riceflour cakes is generally considered easier than cultivation on cased rye grain and is a method often employed by novice cultivators. A properly prepared and inoculated cake may produce up to 200 grams of fresh mushrooms (500 ml cake) in three flushes.
All cubensis strains can be grown on these cakes, even those that are somewhat harder to fruit on cased rye grain.

Overview

Mycelium of Psilocybe cubensis is grown on a sterilised substrate of brown riceflour, vermiculite and water. Substrate jars are prepared and subsequently sterilised in a pressure cooker. Inoculation is done by injecting spores with a syringe. After colonisation the substrate cakes are taken out of their containers and placed on wet vermiculite in a filter patch bag. After some time mushrooms form on the riceflour cakes. After the mushrooms have been picked the vermiculite is re-moistened to allow for a second and third flush.

Substrate containers

Glass jars can be used. Canning jars are the best but it may be difficult to locate them. An alternative that can be found in the supermarket is 'Bon Maman' jelly which comes in typical looking jars with a red/white blocked lid. These jars are good although a little on the small side.

Jars need to be non-tapered (no shoulders) or the colonised cake can not come out without smashing the jar.

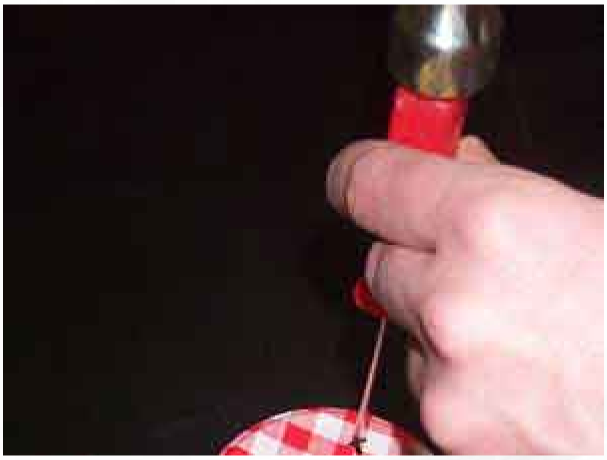
These jars should be cleaned out...

and have their labels taken off

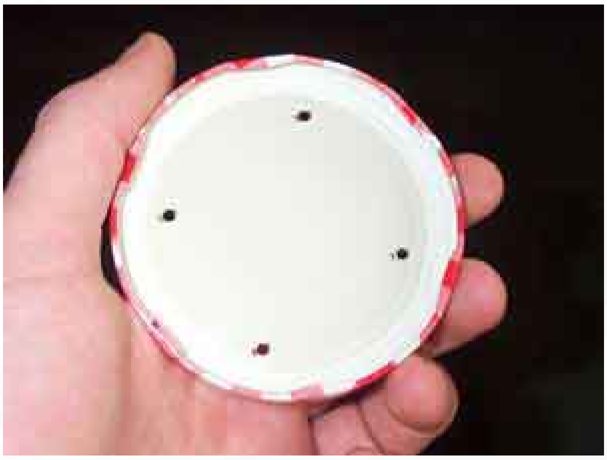
A very suitable container is the microbox: A non-tapered polypropylene jar with a filter in the lid. These jars can be pressure cooked, are reusable and provide an excellent alternative to glass jars.

Preparation of the lid

The lids will need to be fitted with 4 inoculation holes. A heated needle or pin can be used to melt holes in the lid of the microbox.
With a hammer and a small screwdriver (or similar object) holes can be punched in metal lids of glass jars.
The holes are spaced evenly apart near the edge of the lid.

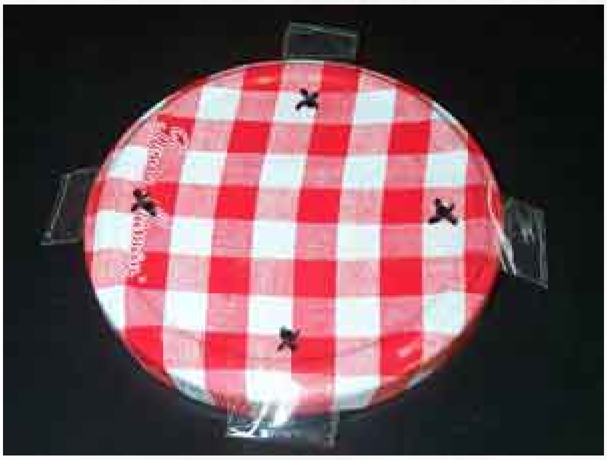


With a screwdriver and a hammer holes are poked

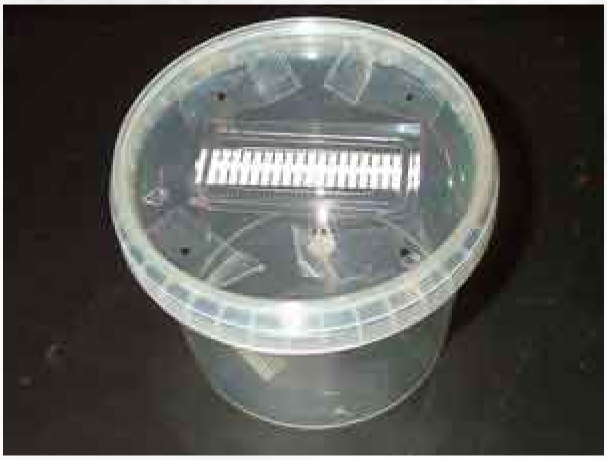


A metal lid showing the correct location of the holes

To prevent the entry of contaminant organisms into the jars, these holes are taped shut, only to be opened for a few seconds during inoculation. Pieces of tape are prepared by folding back one end onto itself. This makes it easier to remove them during inoculation. The pieces of tape are then placed over the holes.



This metal lid is ready



As is this microbox

Some types of tape can not be used. These will melt or lose their stickiness. Still we found that most types can be pressure cooked with reasonable success although they might curl up a little on the edges.
Polypropylene or nylon tape generally works fine. Masking tape can be pressure cooked but some types might harden out during sterilisation.

If suitable tape can not be found it's possible to sterilise the jars without tape and to tape the holes directly after inoculation. This however, is not recommended because of increased contamination risk.

Substrate preparation

The mycelium will be cultured on a substrate composed of brown riceflour, vermiculite and water.

Vermiculite and brown riceflour

Substrate recipe:

- 1,5 parts brown riceflour
- 4 parts vermiculite
- 2 parts water

(all by volume)

The mycelium will have difficulty growing in a substrate that does not have the correct moisture content.

First the dry ingredients are mixed. Then, while stirring, the water is slowly added.

The dry ingredients are mixed

Adding the water

The finished substrate should not be soggy. If too much water was added and the substrate ends up too wet, some dry vermiculite/riceflour can be added to absorb excess moisture.

A properly prepared batch of substrate

Filling the jars

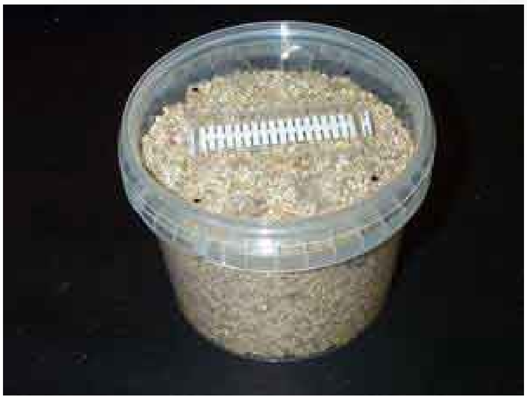
The jars are filled with the freshly prepared substrate. It's best to avoid having to store the substrate for longer than a few hour since bacteria will flourish in this moist, nutrient-rich medium.

The substrate is spooned loosely into the jars and compacted lightly by tapping the jars. Approximately 2 cm is left between the top of the substrate and the lid of the jar. This space is filled with a layer of dry, clean vermiculite. Since clean vermiculite does not support the growth of any competiting organisms, this layer helps to prevent the entry of contaminant organisms into the substrate during inoculation and incubation.

The rim is cleaned

Clean vermiculite is put on

In the case of a microbox the lid is closed for 3/4 or left loosely on top of the jar.
Microboxes should never be fully closed during sterilisation or they will implode/explode and/or deform!



A filled microbox, lid 1/4 open

Filled glass jars

Screw-type lids of glass jars are put on loosely but never screwed tight.

Both types of container should be covered with a double layer of aluminum foil to keep the lids in place and to prevent them (and the tapes) from getting (too) wet.

The lid should still be loose

Ready for sterilisation

Sterilisation of cakes

Originally the PF-tek uses a sort of semi-sterilisation in a normal pot at 100° Celsius. The results of this method are unpredictable to say at the least. Therefore it will not be discussed here.

The only proper way to sterilise the riceflour substrate is with a pressure cooker. For more information about pressure cooking look here.

Both types of jars are sterilised for 60 minutes at 121° Celsius. Every jar is inspected before it is put in the cooker to make sure that the lid is still on loosely, or in the case of microboxes, the lid is at least 1/4 open.

Again, the lids should be loose!

When letting the jars cool down, make sure that the lids are still on loosely. For microboxes the lids should preferably be closed completely as soon as they come out of the cooker. The jars/microboxes are left to cool in a clean spot.

These jars are hot!

The lid of the microbox is closed

Inoculation of cakes

Once the jars have cooled down completely to room temperature they can be inoculated with spores. A spore syringe (bought or self-made) is used to inject the spores into the substrate so that they can germinate and form a mycelium.

Although the risk of introducing contaminants into the substrate is pretty small because of the small inoculation holes, inoculation should preferably take place in a clean environment. A flow cabinet is best but a glovebox or improvised inoculation hood will also reduce the amount of contamination. The table top is cleaned with alcohol or lysol and remember as always: **BE CAREFUL WITH ALCOHOL AND LYSOL IN THE PRESENCE OF A OPEN FLAME!**

Just for inoculation the screw-type lids should be screwed tight to prevent accidentally tipping them off. After inoculation, during incubation these lids should be loosened again. The foil is taken off and replaced after inoculation. For the microboxes the foil can be discarded after inoculation.

Any moisture that may be present on the lid is wiped off with a clean tissue.

The needle of the spore syringe is flamed until red hot then left to cool for 10-15 seconds. The needle may not touch anything or it should be flamed again.

The needle is heated

The tape of one of the inoculation holes is peeled back and the needle is inserted through the inoculation hole, through the dry layer of vermiculite on top, aimed at the glass. 1/4 ml (or more) Is injected in the substrate. Then the needle is pulled back, the tape is replaced and the next hole is inoculated in the same way. It's not necessary to sterilise the needle after every hole but it's advisable to do this in between jars to prevent cross contamination.

The aluminum foil is replaced on the glass jars and the lid is loosened again. For microboxes the aluminum foil can be discarded.

Aimed at the glass

microbox inoculation

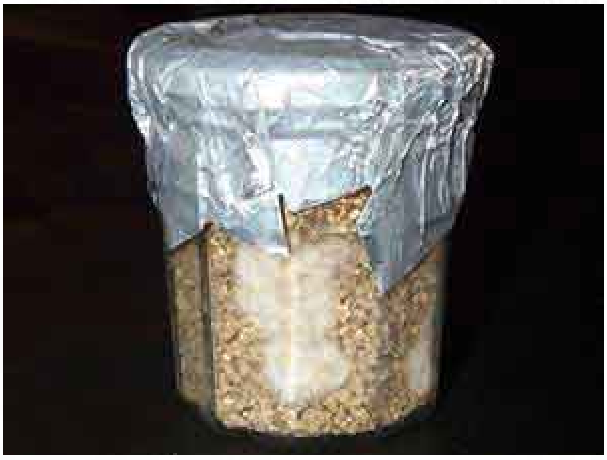
Incubation of cakes

Tha cakes should be incubated in a warm, clean and dark location. Since the microboxes have an air filter they can be placed virtually anywhere. They will not suffer from air contamination even in the most dusty environments. The glass jars however do not have filter and care should be taken not to expose them to drafts.

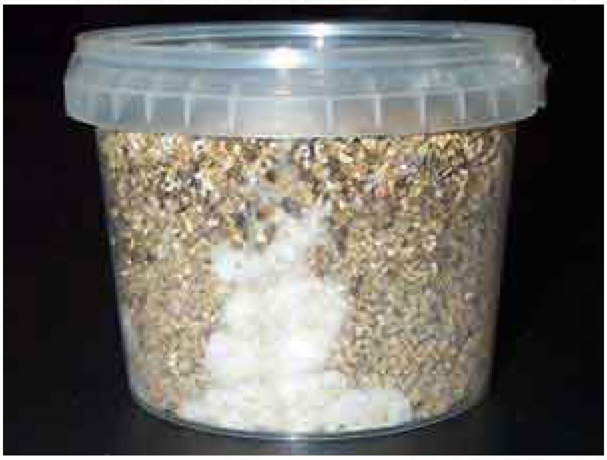
The temperature should be between 20-30°C and the jars should be kept in the dark. Early exposure to light may lead to the formation of mushrooms while the substrate is still partly uncolonised. For this reason the jars should be disturbed as little as possible. A minute of light each day will not make them pin prematurely but an hour may.

Incubation

A few days after inoculation, spots of white fluffy mycelium should be visible. These are the germinating spores. In the following days the mycelium will colonise the riceflour substrate. Often the mycelium will change from fluffy to threaded. These threads are called 'rhizomorphs' and are considered a good thing. Good fruiting cakes often showed strong rhizomorphs during colonisation.

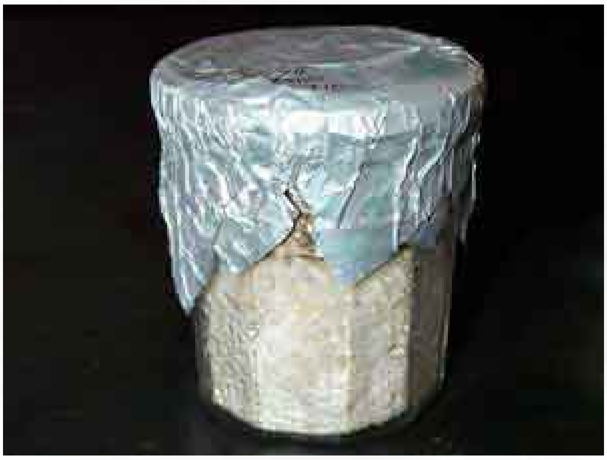


Colonising glass jar

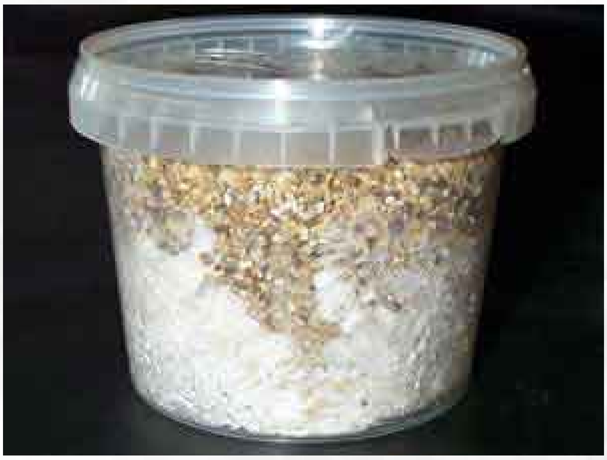


Colonising microbox

Depending on many factors (temperature, substrate composition, mushroom strain etc.) the cakes will be colonised in 7-20 days.



A week later



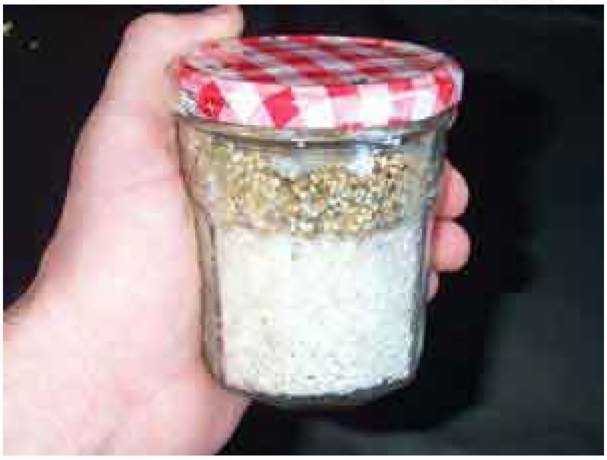
A week later

Once the substrate is totally colonised by the white mushroom mycelium the jars can move to the next step. The dry layer of vermiculite on top usually does not colonise but that's ok.

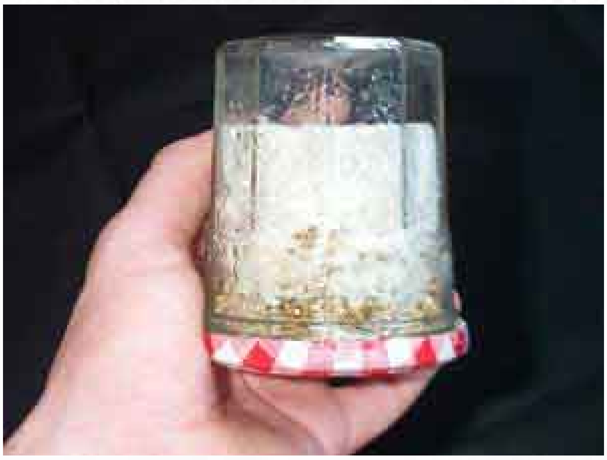
Growth of any other shape or color than the white mushroom mycelium, except maybe from a little blueish tone, can be considered a contamination. Contaminated cakes should be discarded. Although many contaminants are harmles some are toxic and some can cause disease in humans. Therefore contaminated jars should be thrown out completely or they should be sterilised in a pressure cooker before being emptied out. Contaminated jars should NEVER be emptied before having been sterilised.

Fructification

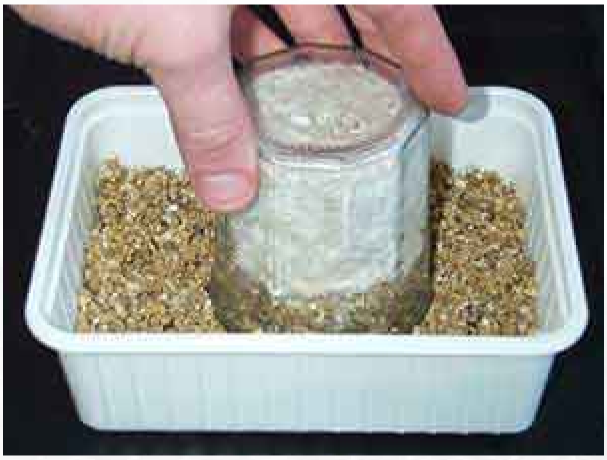
Vermiculite (preferably fine) is soaked and drained to achieve a maximum water content without leaking. A layer of 2 cm is put in a disposable tray. A colonised cake is tapped loose from the jar and placed on the wet vermiculite. The tray with the colonised cake is put in a filter patch bag which is closed on top with two paperclips.



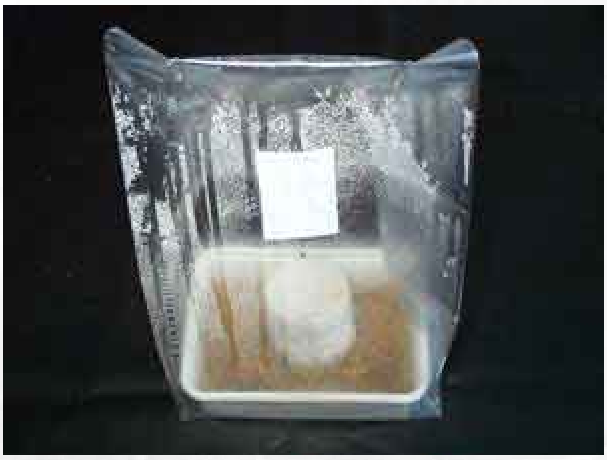
This one is ready



The cake is loosened



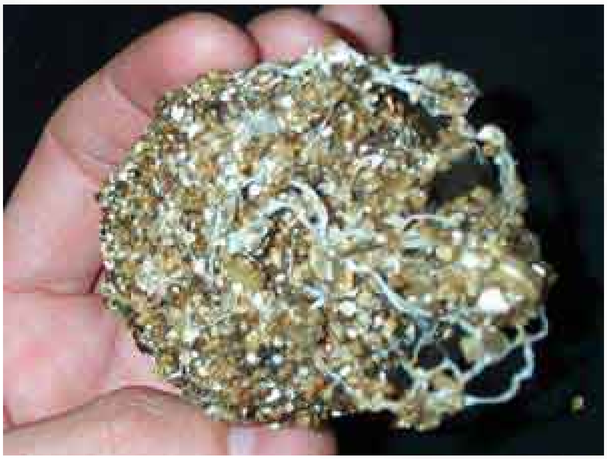
It is "birthed"



The cake in its "terrarium"

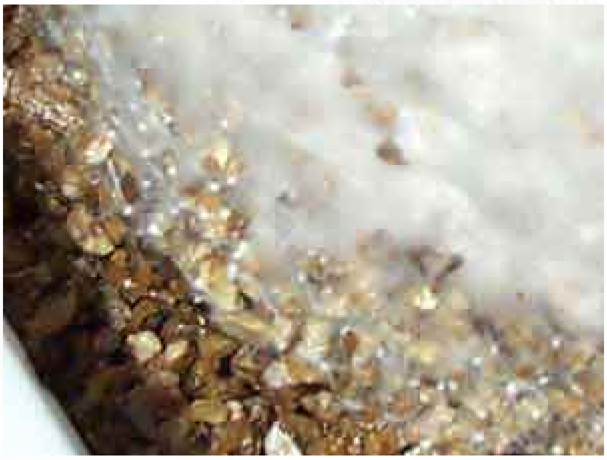
The bag is put in a place where it receives some light (no full sun!) and where temperatures are between 20-30°C. No care is necessary from this point on until the first flush of mushrooms is picked.

The cakes will become fluffy in the next few days and the mycelium will start to grow into the wet vermiculite. The wet vermiculite supplies water to the cakes and this allows for more mushrooms without the need for dunking/soaking.

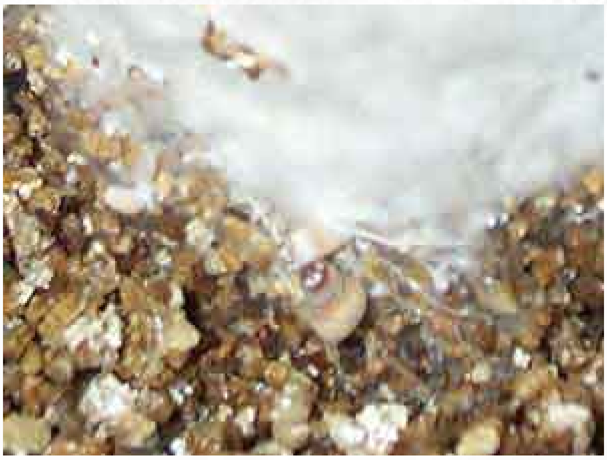


Rhizomorphs on the bottom of a cake

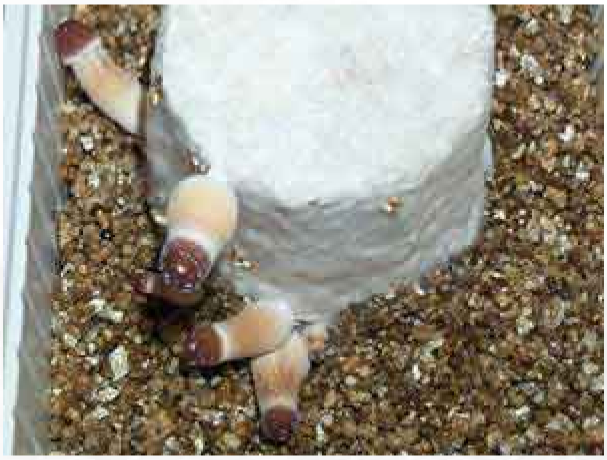
For most strains pinheads will appear after approximately a week. These are usually located on the bottom (former top) of the cake where most moisture is available. They first appear as small (<1 mm) white dots, that over the course of 1-2 days will slowly take on a mushroom shape. They will grow out to mature mushrooms in 5-7 days.



The first sign of mushrooms



The dots take on a mushroom shape



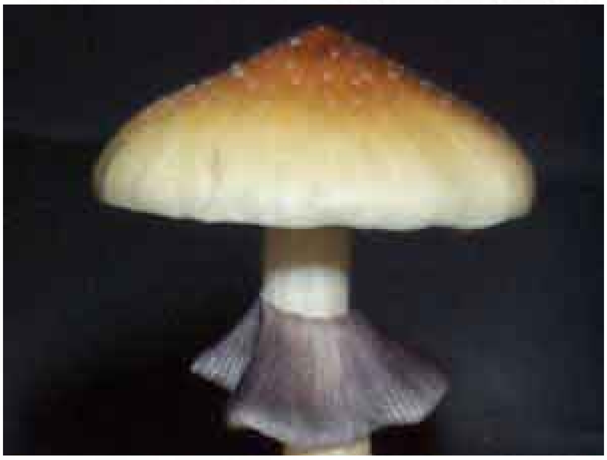
Young mushrooms

One happy cake!

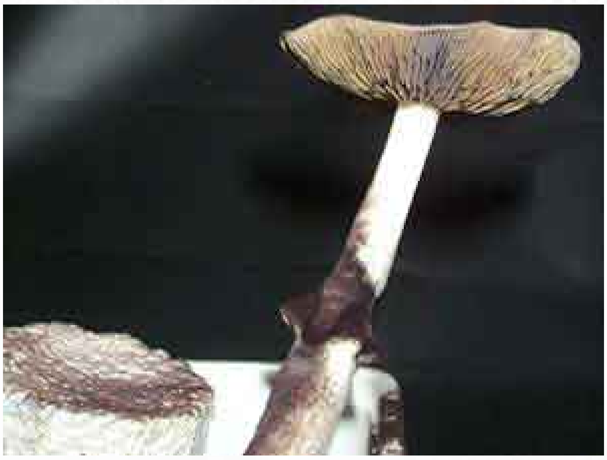
Mushrooms are picked before or just after the veil has teared. Mushrooms left to mature will sporulate and color the mushrooms black. If one desires to make sporeprints of course the mushrooms should be left to mature.

Cambodia cubensis

Cambodia cubensis



The veil has just teared



Sporulation

Once the first flush is picked, the vermiculite in the tray is watered heavily with a spray bottle to replenish the lost moisture. This will allow for a second flush or, when repeated, even a third flush.

Watering will allow for second flush

Cultivation of Panaeolus cyanescens and Panaeolus tropicalis on sterilised substrate

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Ccultivation_of_panaeolus_cyanescens_and_panaeolus_tropicalis&old

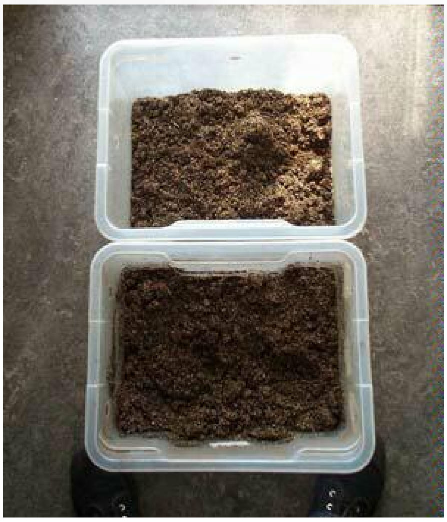
Straw substrate preparation

Substrate for the cultivation of *Panaeolus cyanescens* and *Panaeolus tropicalis* can be prepared in the following manner:
Ingredients: Dried cow dung, vermiculite and soaked straw (submerged in water for 12 hours)
For 4 standard spawn bags we use: 1/2 kilogram dry straw, 4 liters of dried dung, 3 liters of vermiculite and 3-4 liters of water.

Koemest poeder

The dung and vermiculite in dry form are mixed.

Water is added and the mixture is stirred (Make sure that the mixture is not too wet as loose water will often result in bacterial contamination later)



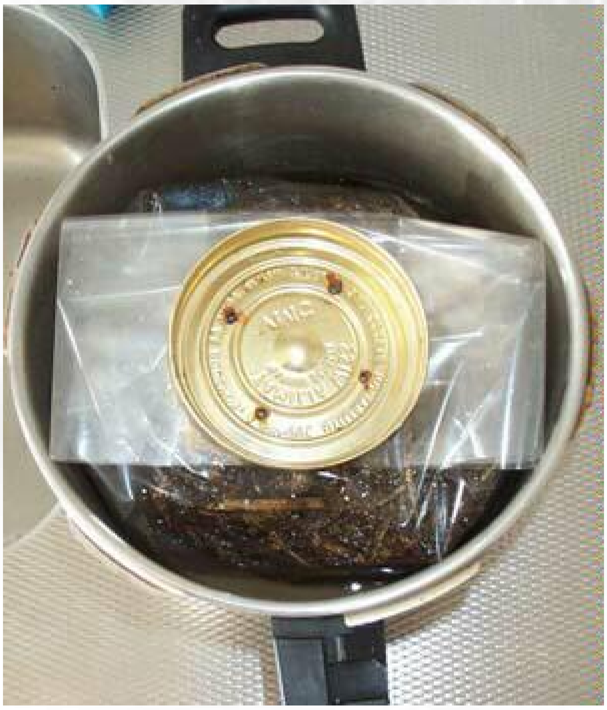
This mixture will look something like this.

The straw is added...

and mixed in thoroughly

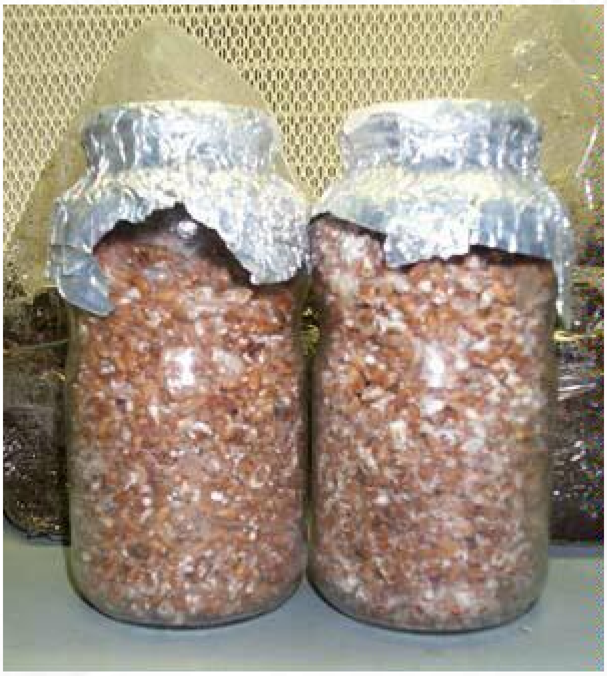
Close up (looks nice doesn't it ;-)

The substrate is divided over four autoclavable spawnbags (with a filter patch)



The flaps are folded and the bags are put into the pressure cooker. A lid is put on top to prevent the bags from blocking the steam valve

After sterilisation (2 full hours!) the bags are allowed to cool down in the flowcabinet.



Two jars with *Panaeolus cyanescens* spawn on rye to be used for the inoculation of the substrate. Note that Panaeolus species do not colonise grain as densely as for instance *Psilocybe cubensis*.

The bags are opened in the flowcabinet (only touch the outside of the bags!) and each bag is spawned with 300 ml of spawn by means of free pouring.

The bags are sealed with an impulse sealer.

Substrate Colonisation

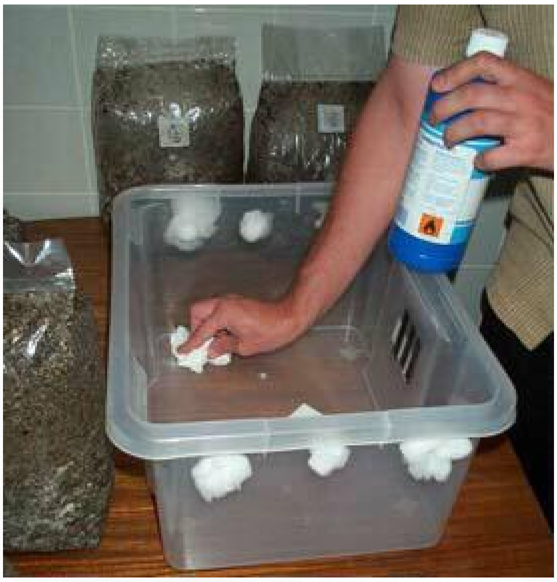
The mycelium will now start to colonise the substrate. Depending on the temperature and the frequency of shaking the substrate will be fully colonised in 5-10 days.

A bag of substrate after 3 days. Note the white mycelium

After some days and regular shaking the substrate is fully colonised.

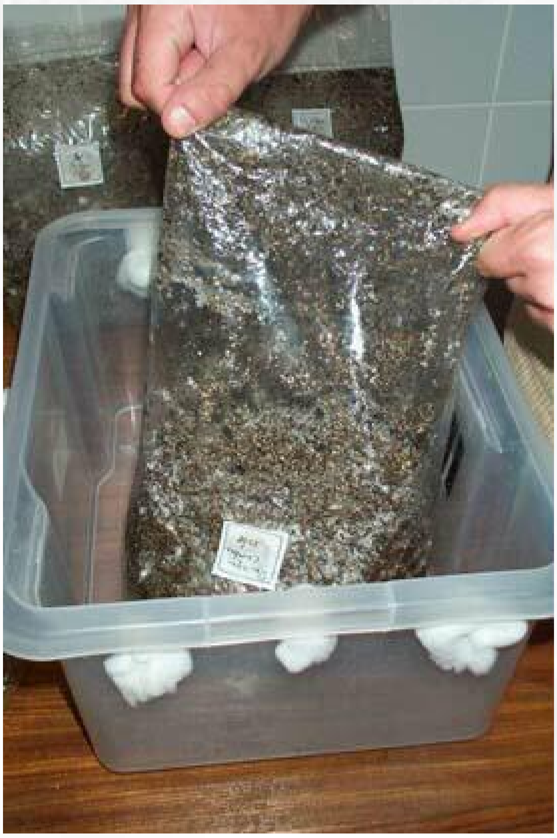
Close up

Casing the substrate

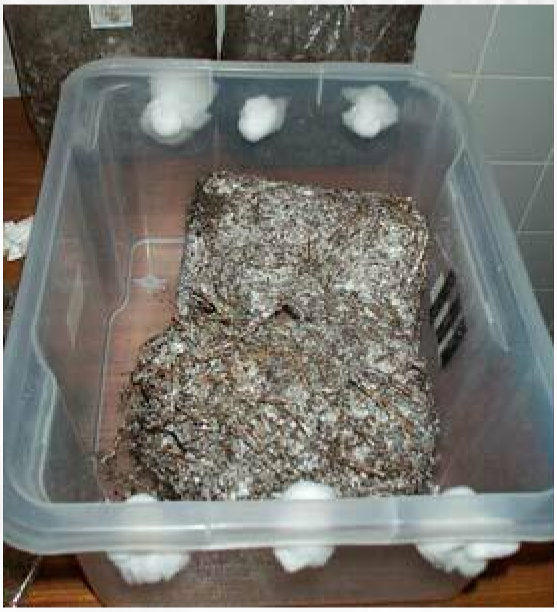


A plastic bin is cleaned with alcohol (note the holes plugged with polyfill).

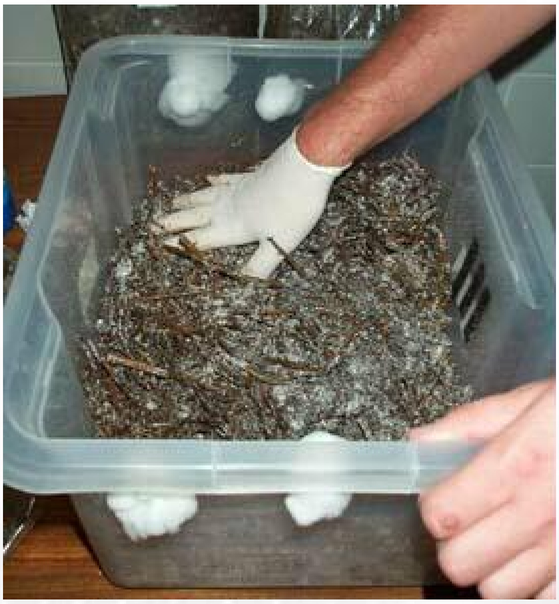
The bags are cut open with scissors.



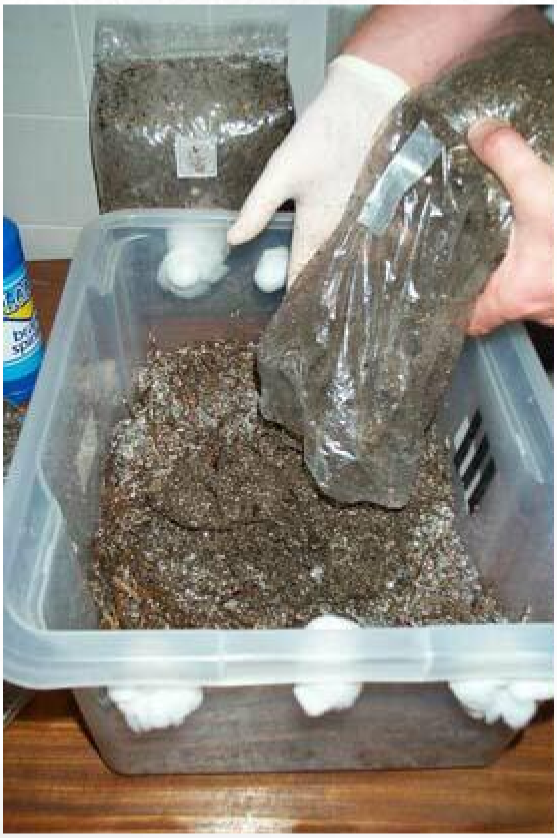
The fully colonised substrate is put into the bin.



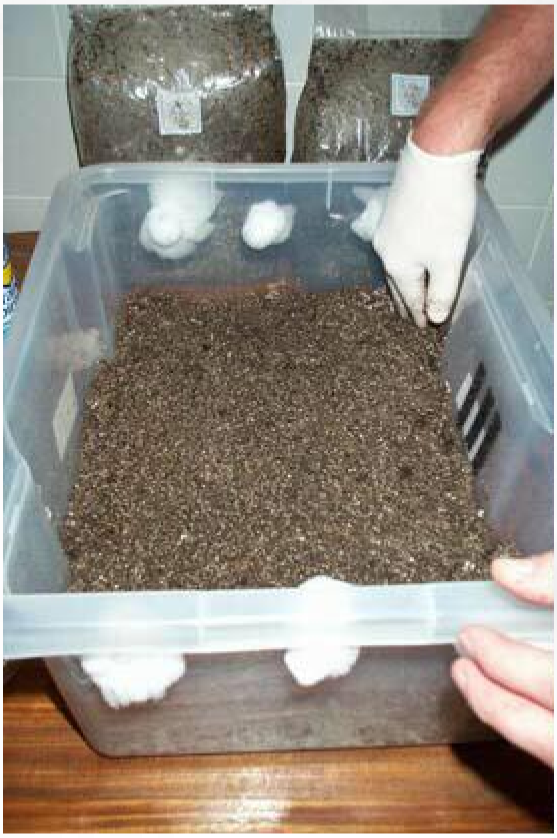
Two bags are used for one bin.



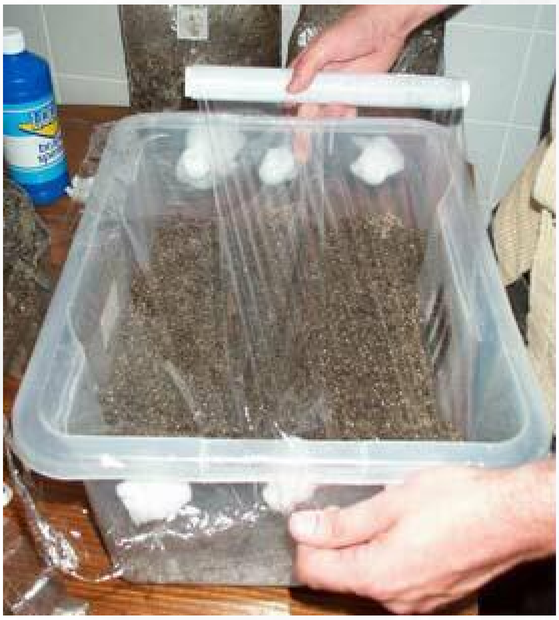
The substrate is levelled by hand (wear gloves!)



A thin layer (1-1.5cm) of sterilised casing soil is put on.

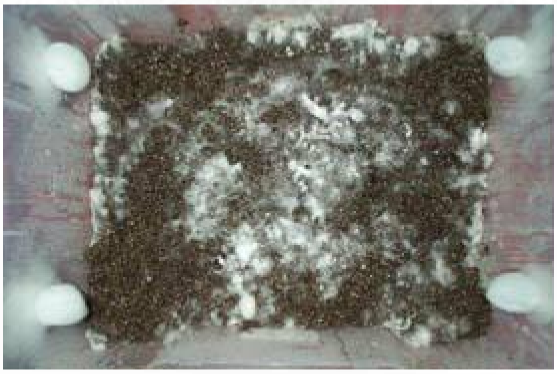


This too is levelled by hand

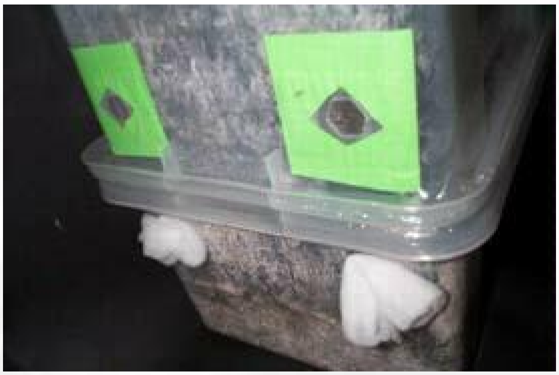


The bin is covered with polyethylene wrap to prevent contamination and moisture loss.

Side view

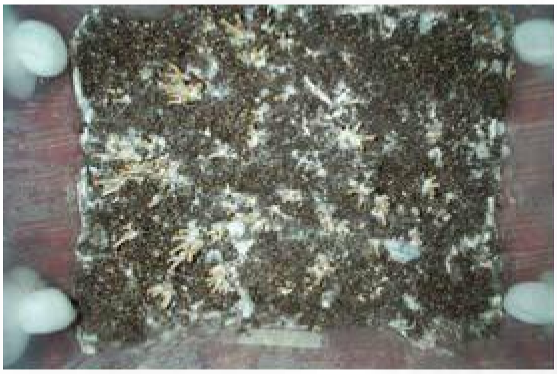


The bins are now put in a warm place for the casing layer to colonise. After 5 or 6 days the mycelium will show up on the casing layer.

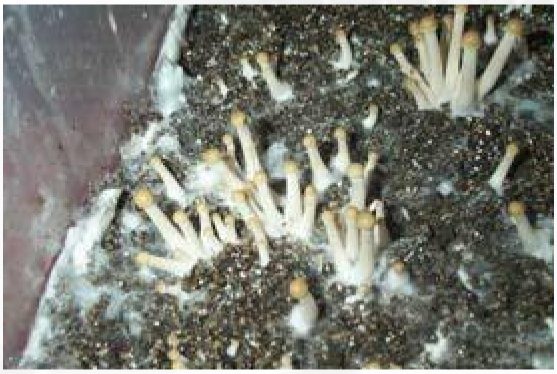


At this moment another bin is put on top (upside down) to create sort of a 'mini-greenhouse'. Note the mesh covered holes in the top bin.

Panaeolus fruiting



After some days the first mushrooms will appear. The casing soil must be kept moist (use a spray bottle).



Close up

The mushrooms will mature in a couple of days

Fully mature and ready to be picked!

Cultivation notes

Paneolus cyanescens and tropicalis are much more sensitive to high CO2 concentrations. We believe the most important reason for people to fail in their research with Paneolus species is that they do not expose their cultures to enough fresh air. When air exchange is insufficient many mushrooms will form but only a few will mature, the rest will abort. Also the mushrooms appearance is influenced. Improper air exchange will result in tall spindly mushrooms with small caps.

These species will grow in a wide range of temperatures but they really flourish when temperatures are around 25°C or a little higher.

Because not all substrains from a multispore germination seem all to viable it is wise to start with a multispore culture and clone the best looking mushrooms for your further investigations into these two species.

Cultivation of fruitbodies and sclerotia on sterilised grass seed

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Ccultivation_of_fruitbodies_and_sclerotia_on_sterilised_grass_seed&old

This document gives instructions on how to prepare substrate suitable for the cultivation of:

- Psilocybe mexicana (mushrooms and sclerotia)
- Psilocybe tampanensis (mushrooms and sclerotia)
- Psilocybe cubensis (mushrooms; rye grain is preferred for this species)
- Panaeolus subbalteatus (mushrooms)

Preparation of the substrate

The substrate is based on grass seed. The most commonly sold form is rye grass seed (Lolium perenne) but we have also used mixtures of different species with great success. Make sure however that it is not treated with fungicides. If seed has been treated with fungicides it should say so on the packaging. You may have to look around a little bit to get some unexpensive seed (we buy ours from an animal feed store where it is sold as birdfeeding).

We use the following formula for 720 ml jars

- 110 grams grass seed
- 180 ml water

After the water and seed have been filled into the jars, the lids are put on but NOT screwed tight! The lids MUST remain loose! Then a double layer of tinfoil is crumpled over the lid and top part of the jar. Now the jars are ready for sterilisation.

NOTE: Different varieties of grass seed and even batches of the same variety can differ greatly in their ability to absorb water. Too much water results in a slimy clump of seed that cannot be shaken, too little results in substrate that is too dry and produces little or no mushrooms/sclerotia. You should experiment a little with these.

Alternatively you can soak the grass seed overnight in water and then fill the jars with soaked grass seed. This will produce a more homogeneous substrate.

Sterilisation of seeds

The jars should be sterilised in a pressure cooker or autoclave, a normal pot will NOT suffice. First a layer of water is poured into the cooker. The jars are placed in the pressure cooker making sure that the lids are loose! Now sterilise the jars for one hour according to the directions supplied with your pressure cooker. If you are using bigger jars then the sterilisation time should be prolonged. (we sterilise 1.5 litre jars and spawnbags always for 2 full hours). Once the cooker is no longer under pressure the jars should be taken out and the grass seed in the jars should be shaken loose to mix the wet and dry kernels. The jars should then be allowed to cool in a clean place. Always check the jars for cracks before shaking! When the jars have cooled to room temperature inoculations can take place. As the jars are cooling down the lids should remain loose or else they will pull a vacuum.

Inoculation of seeds

When the jars have cooled down they are ready to be inoculated. Don't be hasty, be patient! If you inoculate the jars while they are still hot the spores or mycelium might get killed. You can use a spore syringe, mycelium syringe, agar squares or whatever kind of inoculant you want. The most important thing to remember is to WORK CLEAN! When using syringes always flame the needle before commencing inoculations. When using agar squares always flame the scalpel! Be careful! **ALCOHOL AND SPRAY LYSOL ARE HIGHLY FLAMMABLE!!!**

Even a simple hood made of a cardboard box prevents prevent drafts and subsequently contamination. Do not expose the sterilised grain to air longer then absolutely necessary. Open the lids of the jars just a crack and work swiftly. After inoculation the lids of the jars are closed and the jars are shaken. Then the lid is loosened again so the mycelium will be able to breathe.

Colonisation of seeds

After inoculation the jars are put in a clean and draft free location. We normally put our jars at room temperature (20°C) or slightly higher. When mycelium starts to grow in only a few spots we shake the jars to redistribute the colonised kernels. This speeds up colonisation dramatically. Depending on the temperature, the species and the method of inoculation the grass seed can be completely colonised in 5-20 days.

When jars are incubated too long or at too high a temperature the mycelium will excrete yellowish metabolites. This situation is not good, these seed in these jars should be cased as soon as possible.

Casing (for the cultivation of mushrooms)

When the grass seed in the jars is completely colonised it needs to be cased. For this purpose we use 1-litre disposable plastic trays. The colonised grass seed of one jar is shaken loose are poured into a tray. If there are lumps within the seed these can be broken up with the clean rim of the jar. The surface of the grain is levelled evenly. Using a big spoon and a fork the grain is now covered with a thin layer (1.5-2.0 cm) of casing soil. We always try to keep the casing surface even while at the same time keeping it rough (with small valleys and hills). The cased tray is then covered with tin foil and put in a clean location (20-25°C). Within a few days you will notice the mycelium growing through the casing soil. Depending on the strain (some strains fruit earlier and easier then others) the casings are now ready to be exposed to air and light to start the fruiting cycle.

Recipe and Preparation of the casing soil for seeds

We use the following recipe:

- 10 parts of peat
- 5 parts of vermiculite
- 2 parts of limestone (Marl)

The ingredients are mixed in dry form and while stirring water is added. The amount of water of course depends on the moisture content of the peat. The object is to get as much water in the casing soil as possible without turning it into mud. If the casing gets too wet just add a little more dry ingredients. This casing soil is then filled into oven bags (made of nylon), autoclave bags (PP) or jars and these are sterilised for one hour in the pressure cooker. When the soil has cooled down to room temperature it's ready to use.

We know that some authors advise against sterilisation of casing soil because it would kill all the beneficial organisms. We however have had only bad experiences with untreated or pasteurised casing soils. We just tell what works best for us!

Fruiting of seeds

Some cultivators use very elaborate set-ups with humidifiers, cool-mist devices and such. We have never found this necessary. The fruiting containers that we use consist of simple clear plastic bins that are covered with polyethylene sheeting. These bins are stackable and thus very space efficient. For air exchange some hole are melted in the sides of the bins. These holes can be covered with mesh to keep out flies. Basically, five cased trays are put in one bin and the evaporation from the casing surface is enough to maintain the proper moisture inside the bin. The holes provide some air exchange. We always cold-shock the harder-to-fruit strains (we put them in the fridge for one night before putting them in the bins). For easy fruiting strains (i.e. Ecuador cubensis) this is not necessary. *Psilocybe mexicana*, *Psilocybe tampanensis* and *Panaeolus subbalteatus* do not benefit from such a treatment. The casings are misted each day and the casing is never allowed to dry out. Directly after a flush is picked watering is increased because the maturing mushrooms pull a lot of moisture from the casing soil. It's very difficult to give explicit directions on a watering regime. You will have to develop a 'feeling' for it. Depending on the strain the first pinheads will appear 6-15 days after putting the casings in the bins. The mushrooms will mature in 5-7 days after which they can be picked. We normally let the casings produce 3 flushes, but they may (when watered properly) produce 5 or even 6 flushes. *Psilocybe mexicana* usually produces one big flush and a small second flush. Other mentioned species produce more constant.

Keep the surface of the casing as clean as possible by removing dead pinheads (aborts) as these can lead to moulds showing up on the casing surface.

Sclerotia

The mycelium of *Psilocybe tampanensis* and *Psilocybe mexicana* can produce sclerotia while still in the jar. Colonised grass seed need not be cased for this to happen. In our experience (with tampanensis) sclerotia will continue to enlarge until 4 months after inoculation. The jars should be put in a clean (preferably dark) location. Sclerotia of these species also form in the casing layer of cased trays.

Making spawn for the woodloving outdoor species

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/wood.html

This procedure describes a method of making spawn for the woodloving outdoor species (i.e. *Psilocybe azurescens*, *Psilocybe cyanescens*, *Psilocybe bohemica*).
This spawn can be used to inoculate outdoor beds with woodchips. The creation of outdoor patches is (will be) described in another document.

Procedure

The spawn is based on small woodchips that can be bought in a pet-store. It is used as animal bedding but can also be used to smoke fish and meat. These chips are made from beech.

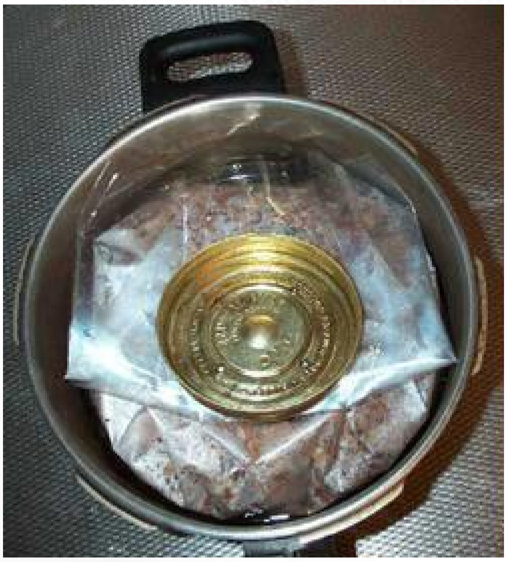
The chips are boiled in water until they sink (approx 1 hour). Alternatively you can soak them in water for some time. Moisture content is right when they sink.

Now drain the chips and let all the loose water run off.

Some oatmeal is added to the mixture (approximately one cup for every 3 litre wood chips). This is to boost and speed up mycelial growth. You can also use bran instead of oatmeal.

The oatmeal is mixed in

This mixture is filled into autoclavable spawn bags (or jars)



To prevent the bags from blocking the steam valve, a metal lid is placed on top the bags

The bags are sterilized for 2 hours in a pressure cooker (for jars 1 hour will suffice)

The bags/jars are cooled down in front of a laminar flow hood

When they have cooled down they can be inoculated from rye grain spawn. Don't use too much as this will give problems when it is placed outside in the beds as grain attracts vermin.

We use about 300 ml for one spawnbag

After spawning the bags are sealed with an impulse sealer

They are checked for leaks and punctures.

Finally they are shaken and incubated. Depending on the temperature and species used, bags will completely colonise within 2-3 weeks. Bags can be placed at room temperature.

Growing the woodlovers outdoors

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Cgrowing_the_woodlovers_outdoors&old

Overview of procedure

Spawn is prepared on sterilised woodchips. In the spring the colonised woodchips are used to inoculate more (non-sterile) woodchips in outdoor beds. The beds are covered with plastic and watered on a regular basis. In autumn the plastic is removed and watering is increased. In the late autumn or begin winter the beds will fruit.

Preparation of grain spawn

The preparation of grain spawn is described here. It will not be repeated here.

Mycelium is cultured on agar

And transferred to sterilised grain

Growing mycelium on sterilised wood chips

Preparation of the wood chip substrate

Although some people use colonised grain to directly inoculate their outdoor beds this is not the preferred method. The grain attracts all kinds of bugs and rodents. The grain is also more likely to contaminate than properly prepared wood chip spawn.

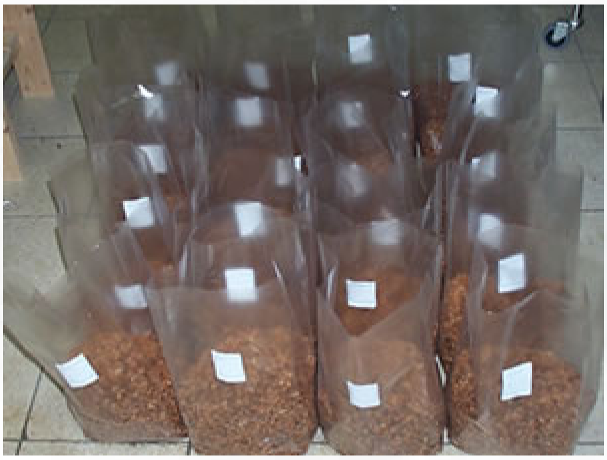
The woodchips we use are made of beech (Fagus sylvatica) and are sold as animal bedding. We use the smaller size for spawn and the larger as substrate for the beds.

The chips are soaked in water for 48 hours. Don't wait longer than this or fungi may start growing on the wood. The chips are then drained.

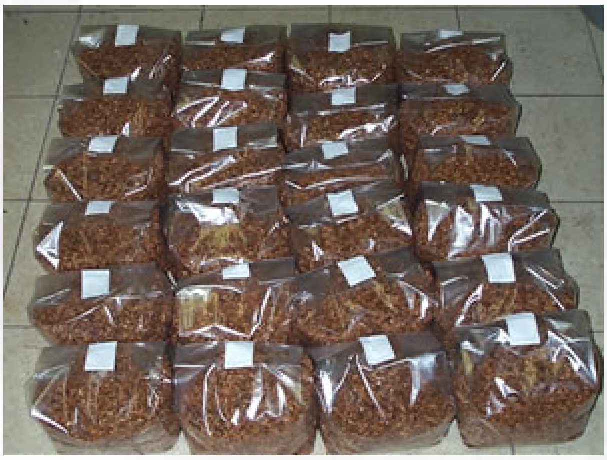
Beech wood chips

Make sure all water runs off

The soaked chips can be supplemented with something like oatmeal or boiled grass seed to speed up mycelial growth. About one half cup per bag is used.

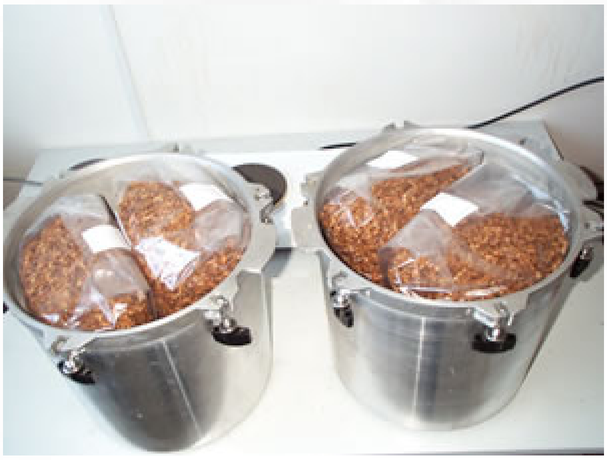


Bags filled with supplemented wood chips

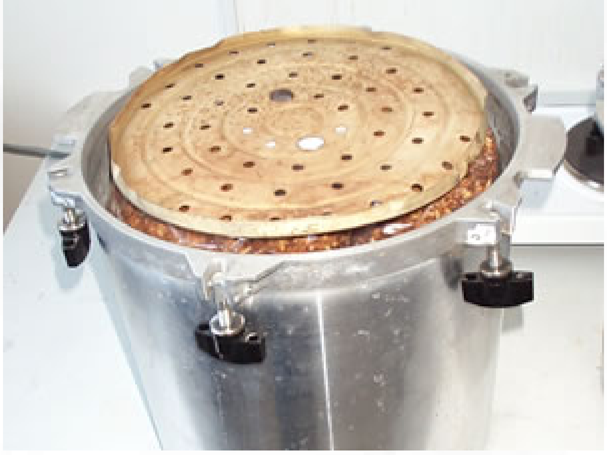


The flaps are folded down, ready for sterilisation.

The bags are placed in the pressure cooker and a rack is put on top to prevent them from blocking the vent pipe.



Four of these bags fit in this cooker



The rack on top is very important

Subsequently the bags are sterilised for 3 hours at 121°C and left to cooled down in the flow cabinet.

Sterilise the full 3 hours, don't cut corners

Bags cooling down in the flow cabinet

Inoculating the wood chip substrate

The cooled bags are placed in the flow cabinet. The bag is opened taking care not to touch the inside and colonised grain spawn is poured in.

Opening the bag...

...and pouring the spawn in

Now the bag is sealed with an impulse sealer, and the seal is tested. If the bag is leaking at the seal it is sealed again.

Sealing the bags

Testing the seal

The strain and date are written on the bag and the bag is shaken to distribute the spawn. The bags are now incubated at 20°C for 3-4 weeks after which they are ready for use.

Making the outdoor bed

For the bed we choose a shaded place surrounded by bushes. First a shallow hole is dug by Cowboy Luuk.

Cowboy Luuk digging a hole

The woodchips that are the same as those used as spawn but they are much coarser (larger particles). The chips are put in bags and these bags are filled with water. The chips are soaked like this for 24 hours.

The hole is filled with drained chips and the spawn is mixed in. A ratio of 1:20 should suffice although higher rates are preferred if the spawn is available.

Colonized wood chip spawn

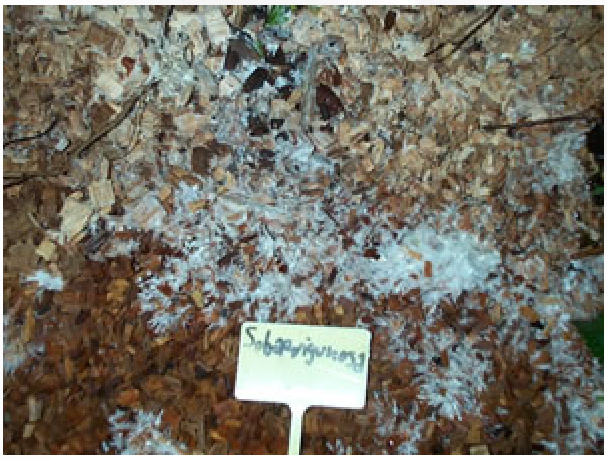
Cowboy Luuk mixing in the spawn

Now the bed is given a final watering and it is covered with a piece of plastic to prevent dehydration.

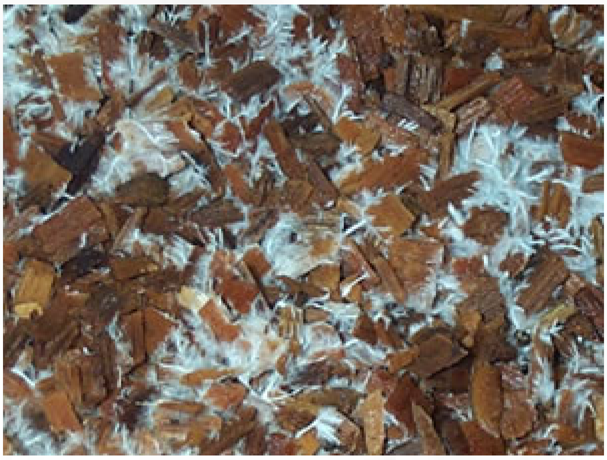
Keep the bed covered until September

Maintenance

Every week or so you should check to see if the bed is still moist on the inside and water if needed.



Mycelium is clearly visible on the woodchips



Close up

Replace the plastic after watering. There will probably be all kinds of insects running underneath but don't worry about them. In September the plastic is removed and the bed is watered on a regular basis to prevent it from drying out.

These will be under the plastic

Mushrooms!

Once the temperatures are right for the species being cultivated the bed will start to fruit. Do not water the mushrooms unless it's really dry. It helps to live in the neighbourhood of the beds, and not like us, a 2 hour drive away. Usually one or two flushes pop up. In spring next year fresh chips can be added to the beds to promote further fruitings.

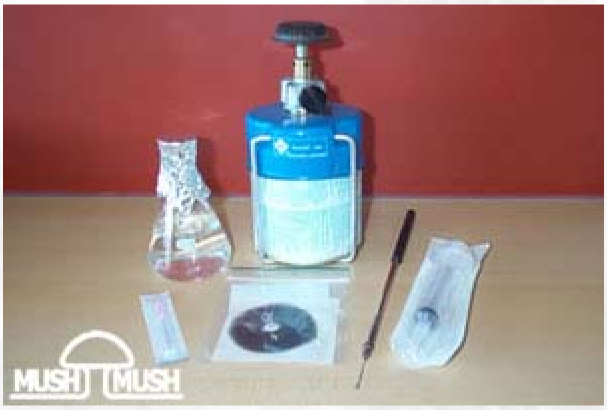
Making a sporesyringe

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Cmaking_a_sporesyringe&old

Although the photographs show the procedure in the open air we make all sporesyringes in a flow cabinet!

To make a sporesyringe you will need the following items:

- Inoculation loop/scalpel (something to pick up the spores)
- Sporeprint
- Syringe and needle (sterile)
- Small amount of sterilised water in a bottle (capped with tinfoil)
- Clean flame source (gas- or alcohol burner)
- Latex gloves (optional)

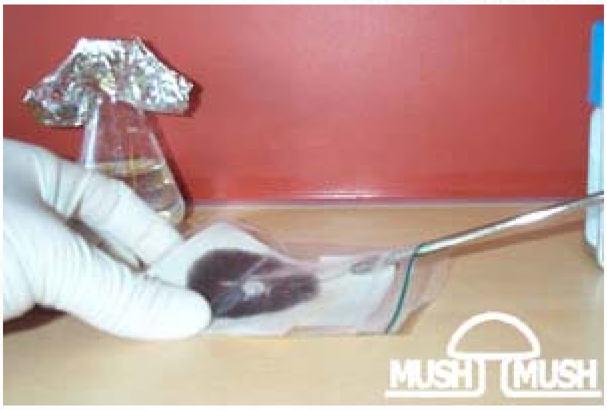


The most important thing in the whole process is to work clean. If possible perform the following procedure in a glovebox or HEPA filtered environment. If you do not have access to one of these you can perform it in the open air, but chances of success or smaller. If available wear gloves that have been disinfected with alcohol 70% or lysol.

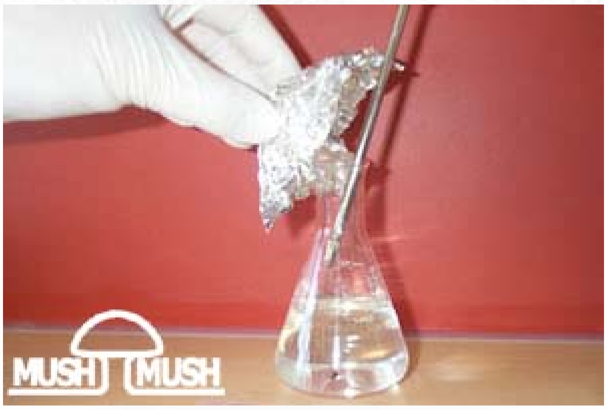
CAUTION: Most disinfectants are flammable, use extreme caution when using these in combination with an open flame!

Before you start clean the working surface with alcohol or lysol. Allow it to dry before proceeding!

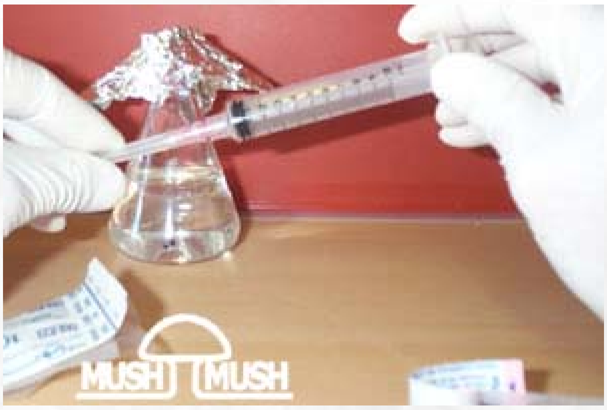
The inoculation loop or scalpel is flamed until red hot, and left to cool. Alternatively you can use a presterilised inoculation loop.



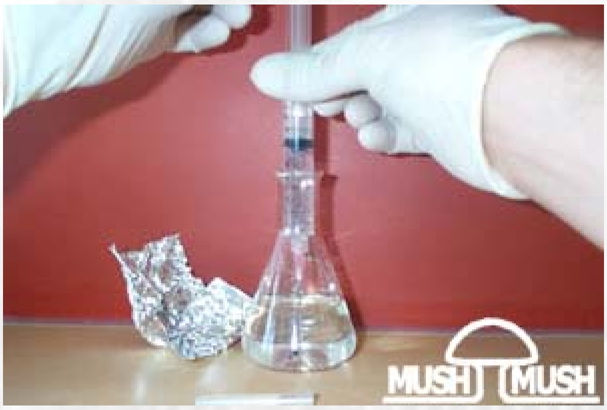
Peal back the tinfoil of the flask so that it can be removed easily but leave it covering the flask. Open the baggie with the sporeprint and scrape some of the spores of the paper. If the loop is too hot the spores will be killed or the plastic will melt to it.



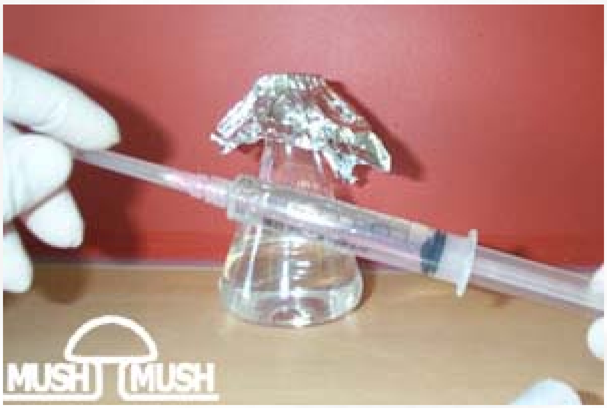
Deposit the spores into the water and quickly replace the tinfoil. Repeat if not enough spores have been transferred. If the spores are visible in the water there should be enough.



The syringe is assembled. Most syringes can be reused by sterilising them in a pressure cooker. Just wrap them in tinfoil and sterilise for 25-30 minutes.



Some spore suspension is sucked up in the syringe. Pull the plunger back and forth a few times to disperse the spores in the water. Syringes can then be filled with spore suspension.



The needle cap is replaced and the syringes are put in the fridge until ready to use. Don't forget to label them with strain and date. Syringes can be kept like this for several months after which they become noticeably less viable.

Steam sterilisation

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Csteam_strelisation&old

The delicate art of pressure cooking

In laboratories worldwide autoclaves are used to sterilise nutrient media, substrates and instruments. Wouldn't it be nice to have an autoclave at home? Autoclaves are expensive, very expensive...... Luckily, an autoclave is really nothing more than a fancy pressure cooker!

Pressure cookers are relatively cheap, easily available and they come in all shapes and sizes. Still they all work on the same principle. The cooker is an enclosed system. Heat turns the water into steam which builds pressure. At higher pressures the boiling point of water rises. At 1,0 kg/cm^2 overpressure (= 1 bar) this is 121°C. This is the standard sterilisation temperature.

Always observe and obey the safety instructions that came with your cooker. Never make modifications to it and use only original spare parts. Not doing so may result in an explosion! You have been warned!

Typical sterilisation cycle

Not all cookers work the same. Some need the weight to be placed on from the start on and some don't even have a weight but a spring loaded pressure regulator. For a 'standard' cooker with a weight a typical sterilisation cycle goes as follows, it might be different for your cooker!

A rack is placed in the cooker so that the items to be sterilised are not in direct contact with the bottom.
If items are in direct contact with the bottom of the cooker they might melt (polypropylene) or crack (glass). A simple rack keeps the contents of the cooker 1-2 cm from the bottom and prevents this.

An appropriate amount of water, usually a few centimeters to cover the bottom, is put in the cooker.
An appropriate amount is enough to keep the cooker from running dry but not so much that it takes ages to heat up. A cooker that has run dry is bad news because: A. The contents is ruined B. It stinks up the place C. The cooker will need to be cleaned on the inside D. The metal of the cooker itself may warp When the pressure/temperature is regulated precisely so that no excessive steam escape takes not much water is needed. Of course more water should be added if the contents is sterilised for a longer time. Usually 3-4 centimeters of water on the bottom is enough but this may be different for each cooker/sterilisation regime.

The items to be sterilised are placed in the cooker. For bags a rack is put on top.
Flasks, Jars, bags and instruments are placed in the cooker. Jars and bags can be stacked if the cooker is high enough. When autoclaving bags, a rack is put on top to prevent the expanding bags from blocking the vent pipe on the inside.

The lid is closed and the heat is turned on.
The lid is now placed on the cooker. It is closed by means of rotating the lid or by fastening some wing nuts. The weight, which regulates the pressure, is not put on yet. An electric heating plate or a gas stove may be used. It can be turned to full heat unless it's a really big burner for a small cooker which might lead to the glassware inside cracking.

When a steady head of steam is blowing from the vent pipe the weight is put on.
After some time the water in the cooker will start to boil. Steam will start escaping from the vent pipe. The weight is not placed yet. After a few minutes the steam will flow continuously from the vent pipe and all air that was inside of the cooker is now expelled. This forms a saturated steam environment. The weight is now placed on the vent pipe.

The cooker will start building up pressure.
Since the weight is now blocking the steam flow, pressure will start to rise in the cooker. The rise in pressure corresponds with a rise in temperature. If hissing or leaking is visible the rubber ring that seals the lid to the cooker needs to be cleaned or replaced. The heat is adjusted to keep the weight rocking slowly

When the pressure has reached 1 bar the weight will be lifted by the steam pressure. This releases pressure and the weight will go down again. The temperature is regulated so that the weight keeps rocking and hissing but no excessive steam escape takes placed. As long as the weight is rocking, the contents is at the correct temperature.

After the appropriate time the heat source is turned off.
Sterilisation time is measured from the moment that the cooker reaches 121°C until the moment that the heat is turned off. The cooker is left to cool until the pressure has returned to zero. When the pressure has returned to zero, the cooker can be opened.

Items that can be used when they are cool can be left like this. When the contents has to be used while still hot (agar for instance) or when the cooker needs to be used again as fast as possible the hot content may be removed. Always remove the weight first to ensure that the pressure has dropped to zero before opening the cooker.

The cooker is unloaded and is ready for a new cycle.
The hot items are removed from the cooker with heat insulating gloves. Cold items can be removed bare handed. Sealed bags and jars with a filter can be left to cool anywhere. Agar and unsealed bags are left to cool in a running flow cabinet or improvised inoculation hood.

Sterilising sealed bags

Still many people think that it's impossible to sterilise sealed filter patch bags. They sterilise the substrate in an open bag and seal after spawning. This brings with it a great risk for introducing contaminants into the substrate.

We have had great success with autoclaving sealed filter patch bags, however there are a few things you should know:

The bags expand during cooking which means that if the bottoms of the bags stand in water, they will push the water out of the cooker through the vent pipe. This can be prevented by placing the bags on top of a sturdy rack. The water level should be below the rack. This will mean that there is not much water in the cooker. Pressure has to be regulated precise so no excessive steam escape takes place since that may cause the cooker to run dry.

Since the expanding bags may also block the vent pipe a rack of some sort should also be put on top of the bags to prevent this. If water comes out of the vent pipe this means that there's too much water in the cooker and that the expanding bags are pushing the water out.

The cooker should always be fully filled with bags. If the combined volume of the expanded bags is smaller than the volume of the cooker they will burst. Because the bags will all fully expand during cooking they prevent each other from bursting.

As much air as possible is pushed out during sealing of the bags. This makes it easier to put them in the cooker and allows for better steam buildup. A good impulse sealer must be used, poor seals burst during autoclaving.

Sterilisation time for bags is 1,5 - 2,5 hours depending on the weight of the bags.

After sterilisation the bags are removed and shaken. Shaking is not always possible because many bags will come out with little air inside. This doesn't matter since the bags will inflate during incubation and can then be easily shaken.

Since the bags are sealed now, inoculation can only take place by liquid injection. A (self-filling) syringe is used to inoculate the bags. The injection site is cleaned with an alcohol soaked paper towel and then pierced with the needle. Liquid inoculum is injected into the substrate. The hole is shut with a drop of hot glue from a glue gun.

After the glue has hardened the bags are shaken (if possible) and incubated. Shaking can take place as soon as the bags have inflated (after some mycelial growth, often after a few days.)

Usually bags are fully colonised after 14-20 days.

Sterilising jars

First a rack is put in the cooker, than a layer of water is added. If the cooker permits it the jars can be stacked without a problem. If for some reason jars without a filter are sterilised the lids should not be screwed tight.
Usually bags are fully colonised after 14-20 days.

The jars should never be put directly in hot water or they might crack. After one batch of jars is unloaded, the hot water should be poured out and replaced with cold to prevent this.
Usually bags are fully colonised after 14-20 days.

Jars that can be bought for cheap in the supermarket (containing such delicacies as applesauce or green peas) can be autoclaved two or three times after which they are much more likely to break. They are cheap but might be dangerous when used for too long.

Always treat glass jars with caution, handle them (when unloading and shaking) with thick gloves that protect your hands in the case a jar would break.

Sterilisation time for small jars (500 ml) is 45 minutes, for normal jars (720 ml) 60 minutes and for large jars 90-120 minutes (depending on size).

Sterilising liquids

Liquids such as water and agar are sterilised in bottles or Erlenmeyer flasks. Since agar foams during autoclaving the flasks are never filled for more than 2/3. Bottles with water can be totally filled. The caps of bottles or flasks should never be screwed tight but always left a bit open to prevent im- or explosions.

The following table can be used as a guidance for the autoclave time.

vessel size (ml)	sterilisation time (minutes)
25	20
50	25
100	28
250	31
500	35
1000	40
2000	48
4000	63

It's very important that the cooker cools down slowly. When the temperature drops too fast the agar may boil out of it's container which leads to mess.

When agar is sterilised too long it turns dark in color and doesn't gel properly. Sugars are converted to caramel which is toxic to fungi. Care is taken not to let the temperature rise above 121°C for the same reason.

Sterilising other stuff

Items such as scalpel or tweezers can be wrapped in aluminum foil or sealed in tyvek. Most types of syringes are autoclavable as well. These are too wrapped in aluminium foil and sterilised for 15 minutes. Forget about sterilising filled syringe as they will come out of the cooker empty.

MushMush Notes

original source: http://cdn.preterhuman.net/texts/drugs/nansnook3c/tek/mushnotes.htm

Preparing Agar

Recipe for Malt Extract Agar (1 liter)

- 20 grams Malt Extract
- 2 grams Yeast
- 15 grams Agar
- Water

The dry ingredients are put in a flask and the water is added. This is sterilized for 30 minutes at 121 degrees Celsius.

The flask should be twice as large as the volume of the medium that is sterilized to prevent it from boiling over and should preferably have a narrow opening. The opening is stuffed with polyfill, hydrophobic cotton or capped with Tyvek. This is covered with tinfoil.

Pouring Petri dishes

Condensation on the lids can be prevented by:

- pouring Petri dishes when agar has cooled to 40-50 degrees Celsius;
- stacking the dishes with warm agar;
- putting something hot on the top dish of the stack (a mug with hot water for example).

Dishes should preferably be poured in a glove box or HEPA filtered environment.

Incubation of agar cultures

Petri dishes should be taped around the edges with polyethylene cling wrap. This prevents both dehydration and the introduction of contaminants. A small roll, cut from a big roll with a sharp knife is very useful.

Dishes are Incubated upside down so that droplets of condensation will not fall on the agar surface but will remain on the lid until they evaporate.

Keep track of how often a strain is subcultured. Do not subculture for more than 5 Petri dishes or you will risk losing your strain to degeneration. A sure sign of degeneration is the formation of zones of fluffy mycelium. These cultures should preferably not be used. If there's no choice but to use them, use only the rhizomorphic zones.

Storing cultures

For storage of cultures agar slants are used. The agar is prepared by boiling in a pan and then pouring it into test tubes (a big syringe is useful for this). The tubes are loosely capped and sterilized for 25 minutes in the pressure cooker. The tubes should be taken out before the agar solidifies and put under an angle so that upon solidifying the agar has larger surface for mycelial growth.

The tubes can be inoculated by dropping a small piece of colonised agar into the tube. The tube is loosely capped and sealed with cling wrap. The piece of agar can now be forced downwards onto the agar by tapping the tube it with your hand.

After two weeks of growth the tubes can be put in the fridge where they will remain viable for up to 5 years. Every year tubes are taken out and subcultured in Petri dishes to check if they are still viable. After prolonged storage cultures may show some sectoring (the formation of fluffy zones in the mycelium) so only healthy rhizomorphic mycelium is subcultured.

Making a clean sporeprint

Sporeprints are best taken on a smooth surface that allows easy picking up of the spores with an inoculation loop. Most clean smooth materials will work fine as long as they are clean. Most store bought dry products (paper, tinfoil) that are packaged can be considered clean.

Some strains and species do not easily drop their spores. Often sporulation can be stimulated by increasing the humidity. This is especially important when sporeprints are made from small caps. The caps themselves would dry pretty quickly and once they are dry, they will not deposit any spores.
For species such as Psilocybe mexicana and Psilocybe tampanensis a small plastic container that seals well is used some of the stems of the mushrooms are put in this as well to help raise humidity.
Not all strains drop their spores immediately after the veil tears, so it's best to wait until spores can be seen on the stem near the cap.

The mushroom is picked and put on clean tinfoil. With a sharp knife or scalpel the cap is cut off and the cap is put on the printing medium (paper, tinfoil, Petri dish). The container is closed and after 24 hours the cap is removed. A perfect sporeprint should be the result. Store the sporeprints individually sealed in a ziplock type baggie. These can be stored for years in a cool dry location.

Substrates for Psilocybe cubensis

Almost any type of grain can be used to grow this species on but in our opinion rye grain is the best choice. Other grain types and mixtures do not evenly absorb moisture during sterilization and have to be preboiled.

Rye (in dry form) can be combined with water and then sterilized without the need of preboiling. This saves a lot of time and hassle. When the jars or bags are still hot they need to be shaken to disperse the wet bottom kernels with he dryer top kernels. Upon cooling moisture will spread evenly throughout the substrate and the end result can be shaken easily.

Other grains have to be preboiled in plenty of water. Boiling time depends on the type of grain that is used. Mixtures with small kernels often need less time than those consisting of bigger ones. Kernels that have burst open are not good, and too many of these may give problems with bacterial contamination later on. After boiling the grain is drained and filled into jars or bags. These can then be sterilized.

Substrates for Panaeolus cyanescens and Panaeolus tropicalis

Although literature suggests that pasteurized straw can be used yields are poor compared to using a substrate that contains dung. People have reported good success with pasteurized cow and horse dung. We prefer to sterilized the substrate in spawn bags. A mixture of straw or grass seed and dung seems to work best. Vermiculite can be added to improve structure and water holding capacity.

A high yielding substrate can be prepared with the following recipes:

- 7 parts dried cow dung
- 7 parts soaked grass seed Instead of grass seed soaked straw can be used as well
- 2 parts fine vermiculite
- 2 parts coarse vermiculite

Ingredients are mixed in dry form (except the soaked grass seed or straw) and water is added until it is saturated. Squeeze out the moisture and sterilised the mixture in spawnbags for 2 hours. These bags can be inoculated from rye spawn.

Incubating bags produce a lot of heat so watch out for overheating of the substrate!

Sterilization time

Substrates can be effectively sterilized by pressurized steam. A pressure cooker or autoclave are perfectly suitable for this purpose.
The required time for sterilization depends on a variety of factors the most important being:

- the amount of substrate in one container (bag/jar/flask);
- total amount of substrate in the cooker/autoclave;
- solid or liquid substrate.

The more substrate is filled into the containers the longer they should be sterilized. Tightly packed pressure cookers require longer sterilization than empty ones. Liquids (agar, water) require briefer sterilization then solids such as rye or birdseed.

Sterilization time is measured from the moment the pressure cooker or autoclave has reached 121 degrees Celsius (1,0 kg/cm2, 15 psi).

200 ml jar rye 40 minutes
200 ml jar grass seed 40 minutes
800 ml jar rye 60 minutes
800 ml jar grass seed 60 minutes
Spawnbag rye (4 liter) 120 minutes
Spawnbag grass seed (5 liter) 150 minutes
Spawnbag dung mixture (3 liter) 120 minutes
Agar slants 25 minutes
Agar (in bottle) 30 minutes
Water (in bottle) 30 minutes
Scalpel, syringes etc. 20 minutes
Large bag casing soil 60 minutes *partial sterilization*!

Casing soil

Many species benefit from a layer of "casing" soil on top of the colonized substrate. The process of putting such a layer on is called casing.

Recipe:

- 10 parts peat
- 5 parts vermiculite
- 2 parts limestone

The ingredients are mixed in dry form and water is added until the casing soil is almost saturated. The object is to get as much water as possible in without turning it to mud. If too much water has been added some more dry ingredients can be added to compensate.

The casing soil needs to be heat treated before use. Some people have reported success with untreated soils but it seems a big risk to take. There are two practical options: partial sterilization in a pressure cooker and partial sterilization in a microwave.
The wetted soil is put in bag or jars and is 'sterilized' for 1 hour in the pressure cooker or for 25-30 minutes in a microwave at full power. Extra water should be added when a microwave is used.

When it had cooled down the soil is ready to use. If it looks a little dry you can add some clean water to it before applying it to colonized substrate.

The colonized substrate is broken up and poured into trays. The casing mixture is applied and the tray is covered. A normal depth for a casing layer is 1.5-3 cm. *Panaeolus cyanescens* and *Panaeolus tropicalis* also need a casing layer but it must be very thin as these species seem to have trouble growing through it.

Sclerotia cultivation

Some species can form so called "sclerotia" in the casing soil and inside of the substrate. Psilocybe mexicana and *Psilocybe tampanensis* are the two most important species.
Sclerotia are hardened mycelial structures that are formed by the mycelium as a survival mechanism to protect it from floods, forest fires etc. Sclerotia contain 30% dry matter where mushroom only contain 9-10%. Interestingly the sclerotia of the two mentioned species also contain psilocybin and/or psilocin.

Most strains and substrains of these species form sclerotia in the casing soil of cased trays. As a substrate millet and grass seed can be used.

In vitro sclerotia (where the substrate remains in the bags or jars it's growing in) are formed by the "A" strain of mexicana and by some substrains of the *Psilocybe tampanensis*. Sterilized grass seed seems most suitable substrate. It can be prepared by combining the dry grass seed with water in jars or bags followed by steam sterilization.

Recipe (800 ml jars):

- 110 grams grass seed
- 180 ml water

These jars should be sterilized for 1 hour.

Recipe (5 liter spawn bags):

- 4 liters grass seed
- 2 liters water

These bags should be sterilized for 2 1/2 hours.

The substrate is inoculated and shaken after a few days. After some time sclerotia will start to form. Tampanensis forms then only against the glass or inner bag surface, mexicana forms them throughout the substrate. After 3 months (mexicana) or 6 months (tampanensis) growth has halted and the sclerotia can be harvested.

Initiation strategy

One the substrate (and casing layer) are colonized it's time to expose the substrate to fruiting conditions. The three most important changes should be:

- a drop of temperature by a few degrees Celsius;
- lowering of CO2 concentration;
- exposure to light for a few hours a day

Not all strains are as sensitive as others. In general the more fleshy and stout strains of *Psilocybe cubensis* are somewhat more difficult to get to pin than the more slender/thinner strains. Difficult to fruit strains can be 'cold-shocked' by putting the substrate in the fridge for 24 hours before putting them in the fruiting chamber.

Panaeolus cyanescens and *tropicalis* are very sensitive to high CO2 concentrations (much more than Psilocybe cubensis). If they do not receive enough fresh air, the mushrooms will grow tall and spindly and will abort at an early stage.

If the conditions are not right for the species being cultivated often the mycelium will continue to colonize the casing surface without forming any pinheads. The casing becomes a hard closed surface that will not absorb water. If this happens the casing surface should be scratched open with a clean fork and conditions should be corrected to allow fruiting.

Working with agar

original source: http://www.mushmush.nl/?page=begin%5Cmethods%5Cworking_with_agar&old

What is agar?

Agar is a polysaccharide found in the cell walls of some red algae from which it's extracted by boiling. This raw agar is then purified.
When agar is dissolved in boiling water and left to cool it will form a gel (very much like gelatin). It can be bought in many different grades from food-grade to purified tissue culture grade.

It's main uses are in the field of microbiology, tissue culture and food preparation (as a vegetarian substitute for gelatin).

Why is agar important?

We use agar as a gelling agent for nutrient media. By adding nutrients (agar itself does not contain digestible compounds) a nutrient base can be made on which mushroom mycelia can be cultivated in a flat two-dimensional way.
It can not be substituted by gelatin since gelatin is digestible and does not gel after autoclaving.

Preparing nutrient medium

There are many recipes that work well but the simplest and easiest to prepare remains:

MEA (Malt Extract Agar):

- 20 grams light malt extract
- 2 grams yeast
- 15-20 grams agar
- 1 liter water

(Smaller volumes can be prepared by simply using less ingredients in the same ratio)

The dry ingredients are put in a flask (Erlenmeyer or similar) and water is added. Take care not to fill the flask for more than 2/3 of it's volume or it will boil over.
When the water and dry ingredients are put in the flask the opening is stuffed with polyfill or hydrophobic cotton. Another option is to put a piece of Tyvek over it held in place with rubber bands. This allows for the agar to be re-melted in the microwave. A piece of aluminum foil is put on top and the flask is swirled.

The flasks are then sterilised in the pressure cooker at 121°C for 40 minutes.

This medium will support the growth of most saprophytic fungi. Other often used formulations are PDA (Potato Dextrose Agar) and DFA (Dog Food Agar).

When making your own recipes keep in mind that more is not always better. When media are too rich in nutrients mycelium will not grow or grow very poorly secreting yellowish metabolites.

Pouring dishes

When the flasks come out of the pressure cooker or autoclave the temperature of the agar will be close to 100°C. The medium will be liquid until the temperature drops below 40°C. The agar is left to cool until it has almost reached this temperature. As a rule of thumb: If you can hold the bottle in your bare hand for 10 seconds without real discomfort the temperature is right. Do not let it cool too much or it will solidify in the bottle. Better to pour a little too hot than having to reliquify the agar.

Since the lids of the dishes will be removed for a few seconds it's very important to prepare a clean workplace. A laminar flowhood is best but an improvised transfer hood will usually give adequate results.

Whichever is used the table top is cleaned with alcohol or lysol **(CAREFUL! THESE ARE FLAMMABLE!)** and the dishes are taken out of the tube in which they were packaged and put in stacks of 10 dishes.

When working in less then totally sterile environments it's important to work as fast as possible, limiting the direct contact of agar with outside air.

The flask is swirled to mix the ingredients and the aluminum foil and polyfill are removed.

The lid of the bottom dish is lifted (in fact lifting the lid and the 9 dishes on top). Swiftly a layer of nutrient medium is poured in the dish (to 0,3-0,5 cm depth) and the lid is replaced. Quickly lift the second lid (and the 8 remaining dishes) and work your way up in this fashion.

By letting the agar cool before pouring and by stacking the dishes condensation on the lids is minimized. When a mug or jar with near boiling water is put on the top dish of a stack condensation will be even less.

When the agar in the has solidified the dishes are ready to use.

Preparing agar slants

The normal way to store cultures is in so-called slants. Slants are test tubes in which the agar was cooled on a sloped surface to give the agar a larger surface area.

Slants are prepared a little differently then Petri dishes since the tubes are sterilized with the agar in them opposed to dishes which come pre-sterilized and which are filled with sterilized agar.

The nutrient medium is prepared by bringing the appropriate amount of water to a near boil in a pot on the stovetop. The ingredients are added and the mixture is stirred to let them dissolve. Agar should first be mixed

with a little bit of cold water before adding or it will form lumps. Careful, adding agar to boiling water will cause the medium to foam and boil over. Boiling agar can cause serious burns!
Let the agar boil for a few minutes, then turn off the heat.

Tubes are filled with 5-6 ml of medium and loosely capped. A small funnel and a big syringe are very useful here. The tubes are sterilized for 25 minutes at 121°C.

When they come out they are left to cool on a sloped surface to increase to surface area of the agar. When the agar has solidified the slants are ready to use.

Starting a culture from spores

To start cultures from spores one needs a sporeprint and a tool that can be sterilized to pick up the spores (inoculation loop, scalpel or similar).

With a sterilised inoculation loop some spores are scraped from the spore print and the loop is streaked across the surface of the agar in an 'S' pattern. The inoculation loop is resterilised before using it for other inoculation.

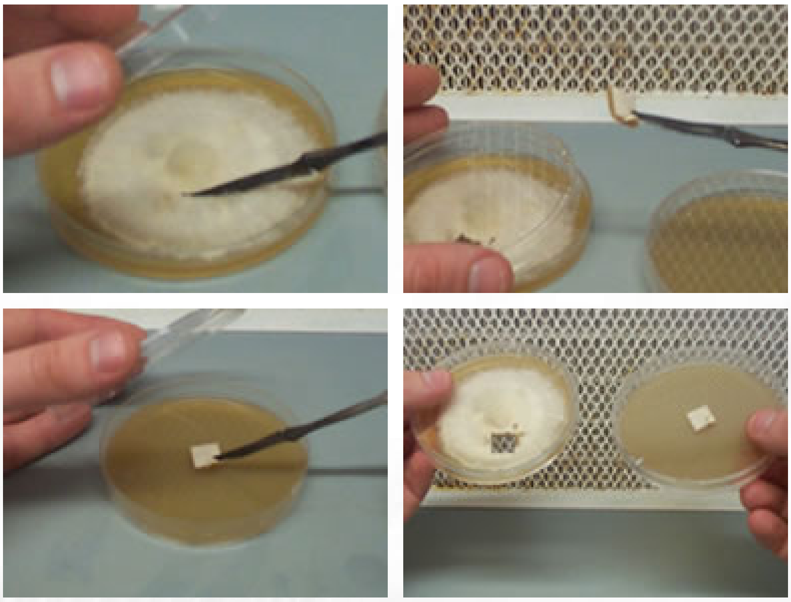
Often spore germination is visible within a few days but it may take as long as four weeks before visible germination takes place. If no germination takes places it may be necessary to rehydrate the spores in some sterile water for 24 hours before streaking them on agar.

If contaminants are encountered one can choose to discard the whole dish or one can transfer the mycelium away from the contamination to a new dish. When bacterial contamination is present this can take place in a flowhood. If sporulating molds are present isolation should take place in a still-air environment to prevent the release of mold spores.

The germinating spores will form a mycelium that by itself is not capable of fruiting called a 'monokaryon'. When the mycelia of two spores fuse they will form a new type of mycelium that IS capable of fruiting, a 'dikaryon'. This process will happen by itself and one dish with germinated spores will often contain dozens of these combinations.

A dish with germinated spores will often look a little bit messy, with monokaryons and dikaryons competing with each other for nutrient sources. Here one has two options: use this mixture of substrains (a 'multispore') or select a pure substrain. Each substrain has it's own properties but generally resembles it's parents. Generally speaking flushes from pure substrains are more uniform and better yielding than a mixture of substrains.

To select pure substrains small agar squares from a multispore germination are transferred to fresh media. Growth from these squares will still be pretty messy but often some sectors will develop that show healthy growth. These healthy sectors should be transferred to new dishes again. This process is repeated until the growth in a dish is uniform and non-sectoring. This is a pure substrain.



One can also use the multispore cultures to directly inoculate spawn. Since mushrooms are composed of mycelial threads (of one substrain, not of a mixture) one can always isolate pure strains from mushrooms as soon as they emerge from this multispore culture.

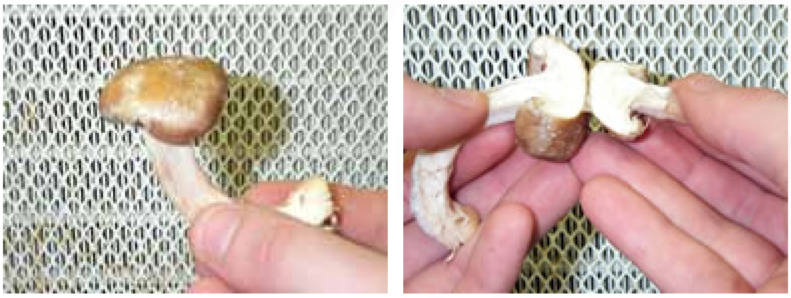
Starting a culture from a fruitbody

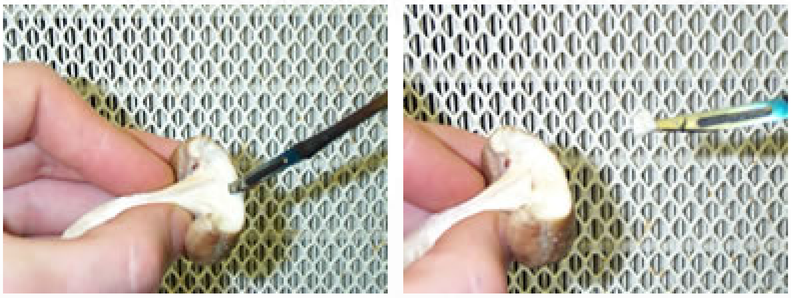
Since mushrooms are composed of mycelial threads (of one substrain, not of a mixture) , as mentioned before, one can use tissue from a mushroom to start new cultures. However there is no advantage to cloning a mushroom that is grown from a pure strain. Cloning mushrooms is useful when one starts with multispore inoculations or for cloning wild specimens.

We like to isolate pure lines by letting multispore cultures fruit and consequently isolating mycelia from the healthiest looking fruitbodies. This saves time and ensures that the obtained strain is indeed one that is willing to fruit on the selected substrate under the same environmental conditions.

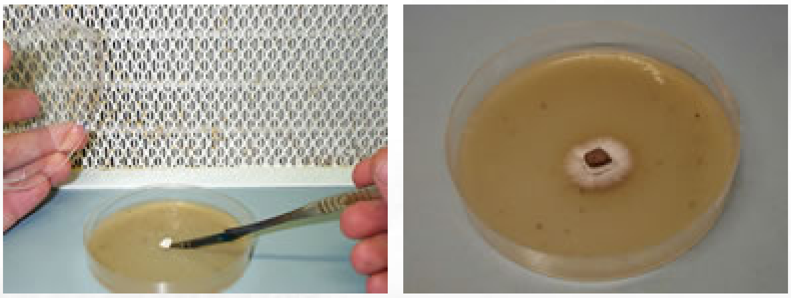
Most mushroom species produce fruitbodies that are sterile on the inside. The practical approach to isolating some tissue is to split open the mushroom and to cut a piece of tissue from the inside. This mushroom fragment is put on agar. Care is taken to not let the scalpel or the fragment come in contact with the outside of the mushroom. This will surely lead to bacterial contamination.

To increase the chance of success at least 10 dishes are inoculated taking care not to cause cross-contamination (re-sterilize the scalpel in between isolations).





Often within a few days the fragment will spring to life. Becoming fuzzy and showing new growth on the agar surface. If contaminants are visible one can try to isolate the mycelium away from the contaminants.



Even though a pure (sub)strain should be growing on the agar sectoring may be visible, often healthy zones mixed with cottony or fuzzy ones. The reason for this is not known. Some strains have a tendency to show this phenomenon more than others. The healthy mycelium is then transferred to a new dish until a healthy pure culture is established.

Taping dishes and tubes

To prevent moisture loss and the introduction of contaminants dishes and tubes are taped. For this purpose small rolls of clingfilm are cut from a big roll with a sharp serrated knife. The clingfilm is stretched out a bit and wrapped around the dish, effectively taping the dish and lid together. Polyethylene clingfilm allows for slow gas exchange.

Storing slant cultures

To store cultures slants are inoculated with small agar squares. The cap is put on loosely and the tube neck is taped with polyethylene clingfilm. Once the agar is fully colonized the slants are put in the fridge where they can be kept for at least a year. It's wise to check the viability of cultures each year by inoculating some dishes with the culture.

Incubating cultures

Cultures should be incubated at the right temperature. If the temperature is too high mycelia will often start to sweat, sickening the culture. If the temperature is too low mycelia will grow slowly. In general too low is better than too high.

It's also very important not to let the temperature fluctuate too much as this causes condensation to form on the lids. The temperature should be kept as constant as possible. Dishes are incubated upside down so even if condensation forms it will not disturb mycelial growth.

FOREWORD by Dr. Andrew Weil

Ever since French growers pioneered the cultivation of the common Agaricus more than two hundred years ago, mushroom cultivation in the Western world has been a mysterious art. Professional cultivators, fearful of competition, have guarded their techniques as trade secrets, sharing them only with closest associates, never with amateurs. The difficulty of domesticating mushrooms adds to the mystery: they are just harder to grow than flowering plants. Some species refuse to grow at all under artificial conditions; many more refuse to fruit; and even the familiar Agaricus of supermarkets demands a level of care and attention to detail much beyond the scope of ordinary gardening and agriculture.

In the past ten years, interest in mushrooms has literally mushroomed in America. For the first time in history the English-speaking world is flooded with good field guides to the higher fungi, and significant numbers of people are learning to collect and eat choice wild species. In the United States and Canada mushroom conferences and forays attract more and more participants. Cultivated forms of species other than the common Agaricus have begun to appear in specialty shops and even supermarkets.

The reasons for this dramatic change in a traditionally mycophobic part of the world may never be known. I have been fascinated with mushrooms as symbols of the unconscious mind and think their growing popularity here is a hopeful sign of progress in the revolution of consciousness that began in the 1960s. A more specific reason may be the rediscovery of psychedelic mushrooms - the Psilocybes and their allies - which have thoroughly invaded American society in recent years.

The possibility of collecting wild psychoactive mushrooms in many parts of North America has motivated thousands of people to buy field guides and attend mushroom conferences. The possibility of growing *Psilocybe cubensis* at home, one of the easier species to cultivate, has made many people eager to learn the art of mushroom production. As they pursue their hobby, fans of Psilocybes often find their interest in mushrooms broadening to include other genera that boast non-psychoactive but delicious edible species. Other mycophiles, uninterested in altered states of consciousness, have grown so fond of some edible species as to want better access to them than foraying in the wild provides. The result has been a demand from a variety of amateurs for the trade secrets of professional cultivators.

The book you are about to read is a milestone in the new awareness of mushrooms. THE MUSHROOM CULTIVATOR by Paul Stamets and Jeff Chilton is easily the best source of information on growing mushrooms at home. Both authors are experts on the higher fungi, on their technical aspects as well as the practical methods of working with the most interesting species. Paul Stamets is a recognized authority on the Psilocybes and their relatives; Jeff Chilton has been a professional consultant to large-scale, commercial producers of the common Agaricus and the once-exotic shiitake of Japan and China. Together they have organized a number of successful mushroom conferences in the Pacific Northwest and have championed the cause of growing at home. Unlike experts of the past (and some of the present), they are willing and ready to share their knowledge and practical information with all lovers of mushrooms, whether they are amateurs or professionals, devotees of *Psilocybe* or of *Pleurotus*.

THE MUSHROOM CULTIVATOR is indeed "A Practical Guide to Growing Mushrooms at Home," as its subtitle indicates. It covers every aspect of the subject in a readable style and in sufficient detail to enable both rank amateurs and serious mycologists to succeed at growing the mushrooms they like. By including a wealth of excellent illustrations, information on obtaining equipment and supplies, and step-by-step directions for every procedure, from starting spore cultures to harvesting fruiting bodies to dealing with contaminants and pests, the authors demystify the art of mushroom cultivation and put mastery of it within everyone's reach. It is a pleasure to introduce this fine book. If you have been searching for information on this topic, you will find it to be all that you have been looking for and more.

Andrew Weil, M.D., F.L.S

PREFACE

The use of mushrooms as food crosses all cultural boundaries. Highly prized by the Greeks, mushroom consumption in European nations has deep traditional roots. The Agari, a pre-Scythian people from Samartia (now Poland and the western Soviet Union), held mushrooms in high esteem and used them medicinally. The early Greeks held a similar fascination for fungi and apparently worked them into their religious rituals, even to the extent that to discuss the use of these sacraments violated strong taboos. For thousands of years, the Chinese and Japanese have prized a variety of mushroom species for their beneficial properties. In the New World, the Aztec and Mazatec Indians of Mexico used mushrooms for both their healing and divining properties. Clearly, mushrooms have played a significant role in the course of human cultures worldwide.

Although the Japanese have cultivated the Shiitake mushroom for two thousand years, the earliest record of European mushroom cultivation was in the 17th century when an agronomist to Louis XIV, Olivier de Serres, retrieved wild specimens and implanted mushroom mycelium in prepared substrates. In those times mushroom growing was a small scale outdoor activity practiced by the rural populace. Materials in which mushrooms grew naturally were collected and concentrated into prepared beds. These beds were cropped and then used to start new beds. As demand increased and new methods improved yields, mushroom growing developed into a large scale commercial business complete with computer controlled indoor environments and scientifically formulated substrates. Spawn with which to plant prepared beds, initially gathered in nature, became standardized as sterile culture techniques were perfected.

It is now known that many of the mushrooms presently under cultivation rank above all vegetable and legumes (except soybeans) in protein content, and have significant levels of B and C vitamins and are low in fat. Research has shown that certain cultivated mushrooms reduce serum cholesterol, inhibit tumors, stimulate interferon production and possess antiviral properties. It is no surprise, therefore, that as food plants were developed into cultivars, mushrooms were among those selected.

Discovering the methods most successful for mushroom cultivation has been a long and arduous task, evolving from the experience of lifetimes of research. As mushroom growing expanded from the realm of home cultivators to that of a multimillion dollar industry, it is not surprising that growers became more secretive about their methods. For prospective home cultivators, finding appropriate information has become increasingly difficult. As a result, the number of small growers decreased and home cultivation became a rare enterprise.

The Mushroom Cultivator is written expressly for the home cultivator and is without bias against any group of interested growers. For the first time, information previously unavailable to the general public is presented in a clear and easy to understand fashion. The book reflects not only the work of the authors but also the cumulative knowledge gained through countless trials by mushrooms growers and researchers. It is the sincere hope of the authors that this work will re-open the door to the fascinating world of mushroom culture. The Mushroom Cultivator is dedicated to this goal as we pursue the Art and Science of mushroom cultivation.

I. INTRODUCTION TO MUSHROOM CULTURE

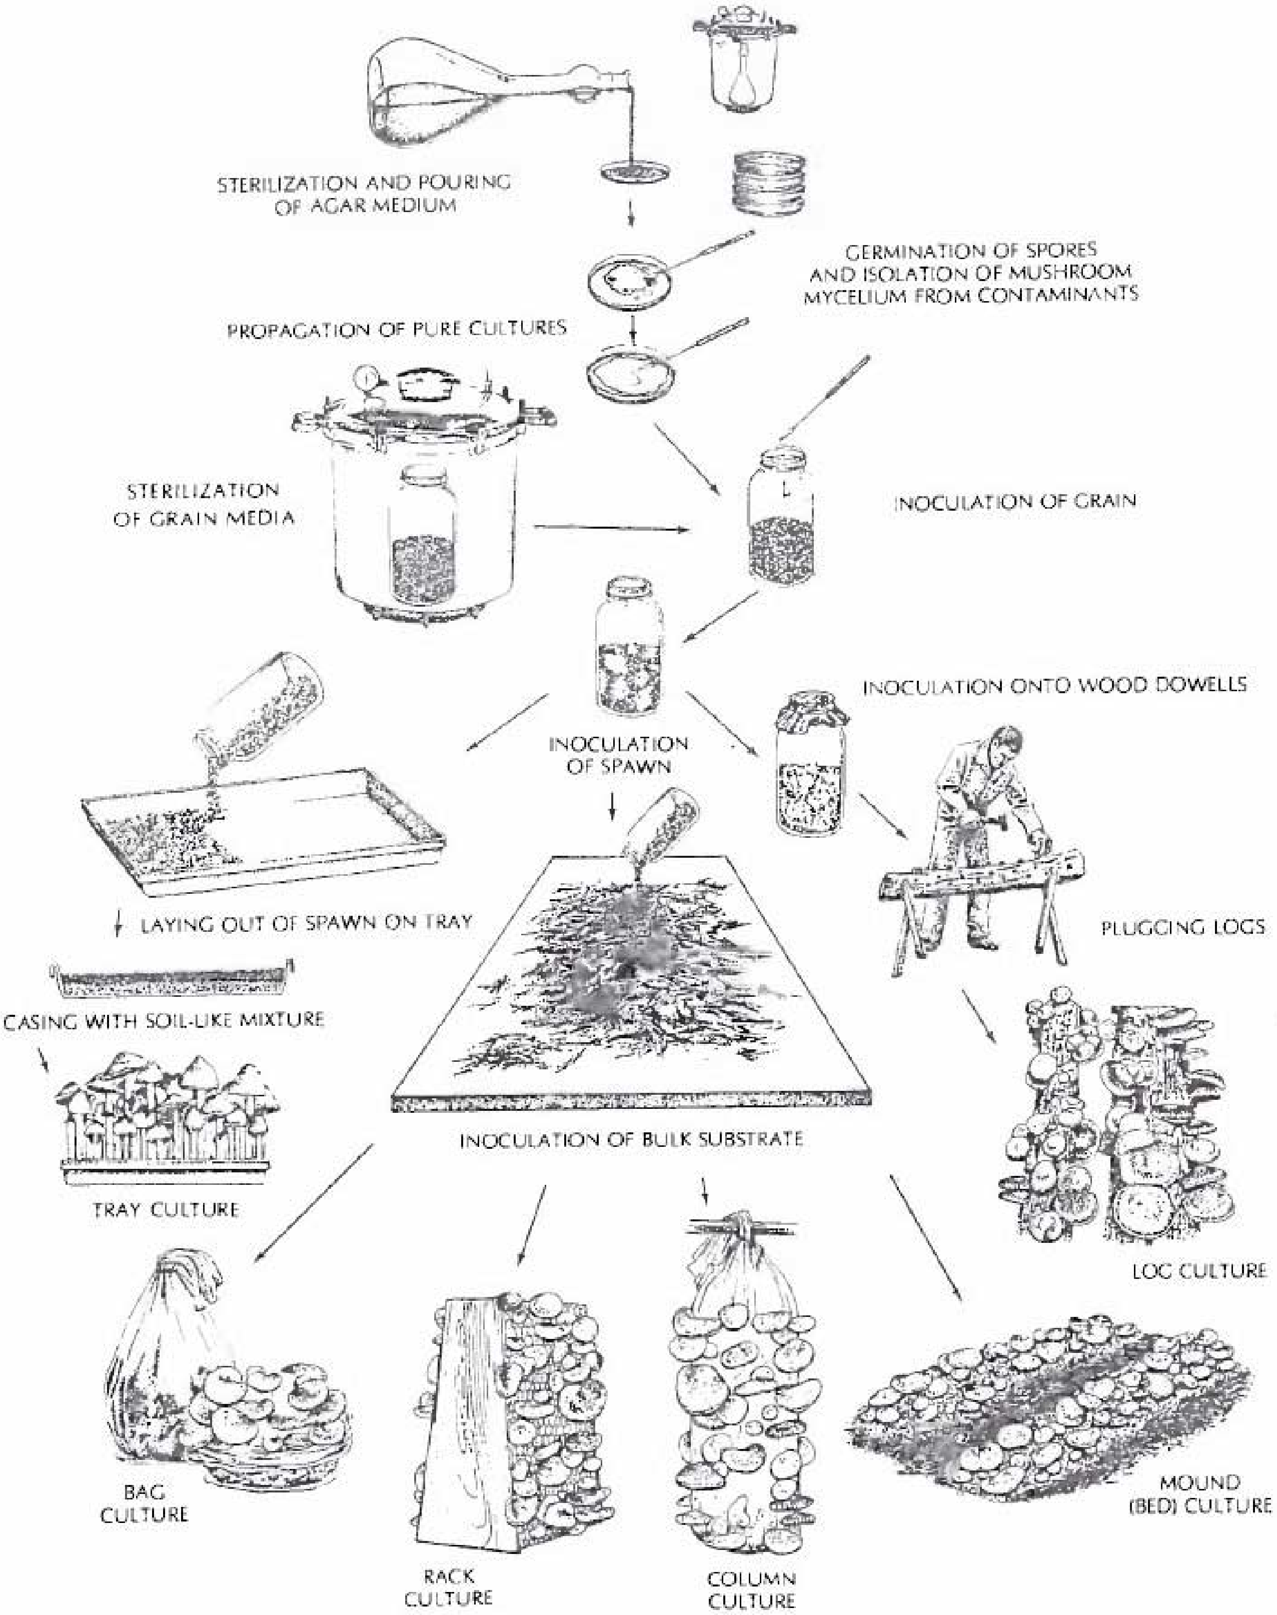
Figure 0 - Wall of *Pleurotus ostreatus* fruitbodies.

An Overview of Techniques for Mushroom Cultivation

Techniques for cultivating mushrooms, whatever the species, follow the same basic pattern. Whereas two species may differ in temperature requirements, pH preferences or the substrate on which they grow, the steps leading to fruiting are essentially the same. They can be summarized as follows:

1. Preparation and pouring of agar media into Petri dishes.
2. Germination of spores and isolation of pure mushroom mycelium.
3. Expansion of mycelial mass on agar media.
4. Preparation of grain media.
5. Inoculation of grain media with pure mycelium grown on agar media.
6. Incubation of inoculated grain media (spawn).
7. A. Laying out grain spawn onto trays. Or
   B. Inoculation of grain spawn into bulk substrates.
8. Casing - covering of substrate with a moist mixture of peat and other materials.

9. Initiation - lowering temperature, increasing humidity to 95%, increasing air circulation, decreasing carbon dioxide and/or introducing light.
10. Cropping - maintaining temperature, lowering humidity to 85-92%, maintaining air circulation, carbon dioxide and/or light levels.



STERILIZATION AND POURING OF AGAR MEDIUM
GERMINATION OF SPORES AND ISOLATION OF MUSHROOM MYCELIUM FROM CONTAMINANTS
PROPAGATION OF PURE CULTURES
STERILIZATION OF GRAIN MEDIA
INOCULATION OF GRAIN
INOCULATION ONTO WOOD DOWELLS
INOCULATION OF SPAWN
LAYING OUT OF SPAWN ON TRAY
PLUGGING LOGS
CASING WITH SOIL-LIKE MIXTURE
TRAY CULTURE
INOCULATION OF BULK SUBSTRATE
LOG CULTURE
BAG CULTURE
MOUND (BED) CULTURE
RACK CULTURE
COLUMN CULTURE

Figure 1 - Diagram illustrating overview of general techniques for the cultivation of mushrooms.

With many species moderate crops can be produced on cased grain cultures. Or, the cultivator can go one step further and inoculate compost, straw or wood. In either case, the fruiting of mushrooms requires a high humidity environment that can be readily controlled. Without proper moisture, mushrooms don't grow.

In the subsequent chapters standard methods for germinating spores are discussed, followed by techniques for growing mycelium on agar, producing grain and/or bran "spawn", preparing composted and non-composted substrates, spawn running, casing and pinhead formation. With this last step the methods for fruiting various species diverge and techniques specific to each mushroom are individually outlined. A trouble-shooting guide helps cultivators identify and solve problems that are commonly encountered. This is followed by a thorough analysis of the contaminants and pests of mushroom culture and a chapter explaining the nature of mushroom genetics. In all, the book is a system of knowledge that integrates the various techniques developed by commercial growers worldwide and makes the cultivation of mushrooms at home a practical endeavor.

Mushrooms and Mushroom Culture

Mushrooms inspire awe in those encountering them. They seem different. Neither plant-like nor animal-like, mushrooms have a texture, appearance and manner of growth all their own. Mushrooms represent a small branch in the evolution of the fungal kingdom Eumycota and are commonly known as the "fleshy fungi". In fact, fungi are non-photosynthetic organisms that evolved from algae. The primary role of fungi in the ecosystem is decomposition, one organism in a succession of microbes that break down dead organic matter. And although tens of thousands of fungi are know, mushrooms constitute only a small fraction, amounting to a few thousand species.

Regardless of the species, several steps are universal to the cultivation of all mushrooms. Not surprisingly, these initial steps directly reflect the life cycle of the mushroom. The role of the cultivator is to isolate a particular mushroom species from the highly competitive natural world and implant it in an environment that gives the mushroom plant a distinct advantage over competing organisms. The three major steps in the growing of mushrooms parallel three phases in their life cycle. They are:

1. Spore collection, spore germination and isolation of mycelium; or tissue cloning.
2. Preparation of inoculum by the expansion of mycelial mass on enriched agar media and then on grain. Implantation of grain spawn into composted and uncomposted substrates or the use of grain as a fruiting substrate.
3. Fruitbody (mushroom) initiation and development.

Having a basic understanding of the mushroom life cycle greatly aids the learning of techniques essential to cultivation.

Mushrooms are the fruit of the mushroom plant, the **mycelium**. A mycelium is a vast network of interconnected cells that permeates the ground and lives perennially. This resident mycelium only produces **fruitbodies**, what are commonly called mushrooms, under optimum conditions of temperature, humidity and nutrition. For the most part, the parent mycelium has but one recourse for insuring the survival of the species: to release enormous numbers of spores. This is accomplished through the generation of mushrooms.

In the life cycle of the mushroom plant, the fruitbody occurs briefly. The mycelial network can sit dormant for months, sometimes years and may only produce a single flush of mushrooms. During those few weeks of fruiting, the mycelium is in a frenzied state of growth, amassing nutrients and forming dense ball-like masses called **primorida** that eventually enlarge into the towering mushroom structure. The gills first develop from the tissue on the underside of the cap, appearing as folds, then becoming blunt ridges and eventually extending into flat, vertically aligned plates. These efficiently arranged symmetrical gills are populated with spore producing cells called **basidia**.

From a structural point of view, the mushroom is an efficient reproductive body. The cap acts as a domed shield protecting the underlying gills from the damaging effects of rain, wind and sun. Covering the gills in many species is a well developed layer of tissue called the **partial veil** which extends from the cap margin to the stem. Spores start falling from the gills just before the partial veil tears. After the partial veil has fallen, spores are projected from the gills in ever increasing numbers. The cap is supported by a pillar-like stem that elevates the gills above ground where the spores can be carried off by the slightest wind currents. Clearly, every part of the mushroom fruitbody is designed to give the spores the best opportunity to mature and spread in an external environment that is often harsh and drastically fluctuating.

As the mushroom matures, spore production slows and eventually stops. At this time mushrooms are in their last hours of life. Soon decay from bacteria and other fungi sets in, reducing the once majestic mushroom into a soggy mass of fetid tissue that melts into the ground from which it sprung.

Figure 2 - The Mushroom Life Cycle.

Cultivating mushrooms is one of the best ways to observe the entirety of the Mushroom Life Cycle. The life cycle first starts with a spore which produces a **primary mycelium**. When the mycelium originating from two spores mates, a **secondary mycelium** is produced. This mycelium continues to grow vegetatively. When vegetative mycelium has matured, its cells are capable of a phenomenal rate of reproduction which culminates in the erection of mushroom fruitbody. This represents the last functional change and it has become, in effect, **tertiary mycelium**. These types of mycelia represent the three major phases in the progression of the mushroom life cycle.

Most mushrooms produce spores that are **uninucleate** and genetically **haploid** (1N). This means each spore contains one nucleus and has half the complement of chromosomes for the species. Thus spores have a "sex" in that each has to mate with mycelia from another spore type to be fertile for producing offspring. When spores are first released they are fully inflated "moist" cells that can easily germinate. Soon they dehydrate, collapsing at their centers and in this phase they can sit dormant through long periods of dry weather or severe drought. When weather conditions provide a sufficiently moist environment, the spores rehydrate and fully inflate. Only then is germination possible.

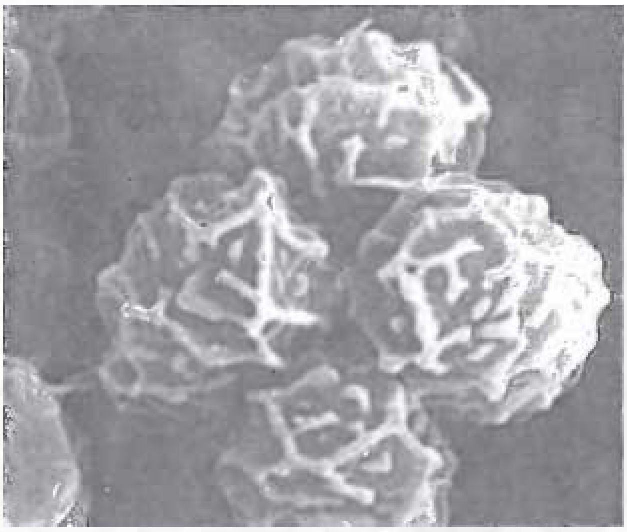

Figure 3 - Scanning electron micrograph of *Russula* spores.

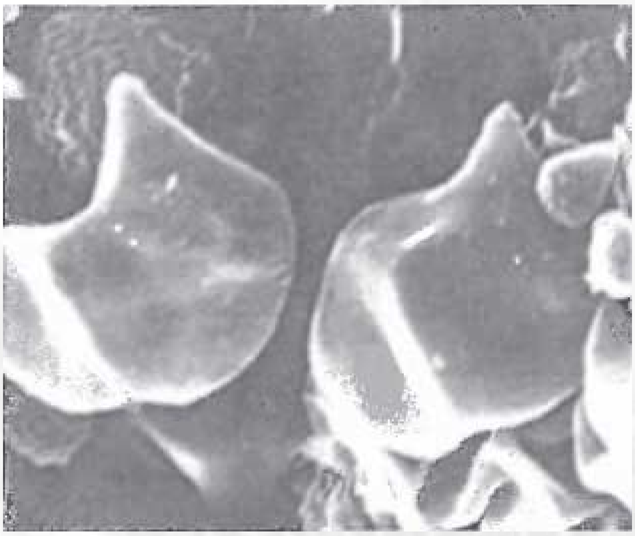

Figure 4 - Scanning electron micrograph of *Entoloma* spores.

Spores within an individual species are fairly constant in their shape and structure. However, many mushroom species differ remarkably in their spore types. Some are smooth and lemon shaped (in the genus *Copelandia*, for instance); many are ellipsoid (as in the genus *Psilocybe*); while others are highly ornamented and irregularly shaped (such as those in *Lactarius* or *Entoloma*). A feature common to the spores of many mushrooms, particularly the psilocybian species, is the formation of an apical **germ pore**.

The germ pore, a circular depression at one end of the spore, is the site of germination from which a haploid strand of mycelium called a **hypha** emanates. This hypha continues to grow, branches and becomes a **mycelial network**. When two sexually complementary hyphal networks intercept one another and make contact, cell walls separating the two hyphal systems dissolve and cytoplasmic and genetic materials are exchanged. Erotic or not, this is "mushroom sex". Hence - forth, all resulting mycelium is **binucleate** and dikaryotic. This means each cell has two nuclei and a full complement of chromosomes. With few exceptions, only mated (dikaryotic) mycelia is fertile and capable of producing fruitbodies. Typically, dikaryotic mycelia is faster running and more vigorous than unmated, monokaryotic mycelia. Once a mycelium has entered into the dikaryophase, fruiting can occur shortly thereafter. In *Psilocybe cubensis*, the time between spore germination and fruitbody initials can be as brief as two weeks; in some *Panaeolus* species only a week transpires before mushrooms appear. Most mushroom species, however, take several weeks or months before mushrooms can be generated from the time of spore germination.

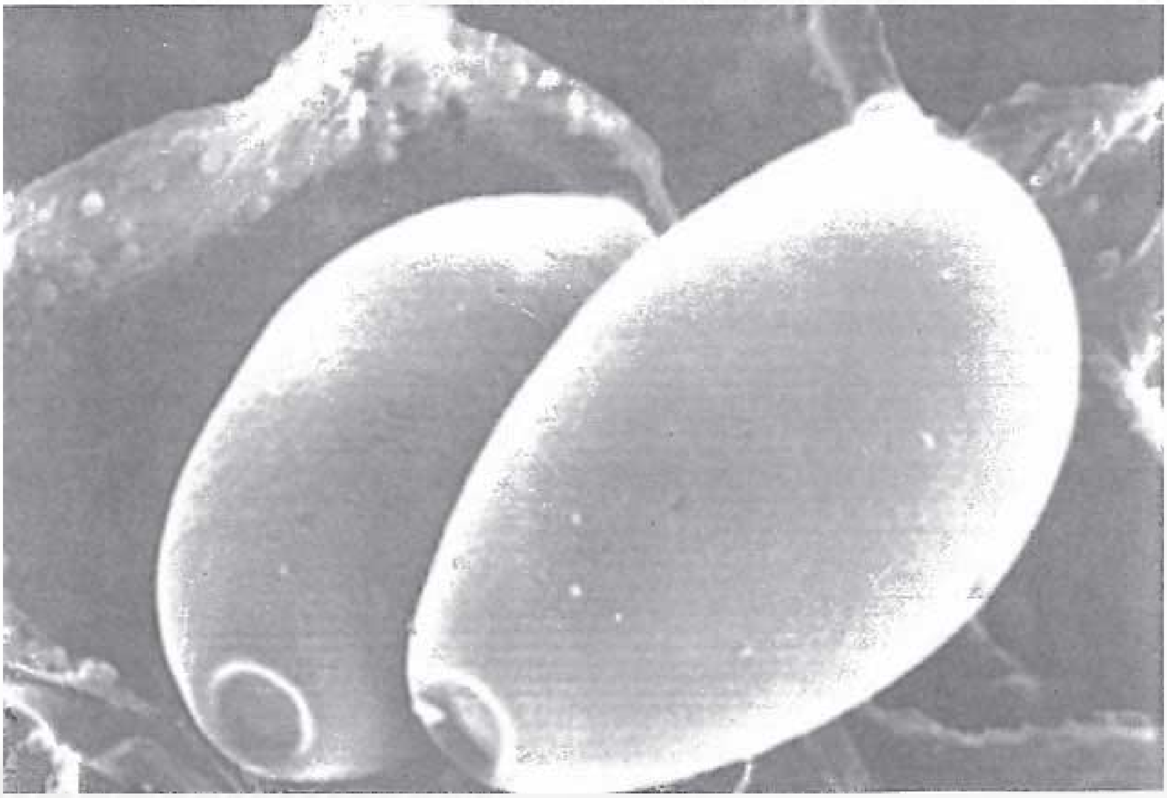

Figure 5 - High resolution scanning electron micrograph showing germ pores of *Psilocybe pelliculosa* spores.

Cultivators interested in developing new strains by crossing single spore isolates take advantage of the occurrence of **clamp connections** to tell whether or not mating has taken place. Clamp connections are microscopic bridges that protrude from one adjoining cell to another and are only found in dikaryotic mycelia. Clamps can be readily seen with a light microscope at 100-400X magnification. Not all species form clamp connections. (*Agaricus brunnescens* does not; most all *Psilocybe* and *Panaeolus* species do). In contrast, mycelia resulting from haploid spores lack clamps. This feature is an invaluable tool for the researcher developing new strains. (For more information on breeding strategies, see Chapter XV.)

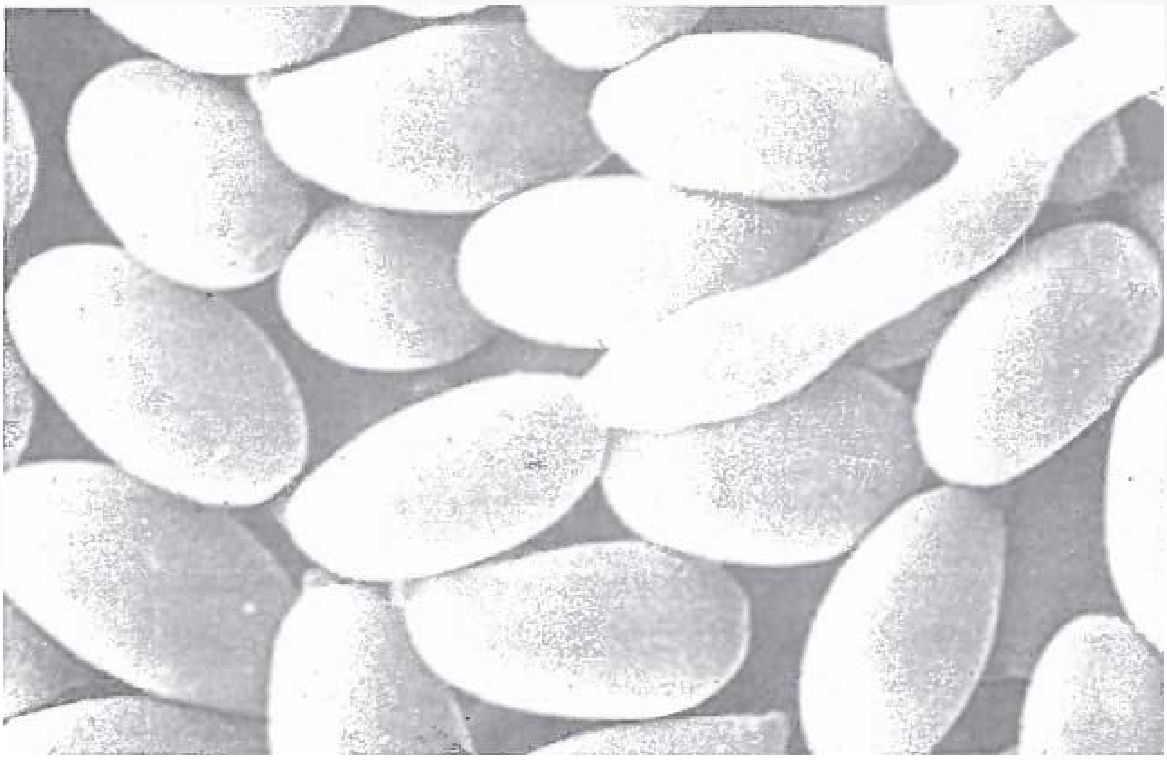

Figure 6 - Scanning electron micrograph of *Psilocybe baeocystis* spore germinating.

Two dikaryotic mycelial networks can also grow together, exchange genetic material and form a new strain. Such an encounter, where two hyphal systems fuse, is known as **anastomosis**. When two incompatible colonies of mycelia meet, a zone of inhibited growth frequently forms. On agar media, this zone of incompatibility is visible to the unaided eye.

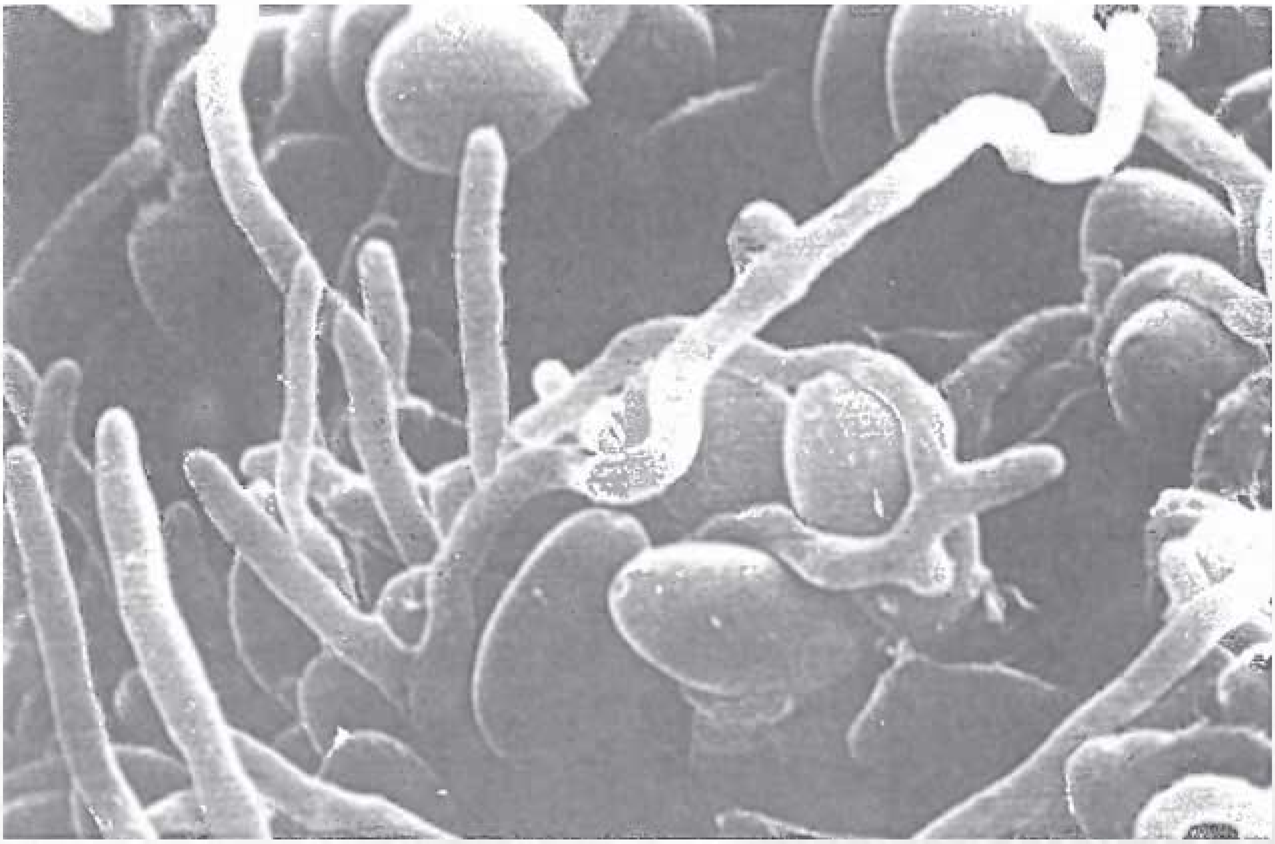

Figure 7 - Scanning electron micrograph of hyphae emanating from a bed of germinating *Psilocybe cubensis* spores.

When a mycelium produces mushrooms, several radical changes in its metabolism occurs. Up to this point, the mycelium has been growing vegetatively. In the vegetative state, hyphal cells are amassing nutrients. Curiously, there is a gradual increase in the number of nuclei per cell, sometimes to as many as ten just prior to the formation of mushrooms. Immediately before fruitbodies form, new cell walls divide the nuclei, reducing their number per cell to an average of two. The high number of nuclei per cell in pre-generative mycelia seems to be a prerequisite for fruiting in many mushroom species.

As the gills mature, basidia cells emerge in ever increasing numbers, first appearing as small bubble-like cells and resembling cobblestones on a street. The basidia are the focal point in the reproductive phase of the mushroom life cycle. The basidia, however, do not mature all at once. In the genus *Panaeolus* for instance, the basidia cells mature regionally, giving the gill surface a spotted look. The cells giving rise to the basidia are typically binucleate, each nucleus is haploid (1N) and the cell is said to be dikaryotic. The composition of the young basidia cells are similar. At a specific point in time, the two nuclei in the basidium migrate towards one another and merge into a single **diploid** (2N) nucleus. This event is known as **karyogamy**. Soon thereafter, the diploid nucleus undergoes meiosis and typically produces four haploid daughter cells.

On the surface of the basidia, arm-like projections called **sterigmatae** arise through which these nuclei then migrate. In most species four spores form at the tips of these projections. The spores continue to develop until they are forcefully liberated from the basidia and propelled into free space. The mechanism for spore release has not yet been proven. But, the model most widely accepted within the mycological community is one where a "gas bubble" forms at the junction of the spore and the sterigmata. This gas bubble inflates, violently explodes and jettisons the spore into the cavity between the gills where it is taken away by air currents. Most commonly, sets of opposing spores are released in this manner. With spore release, the life cycle is completed.

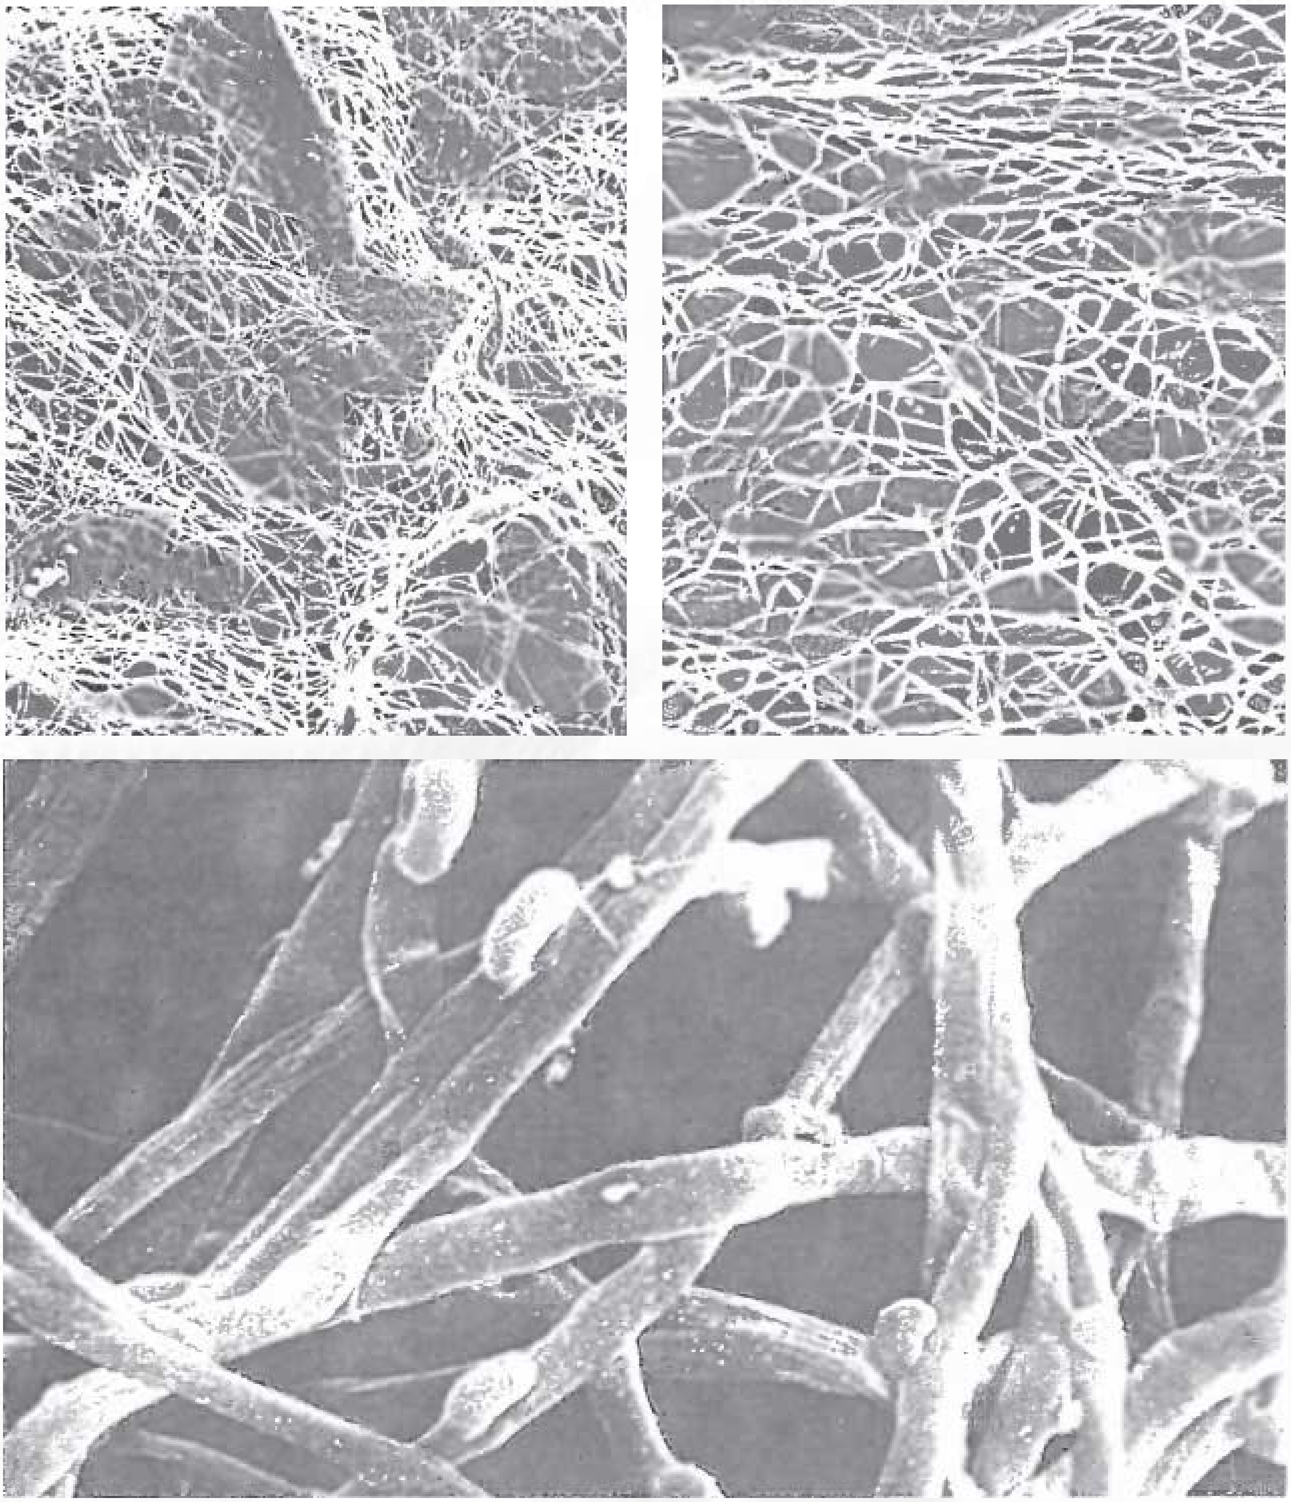

Figure 8, 9, & 10 - Scanning electron micrographs of the mycelial network of *Psilocybe cubensis*. Note hyphal crossings and clamp connections.

Not all mushroom species have basidia that produce four haploid spores. *Agaricus brunnescens* (= *Agaricus bisporus*), the common button mushroom, has basidia with two diploid (2N) spores. This means each spore can evolve into a mycelium that is fully capable of producing mushrooms. *Agaricus brunnescens* is one example of a diploid bipolar species. Some Copelandian Panaeoli (the strongly bluing species in the genus *Panaeolus*) are two spored and have mating properties similar to *Agaricus brunnescens*. Other mushroom species have exclusively three spored basidia; some have five spored basidia; and a few, like the common Chantarelle, have as many as eight spores per basidium!

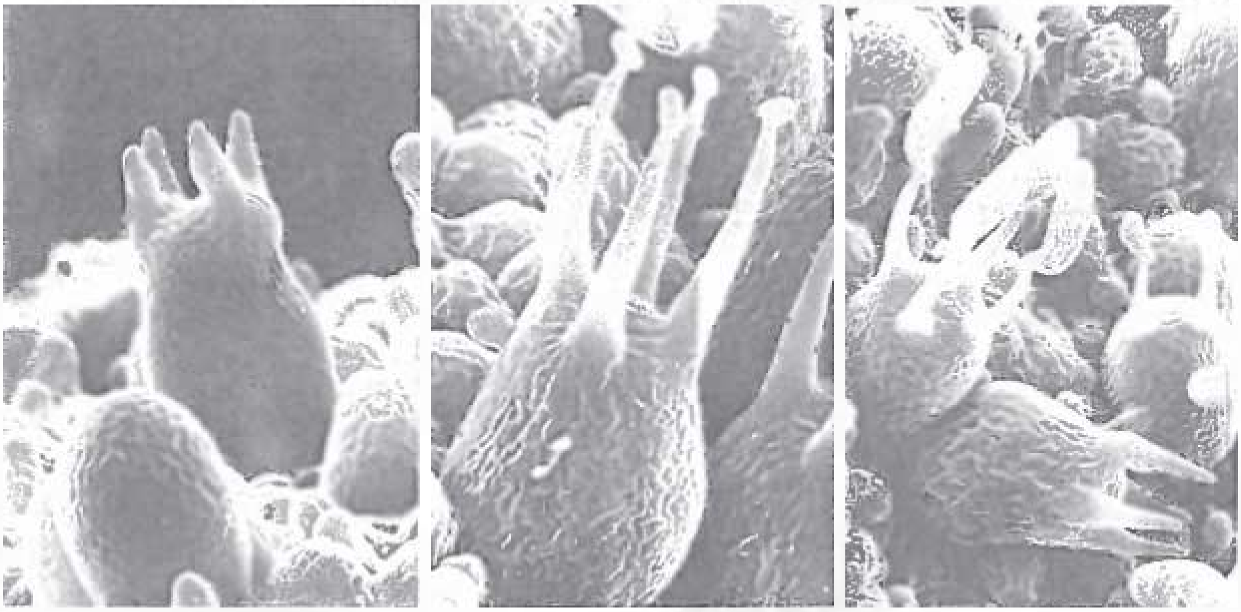

Figure 11, 12 & 13 - Scanning electron micrographs showing the development of the basidium and spores in *Ramaria iongispora*, a coral fungus.

An awareness of the life cycle will greatly aid beginning cultivators in their initial attempts to cultivate mushrooms. Once a basic understanding of mushroom culture and the life processes of these organisms is achieved, cultivators can progress to more advanced subjects like genetics, strain selection and breeding. This wholistic approach increases the depth of one's understanding and facilitates development of innovative approaches to mushroom cultivation.

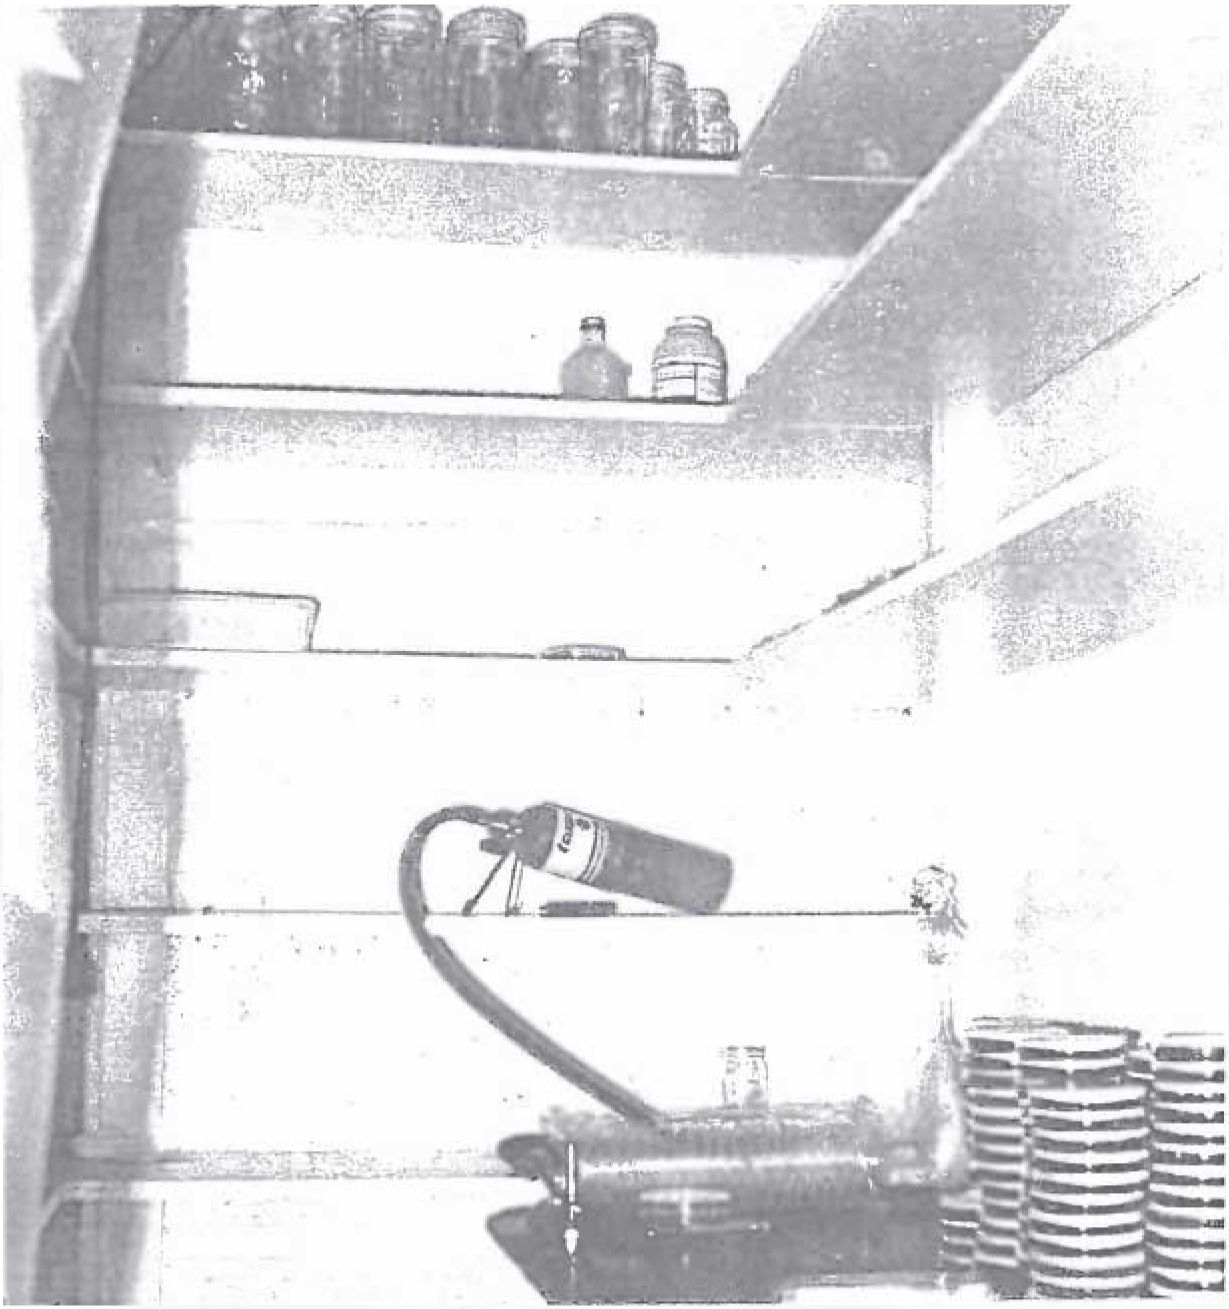
II. STERILE TECHNIQUE AND AGAR CULTURE



Fiqure 18 - A home cultivator's pantry converted into a sterile laboratory.

The air we breathe is a living sea of microscopic organisms that ebbs and flows with the slightest wind currents. Fungi, bacteria, viruses and plants use the atmosphere to carry their offspring to new environments. These microscopic particles can make sterile technique difficult unless proper precautions are taken. If one can eliminate or reduce the movement of these organisms in the air, however, success in sterile technique is assured.

There are five primary sources of contamination in mushroom culture work:

1. The immediate external environment
2. The culture medium
3. The culturing equipment
4. The cultivator and his or her clothes
5. The mushroom spores or the mycelium

Mushrooms - and all living organisms - are in constant competition for available nutrients. In creating a sterile environment, the cultivator seeks to give advantage to the mushroom over the myriad legions of other competitors. Before culture work can begin, the first step is the construction of an inoculation chamber or sterile laboratory.

Design and Construction of a Sterile Laboratory

The majority of cultivators fail because they do not take the time to construct a laboratory for sterile work. An afternoon's work is usually all that is required to convert a walk-in closet, a pantry or a small storage room into a workable inoculation chamber.

Begin by removing all rugs, curtains and other cloth-like material that can harbor dust and spores. Thoroughly clean the floors, walls and ceiling with a mild disinfectant. Painting the room with a high gloss white enamel will make future cleaning easier. Cover windows or any other sources of potential air leaks with plastic sheeting. On either side of the room's entrance, using plastic sheeting or other materials, construct an antechamber which serves as an airlock. This acts as a protective buffer between the laboratory and the outside environment. The chamber should be designed so that the sterile room door is closed while the anteroom is entered. Equip the lab with these items:

1. a chair and a sturdy table with a smooth surface.
2. a propane torch, an alcohol lamp, a bunsen burner or a butane lighter.
3. a clearly marked spray bottle containing a 10% bleach solution.
4. sterile Petri dishes and test tube "slants".
5. stick-on labels, notebook, ballpoint pen and a permanent marking pen.
6. an agar knife and inoculating loop.

All these items should remain in the laboratory. If any equipment is removed, make sure it is absolutely clean before being returned to the room.

A semisterile environment can be established in the laboratory through simple maintenance depending on the frequency of use. The amount of cleaning necessary will be a function of the spore load in the external environment. In winter the number of free spores drastically decreases while in the spring and summer months one sees a remarkable increase. Consequently, more cleaning is necessary during these peak contamination periods. More importantly, all contaminated jars and Petri dishes should be disposed of in a fashion that poses no risk to the sterile lab.

Once the sterile work room has been constructed, follow a strict and unwavering regimen of hygiene. The room should be cleaned with a disinfectant, the floors mopped and lastly the room's air washed with a fine mist of 10% bleach solution. After spraying, the laboratory should not be reentered for a minimum of 15 minutes until the suspended particles have settled. A regimen of cleaning MUST precede every set of inoculations. As a rule, contamination is easier to prevent than to eliminate after it occurs.

Before going further, a few words of caution are required. Sterile work demands concentration, attention to detail and a steady hand. Work for reasonable periods of time and not to the point of exhaustion. Never leave a lit alcohol lamp or butane torch unattended and be conscious of the fact that in an airtight space oxygen can soon be depleted.

Some cultivators wage war on contamination to an unhealthy and unnecessary extreme. They tend to "overkill" their laboratory with toxic fungicides and bacteriocides, exposing themselves to dangerously mutagenic chemical agents. In one incident a worker entered a room that had just been heavily sprayed with a phenol based germicide. Because of congestion he could not sense the danger and minutes later experienced extreme shortness of breath, numbness of the extremities and convulsions. These symptoms persisted for hours and he did not recover for several days. In yet another instance, a person mounted a short wave ultraviolet light in a glove box and conducted transfers over a period of months with no protection and unaware of the danger. This type of light can cause skin cancer after prolonged exposure. Other alternatives, posing little or no health hazard, can just as effectively eliminate contaminants, sometimes more so.

If despite one's best efforts a high contamination rate persists, several additional measures can be implemented. The first is inexpensive and simple, utilizing a colloidal suspension of light oil into the laboratory's atmosphere; the second involves the construction of a still air chamber called a glove box; and the third is moderately expensive, employing high efficiency micron filters.

1. By asperating sterile oil, a cloud of highly viscous droplets is created. As the droplets descend they trap airborne contaminant particles. This technique uses triethylene glycol that is vaporized through a heated wick. Finer and more volatile than mineral oil, triethylene glycol leaves little or no noticable film layer. However a daily schedule of hygiene maintenance is still recommended. (A German Firm sells a product called an "aero-disinfector" that utilizes the low boiling point of tri-ethylene glycol. For information write: Chemische Fabrik Bruno Vogelmann & Co., Postfach 440, 718 Crailsheim, West Germany. The unit sells for less than $50.00).
2. A glovebox is an airtight chamber that provides a semisterile still air environment in which to conduct transfers. Typically, it is constructed of wood, with a sneeze window for viewing and is sometimes equipped with rubber gloves into which the cultivator inserts his hands. Often, in place of gloves, the front face is covered with a removable cotton cloth that is periodically sterilized. The main advantage of a glove box is that it provides an inexpensive, easily cleaned area where culture work can take place with little or no air movement.
3. Modern laboratories solve the problem of airborne contamination by installing High Efficiency Particulate Air (HEPA) filters. These filters screen out all particulates exceeding 0.1 - 0.3 microns in diameter, smaller than the spores of all fungi and practically all bacteria. HEPA filters are built into what is commonly known as a laminar flow hood. Some sterile laboratories have an entire wall or ceiling constructed of HEPA filters through which pressurized air is forced from the outside. In effect, a positive pressure, sterile environment is created. Specific data regarding the building and design of laminar flow systems is discussed in greater detail in Appendix IV.

Some cultivators have few problems with contaminants while working in what seems like the most primitive conditions. Others encounter pronounced contamination levels and have to invest in high technology controls. Each circumstance dictates an appropriate couriter-measure. Whether one is a home cultivator or a spawn maker in a commercial laboratory, the problems encountered are similar, differing not in kind, but in degree.

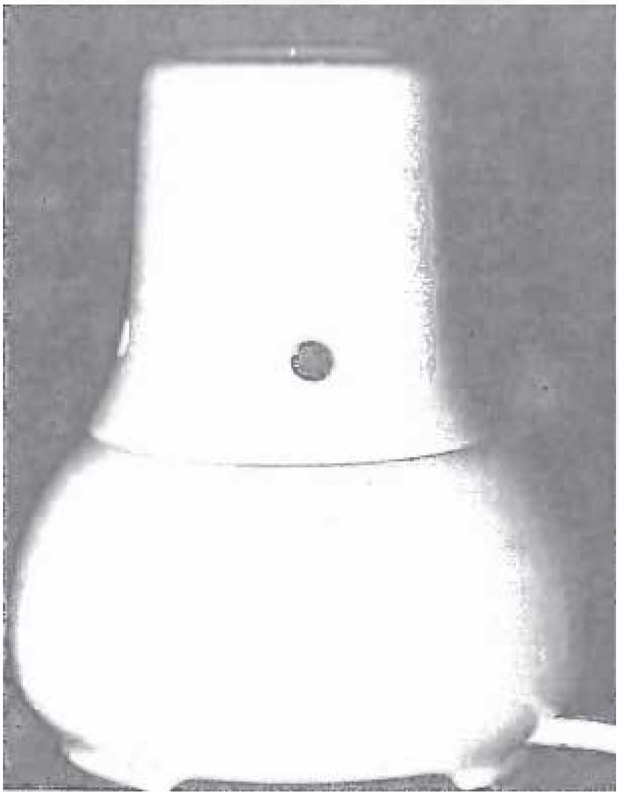


Figure 19 - Aero-disinfector for reducing contaminant spore load in laboratory.

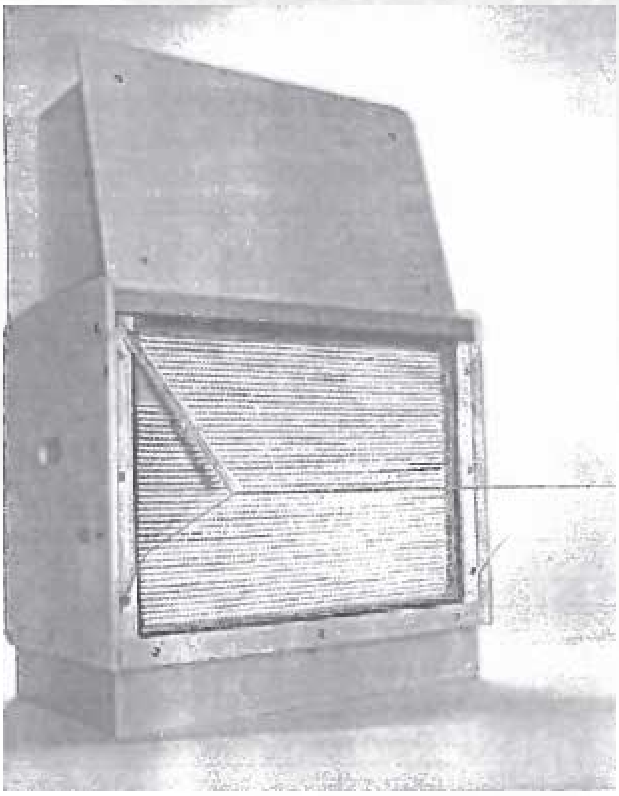

Figure 20 - Laminar flow hood.

Preparation of Agar Media

Once the sterile laboratory is completed, the next step is the preparation of nutrified agar media. Derived from seaweed, agar is a solidifying agent similar to but more effective than gelatin. There are many recipes for producing enriched agar media suitable for mushroom culture. The standard formulas have been Potatoe Dextrose Agar (PDA) and Malt Extract Agar (MEA) to which yeast is often added as a nutritional supplement. Many of the mycological journals list agar media containing peptone or neopeptone, two easily accessed sources of protein for mushroom mycelium. Another type of agar media that the authors recommend is a broth made from boiling wheat or rye kernels which is then supplemented with malt sugar.

If a high rate of contamination from bacteria is experienced, the addition of antibiotics to the culture media will prevent their growth. Most antibiotics, like streptomycin, are not autoclavable and must be added to the agar media after sterilization while it is still molten. One antibiotic, gentamycin sulfate, survives autoclaving and is effective against a broad range of bacteria. Antibiotics should be used sparingly and only as a temporary control until the sources of bacteria can be eliminated. The mycelia of some mushroom species are adversely affected by antibiotics.

Dozens of enriched agar media have been used successfully in the cultivation of fungi and every cultivator develops distinct preferences based on experience. Regardless of the type of agar medium employed, a major consideration is its pH, a logarithmic scale denoting the level of acidity or alkalinity in a range from 0 (highly acidic) to 14 (highly basic) with 7 being neutral. Species of *Psilocybe* thrive in media balanced between 6.0-7.0 whereas *Agaricus brunnescens* and allies grow better in near neutral media. Most mycelia are fairly tolerant and grow well in the 5.5-7.5 pH range. One needs to be concerned with exact pH levels only if spores fail to germinate or if mycelial growth is unusually slow.

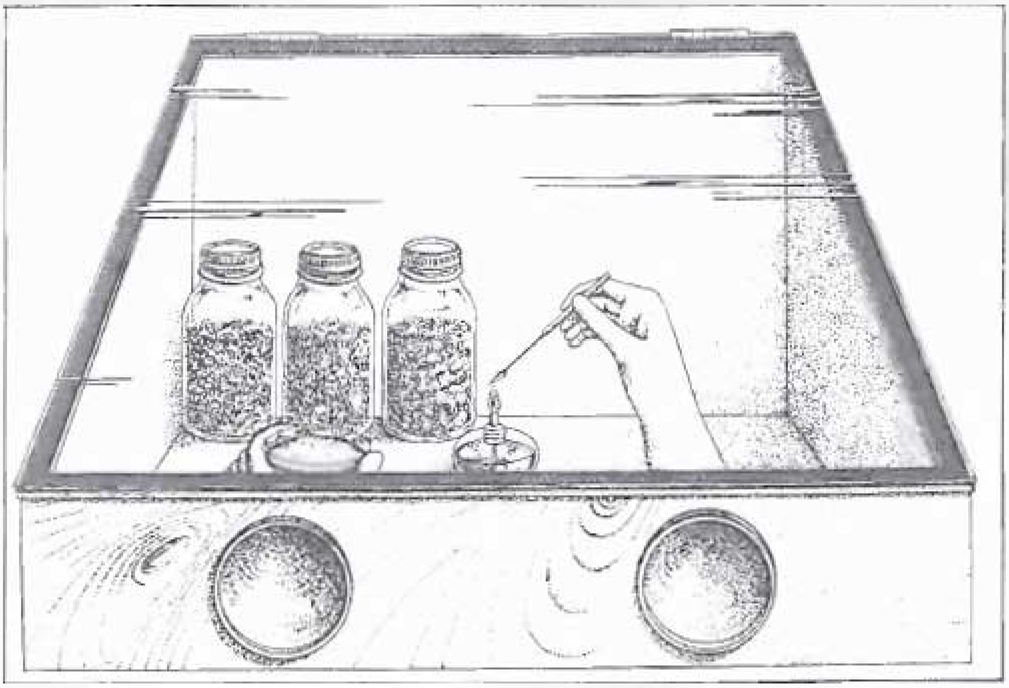

Figure 21 - Standard glove box.

What follows are several formulas for the preparation of nutritionally balanced enriched agar media, any one of which is highly suited for the growth of *Agaricus, Pleurotus, Lentinus, Stropharia, Lepista, Flammulina, Volvariella, Panaeolus* and *Psilocybe* mycelia. Of these the authors have two preferences: PDY (Potatoe Dextrose Yeast) and MPG (Malt Peptone Grain) agar media. The addition of ground rye grain or grain extract to whatever media is chosen clearly promotes the growth of strandy mycelium, the kind that is generally preferred for its fast growth.

Choose one formula, mix the ingredients in dry form, place into a flask and add water until one liter of medium is made.

PDY (Potato Dextrose Yeast) Agar

the filtered, extracted broth from boiling
300 grams of sliced potatoes in 1 liter of water for 1 hour
10 grams dextrose sugar
2 grams yeast (optional)
20 grams agar

MEA (Malt Extract Agar)
20 grams tan malt
2 grams yeast
20 grams agar
(Avoid dark brewer's malts which have become caramelized. The malt that should be used is a light tan brewer's form).

MPG (Malt Peptone Grain) Agar
20 grams tan malt
5 grams ground rye grain
5 grams peptone or neopeptone
2 grams yeast (optional)
20 grams agar

For controlling bacteria, 0.10 grams of 60-80% pure gentamycin sulfate can be added to each liter of media prior to sterilization. (See Resources in Appendix.)

Water quality - its pH and mineral content - varies from region to region. If living in an area of questionable water purity, the use of distilled water is advisable. For all practical purposes, however, tap water can be used without harm to the mushroom mycelium. A time may come when balancing pH is important - especially at spore germination or in the culture of exotic species. The pH of media can be altered by adding a drop at a time of 1 molar concentration of hydrochloric acid (HCL) or sodium hydroxide (NaOH). The medium is thoroughly mixed and then measured using a pH meter or pH papers. (One molar HCL has a pH of 0; one molar NaOH has a pH of 12; and distilled water has a pH of 7).

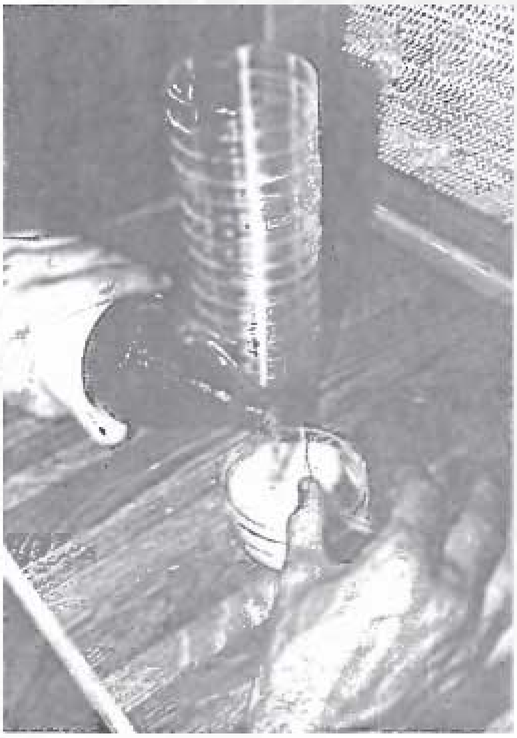
After thoroughly mixing these ingredients, sterilize the medium in a pressure cooker for 30 minutes at 15 psi. (Pressure cookers are a safe and effective means of sterilizing media provided they are operated according to the manufacturer's instructions). A small mouthed vessel is recommended for holding the agar media. If not using a flask specifically manufactured for pouring media, any narrow necked glass bottle will suffice. Be sure to plug its opening with cotton and cover with aluminum foil before inserting into the pressure cooker. The media container should be filled only to ⅔ to ¾ of its capacity.

Place the media filled container into the pressure cooker along with an adequate amount of water for generating steam. (Usually a ½ inch layer of water at the bottom will do). Seal the cooker according to the manufacturer's directions. Place the pressure cooker on a burner and heat until ample steam is being generated. Allow the steam to vent for 4-5 minutes before closing the stop-cock. Slowly bring the pressure up to 15 psi and maintain for ½ hour. Do not let the temperature of the cooker exceed 250°F. or else the sugar in the media will caramelize. Media with caramelized sugar inhibits mycelial growth and promotes genetic mutations. A sterilized pot holder or newly laundered cloth should be handy in the sterile lab to aid in removing the media flask from the pressure cooker. While the media is being sterilized, immaculately clean the laboratory.

The time necessary for sterilization varies at different altitudes. At a constant volume, pressure and temperature directly correspond (a relationship known as Boyle's Law). When a certain pressure (= temperature) is recommended, it is based on a sea level standard. Those cultivating at higher elevations must cook at higher pressures to achieve the same sterilization effect. Here are two abbreviated charts showing the relationships between temperature and pressure and the changes in the boiling point of water at various elevations. Increase the amount of pressure over the recommended amount based on the difference of the boiling point at sea level and one's own altitude. For example, at 5000 feet the difference in the boiling point of water is approximately 10°F. This means that the pressure must be increased to 20 psi, 5 psi above the recommended 15 psi sea level standard, to correspond to a "10°F. increase" in temperature. (Actually temperature remains the same; it is pressure that differs).

Relationship of Pressure and Temperature at Constant Volume		**The Relationship of Altitude to the Boiling Point of Water**	
Pressure (psi)	**°Fahrenheit**	**Altitude**	**Boiling Point(°F.)**
1	212	Sea Level	212
3	220	1,025	210
5	228	2,063	208
10	240	3,115	206
15	250	4,169	204
20	259	5,225	202
25	267	6,304	200
		7,381	197
		8,481	196
		9,031	195

Note that the effect achieved from sterilizing at 60 minutes at 15 psi is the same as that from 30 minutes at 30 psi. Hence a doubling of pressure reduces sterilization time by one half. Most pressure cookers can not be safely operated at this level unless carefully modified according to the manufacturer's recommendations. And some extra time must be allowed for adequate penetration of steam, especially in densely packed, large autoclaves.



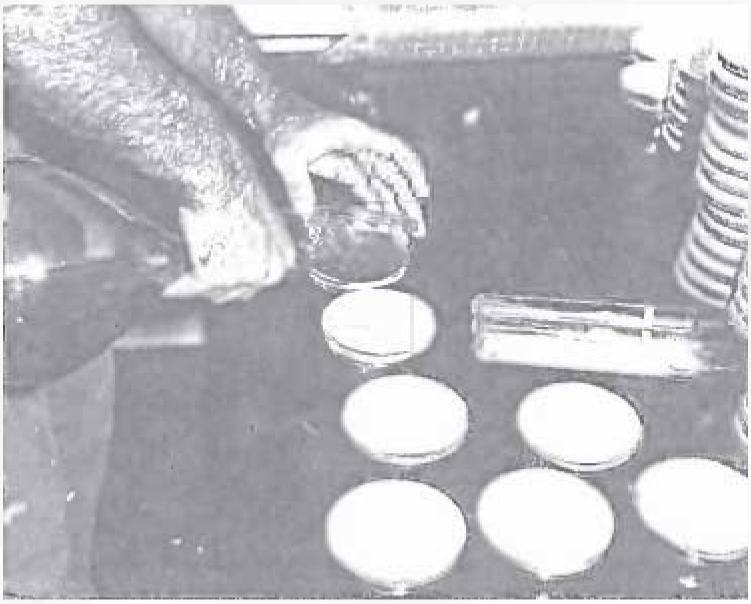


Figure 22 & 23 - Pouring agar media into sterile Petri dishes. At left, vertical stack technique.

Once sterilized, place the cooker in the laboratory or in a semisterile room and allow the pressure to return to 1 psi before opening. One liter of agar media can generously fill thirty 100 x 15 mm. Petri dishes. Techniques for pouring vary with the cultivator. If only one or two sleeves of Petri dishes are being prepared, the plates should be laid out side by side on the working surface. If more than two sleeves are being poured or table space is limited, pouring the sterile Petri dishes in a vertical stack is usually more convenient.

Before pouring, vigorously shake the molten media to evenly distribute its ingredients. Experienced cultivators fill the plates rhythmically and without interruption. Allow the agar media to cool and solidify before using. Condensation often forms on the inside surface of the upper lid of a Petri dish when the agar media being poured is still at a high temperature. To reduce condensation, one can wait a period of time before pouring. If the pressure cooker sits for 45 minutes after reaching 1 psi, a liter of liquid media can be poured with little discomfort to unprotected hands.

Two types of cultures can be obtained from a selected mushroom: one from its spores and the other from living **tissue** of a mushroom. Either type can produce a viable strain of mycelia. Each has advantages and disadvantages.

Starting a Culture from Spores

A mushroom culture can be started in one of two ways. Most growers start a culture from spores. The advantage of using spores is that they are viable for weeks to months after the mushroom has decomposed. The other way of obtaining a culture is to cut a piece of interior tissue from a live specimen, in effect a clone. Tissue cultures must be taken within a day or two from the time the mushroom has been picked, after which a healthy clone becomes increasingly difficult to establish.

Taking a Spore Print

To collect spores, sever the cap from the stem of a fresh, well cleaned mushroom and place it gills down on a piece of clean white paper or a clean glass surface such as a microscope slide. If a specimen is partially dried, add a drop or two of water to the cap surface to aid in the release of spores. To lessen evaporation and disturbance from air currents, place a cup or glass over the mushroom cap. After a few hours, the spores will have fallen according to the radiating symmetry of the gills. If the spore print has been taken on paper, cut it out, fold it in half, seal in an airtight container and label the print with the date, species and collection number. When using microscope slides, the spores can be sandwiched between two pieces of glass and taped along the edges to prevent the entry of contaminant spores. A spore print carelessly taken or stored can easily become contaminated, decreasing the chance of acquiring a pure culture.

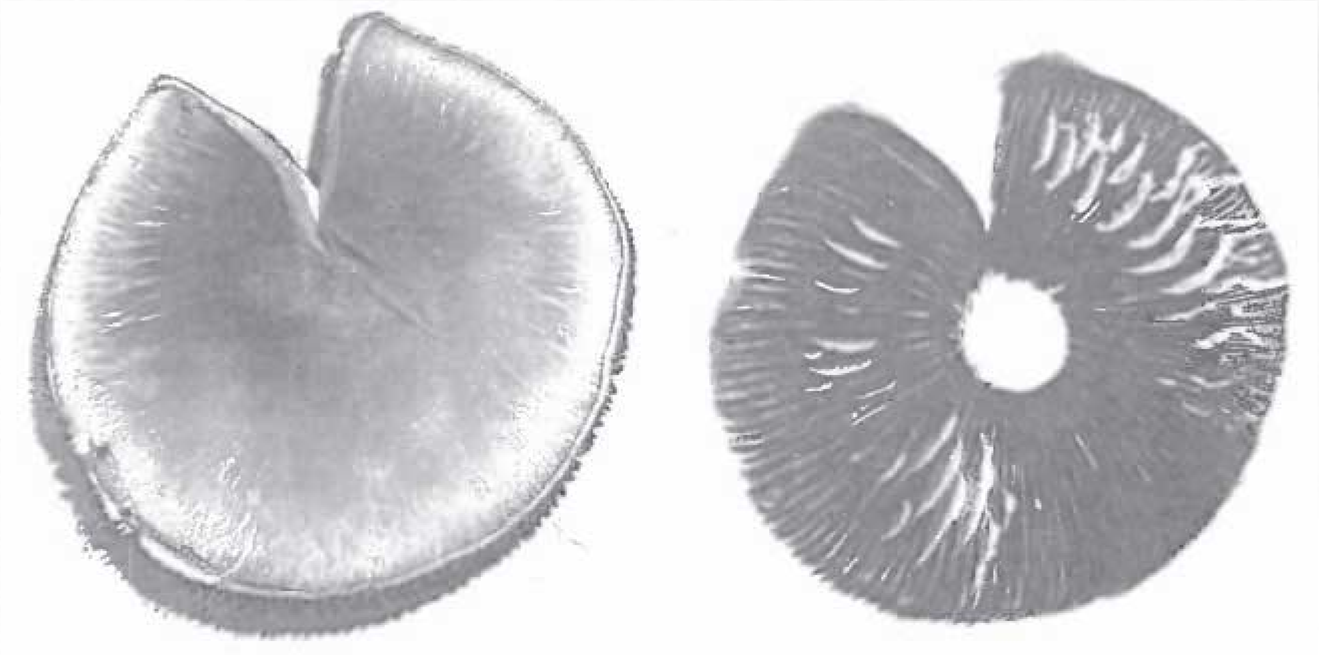

Figure 24a - Taking a spore print on typing paper.

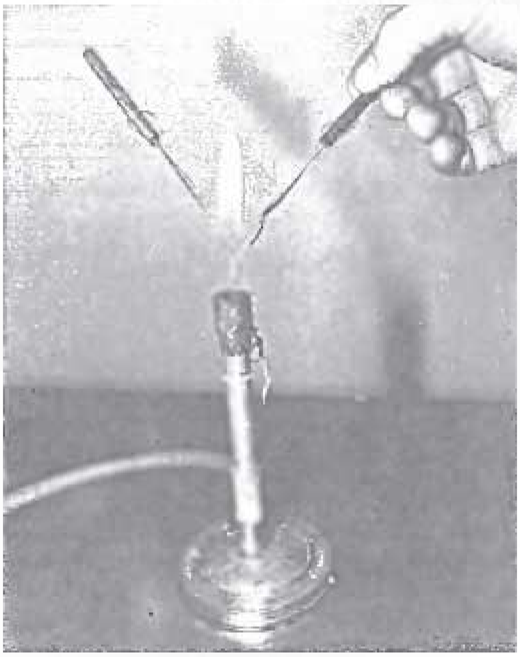
Agaricus brunnescens, *Psilocybe cubensis* and many other mushroom species have a partial veil - a thin layer of tissue extending from the cap margin to the stem. This veil can be an aid in the procurement of nearly contaminant-free spores. The veil seals the gill from the outside, creating a semi-sterile chamber from which spores can be removed with little danger of contamination. By choosing a healthy, young specimen with the veil intact, and then by carefully removing the veil tissue under aseptic conditions, a nearly pure spore print is obtained. This is the ideal way to start a multispore culture.



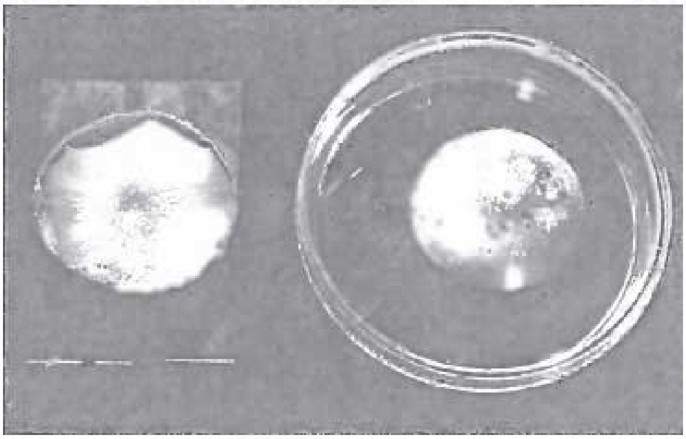


Figure 24b - Taking a spore print on a sterile Petri dish and on glass microscope slides.

Figure 25 - Sterilizing two scalpels speeds up agar transfer technique.

Techniques for Spore Germination

Once a spore print is obtained, mushroom culture can begin. Sterilize an inoculating loop or scalpel by holding it over the flame of an alcohol lamp or butane torch for five or ten seconds until it is red hot. (If a butane torch is used, turn it down to the lowest possible setting to minimize air disturbance). Cool the tip by inserting it into the sterile media in a Petri dish and scrape some spores off the print. Transfer the spores by streaking the tip of the transfer tool across the agar surface. A similar method calls for scraping the spore print above an opened Petri dish and allowing them to free-fall onto the medium. When starting a new culture from spores, it is best to inoculate at least three media dishes to improve the chances of getting a successful germination. Mycelium started in this manner is called a **multispore culture**.

When first produced, spores are moist, inflated cells with a relatively high rate of germination. As time passes, they dry, collapse at their centers and can not easily germinate. The probability of germinating dehydrated spores increases by soaking them in sterilized water. For 30 minutes at 15 psi, sterilize an eye dropper or similar device (syringe or pipette) and a water filled test tube or 25-250 ml. Erlenmeyer flask stopped with cotton and covered with aluminum foil. Carefully touch some spores onto a scalpel and insert into sterile water. Tightly seal and let stand for 6-12 hours. After this period draw up several milliliters of this spore solution with the eye dropper, syringe or pipette and inoculate several plates with one or two drops. Keep in mind that if the original spore print was taken under unsanitary conditions, this technique just as likely favors contaminant spores as the spores of mushrooms.

Characteristics of the Mushroom Mycelium

With either method of inoculation, spore germination and any initial stages of contamination should be evident in three to seven days. Germinating spores are thread-like strands of cells emanating from a central point of origin. These mycelial strands appear grayish and diffuse at first and soon become whitish as more hyphae divide, grow and spread through the medium.

The mycelia of most species, particularly *Agaricus, Coprinus, Lentinus, Panaeolus* and *Psilocybe* are grayish to whitish in color. Other mushroom species have variously pigmented mycelia. *Lepista nuda* can have a remarkable purplish blue mycelium; *Psilocybe tampanensis* is often multi-colored with brownish hues. Keep in mind, however, that color varies with the strain and the media upon which the mycelium is grown. Another aspect of the mycelial appearance is its type of growth, whether it is aerial or appressed, cottony or rhizomorphic. Aerial mycelium can be species related or often it is a function of high humidity. Appressed mycelium can also be a species specific character or it can be the result of dry conditions. The subject of mycelial types is discussed in greater detail under the sub-chapter Sectoring. (See Color Photos 1-4).

Once the mushroom mycelium has been identified, sites of germinating spores should be transferred to new media dishes. In this way the cultivator is selectively isolating mushroom mycelia and will soon establish a pure culture free of contamination. If contamination appears at the same time, cut out segments of the emerging mushroom mycelia away from the contaminant colonies. Since many of the common contaminants are sporulating molds, be careful not to jolt the culture or to do anything that might spread their spores. And be sure the scalpel is cool before cutting into the agar media. A hot scalpel causes an explosive burst of vapor which in the microcosm of the Petri dish easily liberates spores of neighboring molds.

Ramifications of Multispore Culture

Multispore culture is the least difficult method of obtaining a viable if not absolutely pure strain. In the germination of such a multitude of spores, one in fact creates many strains, some incompatible with others and each potentially different in the manner and degree to which they fruit under artificial conditions. This mixture of strains can have a limiting effect on total yields, with the less productive strains inhibiting the activity of more productive ones. In general, strains created from spores have a high probability of resembling their parents. If those parents have been domesticated and fruit well under laboratory conditions, their progeny can be expected to behave similarly. In contrast, cultures from wild specimens may fruit very poorly in an artificial environment. Just as with wild plants, strains of wild mushrooms must be selectively developed.

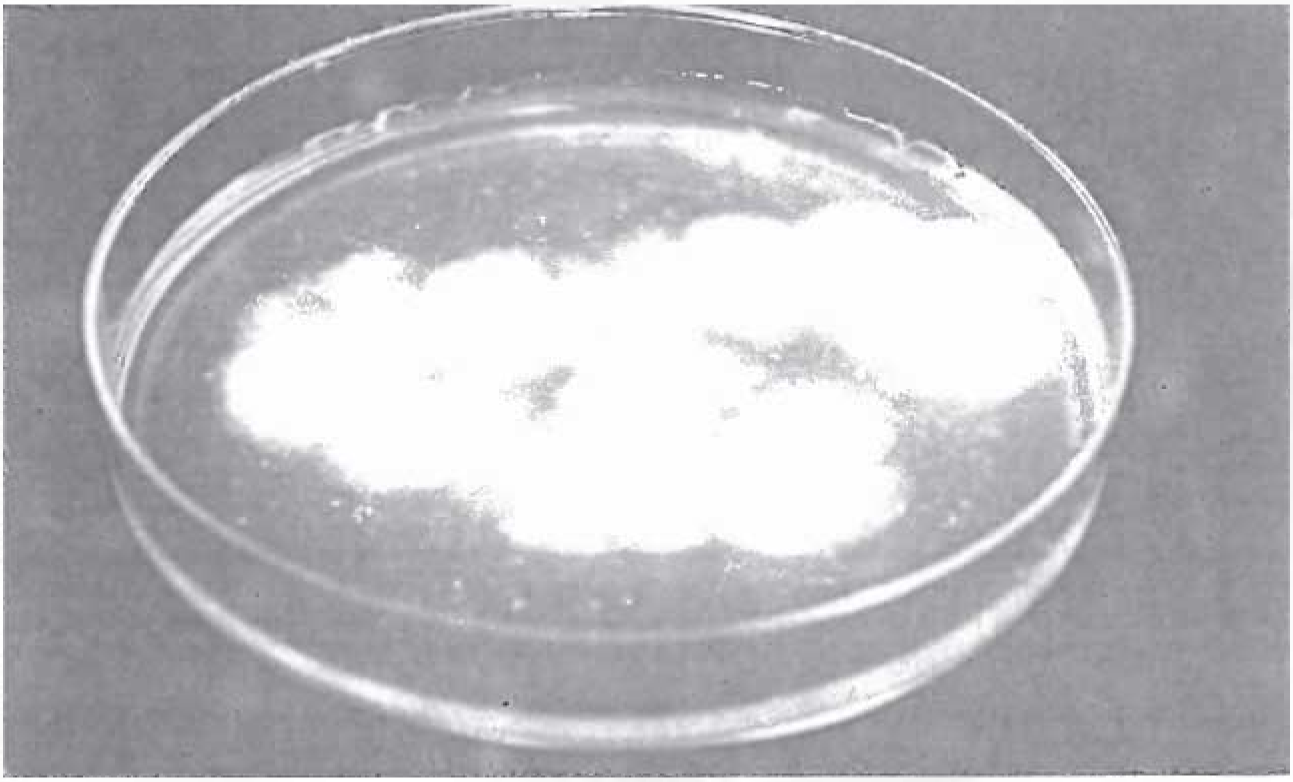

Figure 26 - *Stropharia rugoso-annulata* spores germinating.

Of the many newly created strains intrinsic to multispore germination, some may be only capable of vegetative growth. Such mycelia can assimilate nutrients but can not form a mushroom fruitbody (the product of generative growth). A network of cells coming from a single spore is called a **monokaryon**. As a rule, monokaryons are not capable of producing fertile spore-bearing mushrooms. When two compatible monokaryons encounter one another and mate, cytoplasmic and genetic material is exchanged. The resultant mycelium is a **dikaryon** that can produce fertile offspring in the form of mushrooms. Branching or networking between different dikaryotic strains is known as **anastomosis**. This process of recombination can occur at any stage of the cultivation process: on agar; on grain; or on bulk substrates. The crossing of different mushroom strains is analogous to the creation of hybrids in horticulture.

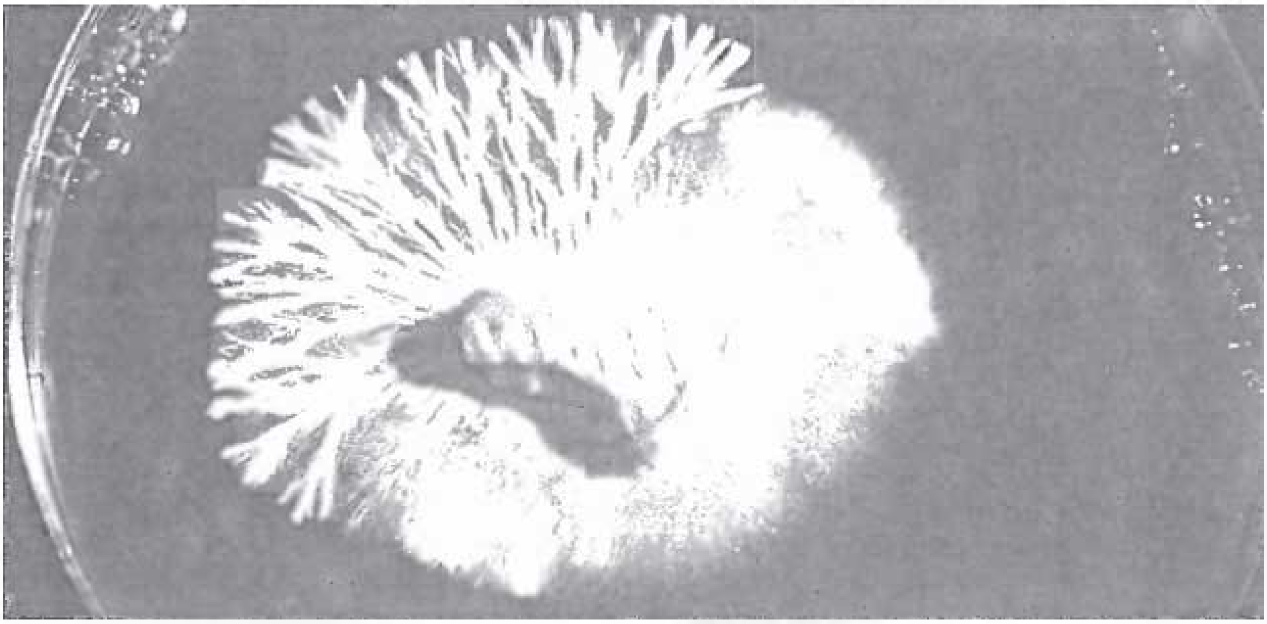

Figure 27 - *Psilocybe cubensis* mycelium growing from agar wedge, transferred from a multispore germination. Note two types of mycelial growth.

Another method for starting cultures is the creation of single spore isolates and is accomplished by diluting spores in a volume of sterile water. This spore solution is further diluted into larger volumes of sterile water which is in turn used to inoculate media dishes. In this way, cultivators can observe individual monokaryons and in a controlled manner institute a mating schedule for the development of high yielding strains. For cultivators interested solely in obtaining a viable culture, this technique is unnecessary and multispore germinations generally suffice. But for those interested in crossing monokaryotic strains and studying mating characteristics, this method is of great value. Keep in mind that for every one hundred spores, only an average of one to five germinate. For a more detailed explanation of strains and strain genetics, see Chapter XV.

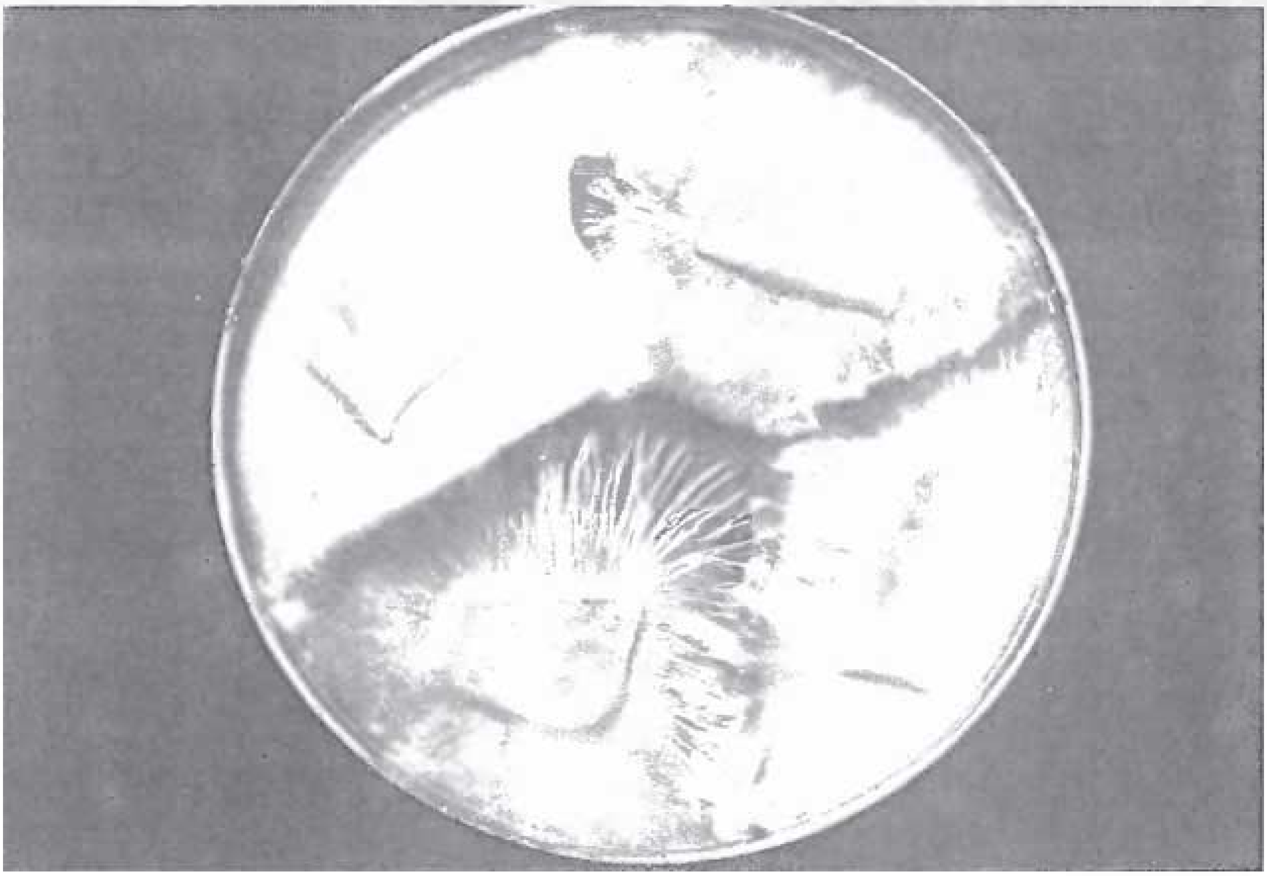

Figure 28 - Four strains of *Psilocybe cubensis* mycelium: (clockwise, upper right) Matias Romero; Misantla; Amazonian; and Palenque.

The greatest danger of doing concentrated multispore germinations is the increased possibility of contamination, especially from bacteria. Some bacteria parasitize the cell walls of the mycelium, while others stimulate spore germination only to be carried upon and to slowly digest the resulting mycelia. Hence, some strains are inherently unhealthy and tend to be associated with a high percentage of contamination. These infected spores, increase the likelihood of disease spreading to neighboring spores when germination is attempted in such high numbers.

Many fungi, however, have developed a unique symbiotic relationship with other microorganisms. Some bacteria and yeasts actually stimulate spore germination in mushrooms that otherwise are difficult to grow in sterile culture. The spores of *Cantharellus cibarius*, the common and highly prized Chantrelle, do not germinate under artificial conditions, resisting the efforts of world's most experienced mycologists. Recently, Nils Fries (1979), a Swedish mycologist, discovered that when activated charcoal and a red yeast, *Rhodotorula glutinis* (Fres.) Harrison, were added to the media, spore germination soon followed. (Activated charcoal is recommended for any mushroom whose spores do not easily germinate.)

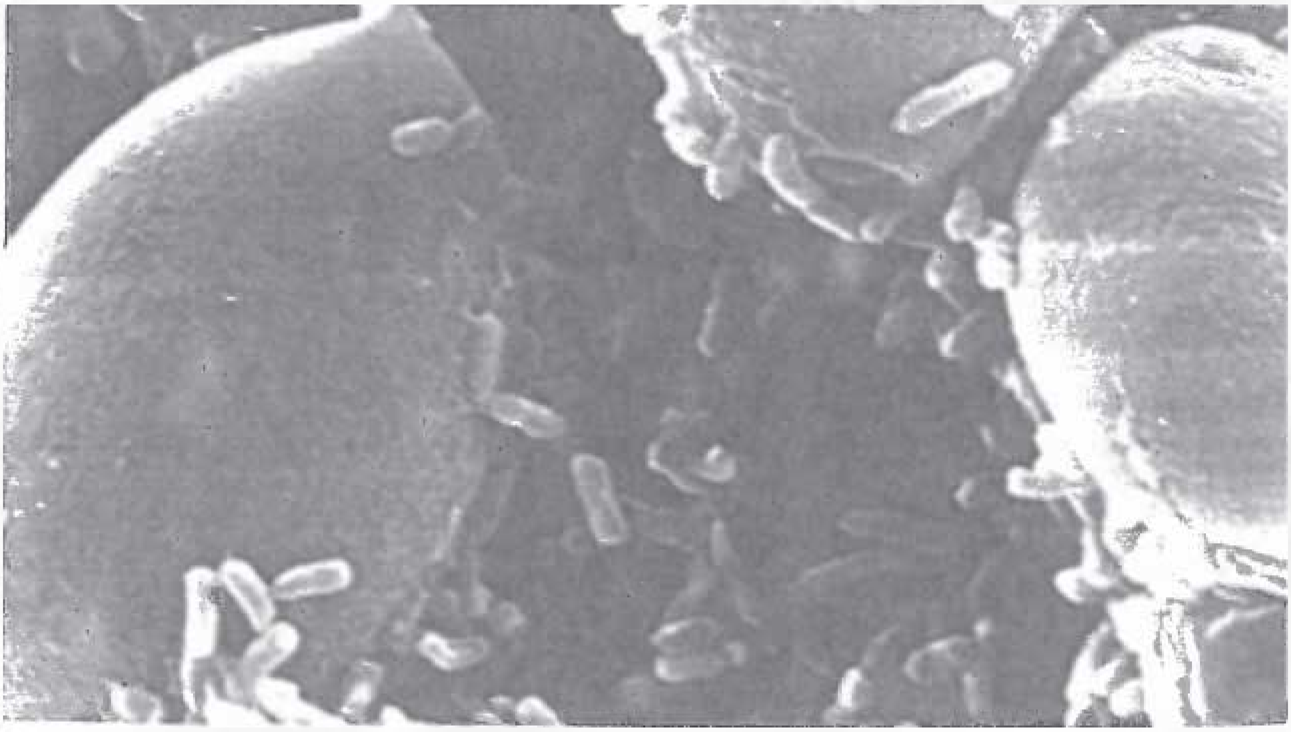

Figure 29 - *Psilocybe cubensis* spores infected with rod shaped bacteria.

Many growers have reported that certain cultures flourish when a bacterium accidentally contaminates or is purposely introduced into a culture. *Pseudomonas putida, Bacillus megaterium, Azotobacter vinelanclii* and others have all been shown to have stimulatory effects on various mushroom species - either in the germination of spores, the growth of mycelia or the formation of fruitbodies (Curto and Favelli, 1972; Hayes *et al*., 1969; Eger, 1972; Urayama, 1961). Techniques utilizing these bacteria are discussed in Appendix III. However, most of the contaminants one encounters in mushroom cultivation, whether they are airborne or intrinsic to the culture, are not helpful. Bacteria can be the most pernicious of all competitors. A diligent regimen of hygiene, the use of high efficiency particulate air (HEPA) filters and good laboratory technique all but eliminate these costly contaminants.

Starting a Culture from Live Tissue

Tissue culture is an assured method of preserving the exact genetic character of a living mushroom. In tissue culture a living specimen is cloned whereas in multispore culture new strains are created. Tissue cultures must be taken from mushrooms within twenty-four to forty-eight hours of being picked. If the specimens are several days old, too dry or too mature, a pure culture will be difficult to isolate. Spores, on the other hand, can be saved over long periods of time.

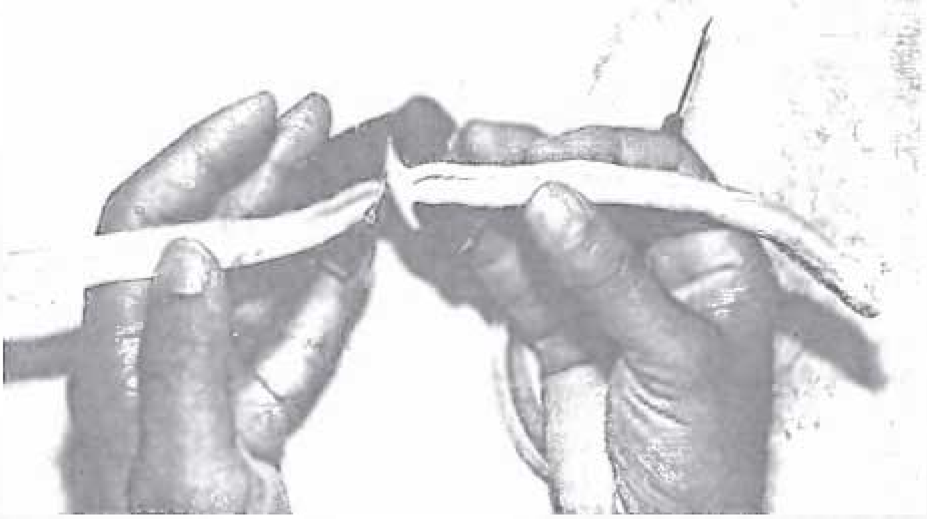

Figure 30 - Splitting the mushroom stem to expose interior tissue.

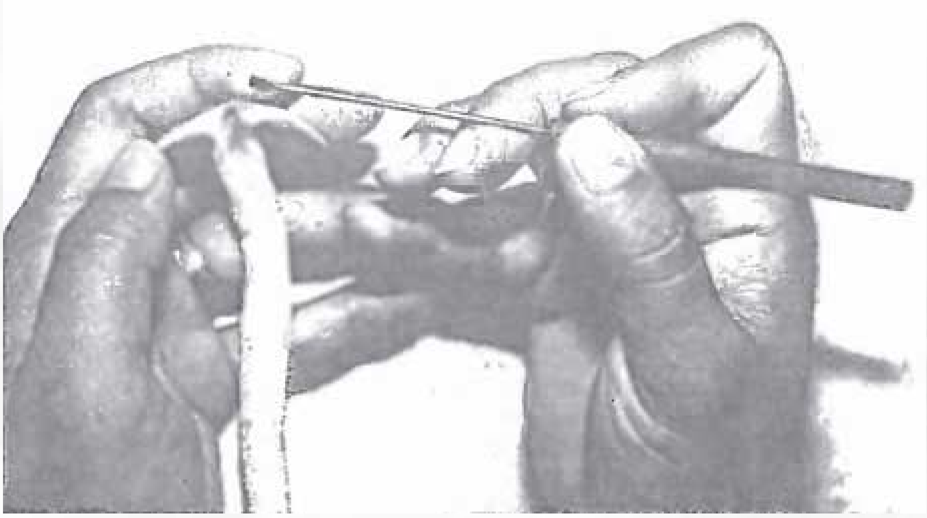

Figure 31 - Cutting into mushroom flesh with a cooled, flame sterilized scalpel.

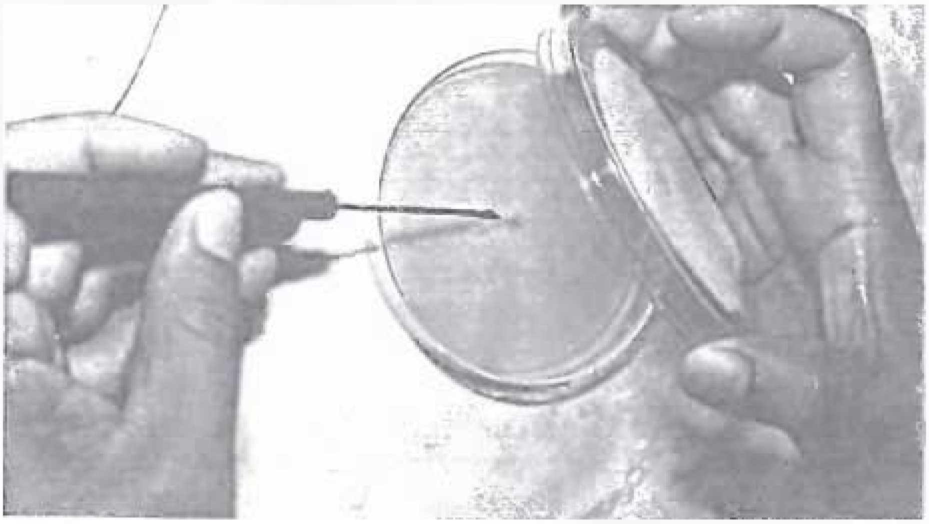

Figure 32 - Excising a piece of tissue for transfer into a Petri dish.

Since the entire mushroom is composed of compressed mycelia, a viable culture can be obtained from any part of the mushroom fruitbody. The cap, the upper region of the stem and/or the area where the gill plate joins the underside of the cap are the best locations for excising clean tissue. Some mushrooms have a thick cuticle overlaying the cap. This skin can be peeled back and a tissue culture can be taken from the flesh underlying it. Wipe the surface of the mushroom with a cotton swab soaked in alcohol and remove any dirt or damaged external tissue. Break the mushroom cap or stem, exposing the interior hyphae. Immediately flame a scalpel until red-hot and cool in a media filled Petri dish. Now cut into the flesh removing a small fragment of tissue. Transfer the tissue fragment to the center of the nutrient filled Petri dish as quickly as possible, exposing the tissue and agar to the open air for a minimal time. Repeat this technique into at least three, preferably five more dishes. Label each dish with the species, date, type of culture (tissue) and kind of agar medium. If successful, mycelial growth will be evident in three to seven days.

An overall contamination rate of a 10% is one most cultivators can tolerate. In primary cultures however, especially those isolated from wild specimens, it is not unusual to have a 25% contamination rate. Diverse and colorful contaminants often appear near to the point of transfer. Their numbers depend on the cleanliness of the tissue or spores transferred and the hygienic state of the laboratory where the transfers were conducted. In tissue culture, the most commonly encountered contaminants are bacteria.

Contamination is a fact of life for every cultivator. Contaminants become a problem when their populations spiral above tolerable levels, an indication of impending disaster in the laboratory. If a five, ten or fifteen percent contamination rate is normal for a cultivator and suddenly the contamination level escalates without an alteration of regimen, then new measures of control should be introduced immediately.

Once the tissue shows signs of growth, it should be transferred to yet another media dish. If no signs of contamination are evident, early transfer is not critical. If sporulating colonies of mold develop adjacent to the growing mycelium, the culture should be promptly isolated. Continue transferring the mycelium away from the contaminants until a pure strain is established. Obviously, isolating mycelia from a partially contaminated culture is more difficult than transferring from a pure one. The mere attempt of isolating mycelia away from a nearby contaminant is fraught with the danger of spreading its spores. Although undetectable to us, when the rim of a Petri dish is lifted external air rapidly enters and spores become airborne. Therefore, the sooner the cultivator is no longer dependent upon a partially contaminated culture dish, the easier it will be to maintain pure cultures. Keep in mind that a strain isolated from a contaminated media dish can harbor spores although to the unaided eye the culture may appear pure. Only when this contaminant laden mycelium is inoculated into sterile grain will these inherent bacteria and molds become evident.

To minimize contamination in the laboratory there are many measures one can undertake. The physical ones such as the use of HEPA filters, asperated oil and glove boxes have already been discussed. One's attitude towards contamination and cleanliness is perhaps more important than the installation of any piece of equipment. The authors have seen laboratories with high contamination rates and closets that have had very little. Here are two general guidelines that should help many first-time cultivators.

1. Give the first attempt at sterile culture the best effort. Everything should be clean: the lab; clothes; tools; and especially the cultivator.
2. Once a pure culture has been established, make every attempt to preserve its purity. Save only the cultures that show no signs of mold and bacteria. Throw away all contaminated dishes, even though they may only be partially infected.

If failure greets one's first attempts at mushroom culture, do not despair. Only through practice and experience will sterile culture techniques become fluent.

Agar culture is but one in a series of steps in the cultivation of mushrooms. By itself, agar media is impractical for the production of mushrooms. The advantage of its use in mushroom culture is that mycelial mass can be rapidly multiplied using the smallest fragments of tissue. Since contaminants can be readily observed on the flat two dimensional surface of a media filled Petri dish, it is fairly easy to recognize and maintain pure cultures.

Sectoring: Strain Selection and Development

As mycelium grows out on a nutrient agar, it can display a remarkable diversity of forms. Some mycelia are fairly uniform in appearance; others can be polymorphous at first and then suddenly develop into a homogeneous looking mycelia. This is the nature of mushroom mycelia - to constantly change and evolve.

When a mycelium grows from a single inoculation site and several divergent types appear, it is said to be **sectoring**. A sector is defined solely in contrast to the surrounding, predominant mycelia. There are two major classes of mycelial sectors: rhizomorphic (strandy) and tomentose (cottony). Also, an intermediate type of mycelium occurs which grows linearly (longitudinally radial) but does not have twisted strands of interwoven hyphae that characterize the rhizomorphic kind. Rhizomorphic mycelium is more apt to produce primordia. Linear mycelium can also produce abundant primordia but this usually occurs soon after it forms rhizomorphs. Keep in mind, however, that characteristics of fruiting mycelium are often species specific and may not conform precisely to the categories outlined here.

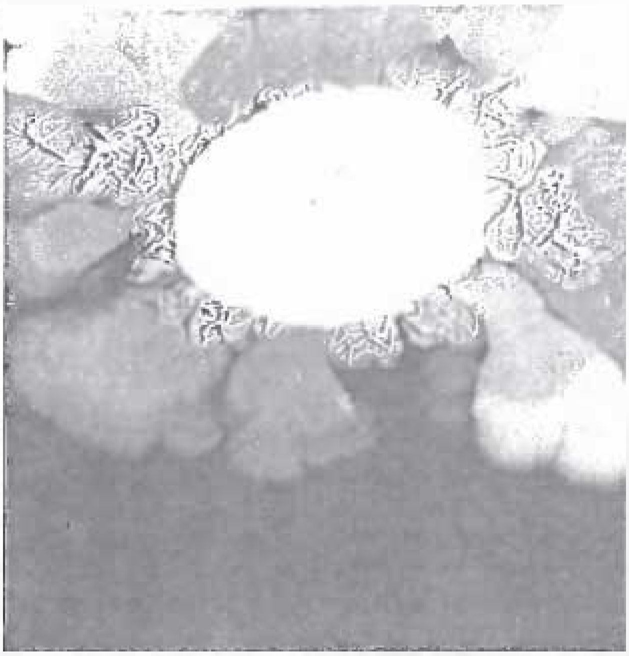

Figure 33 - Bacteria growing from contaminated mushroom mycelium.

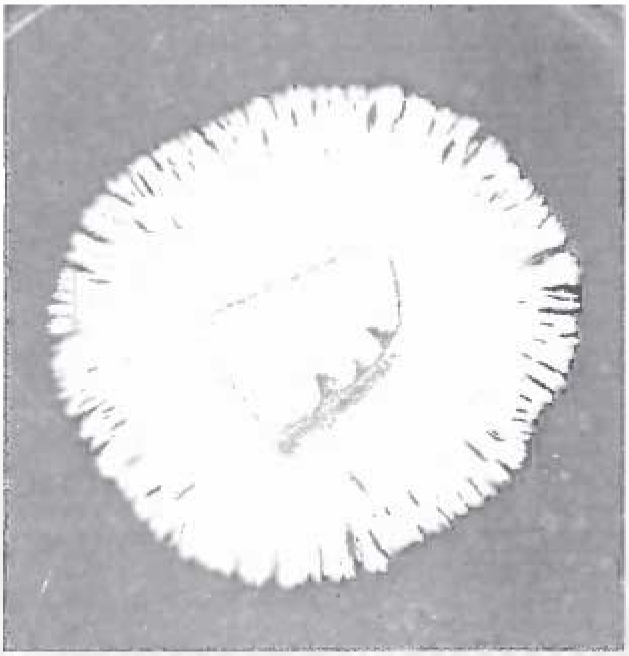

Figure 34 - Rhizomorphic mycelium. Note divergent ropey strands.

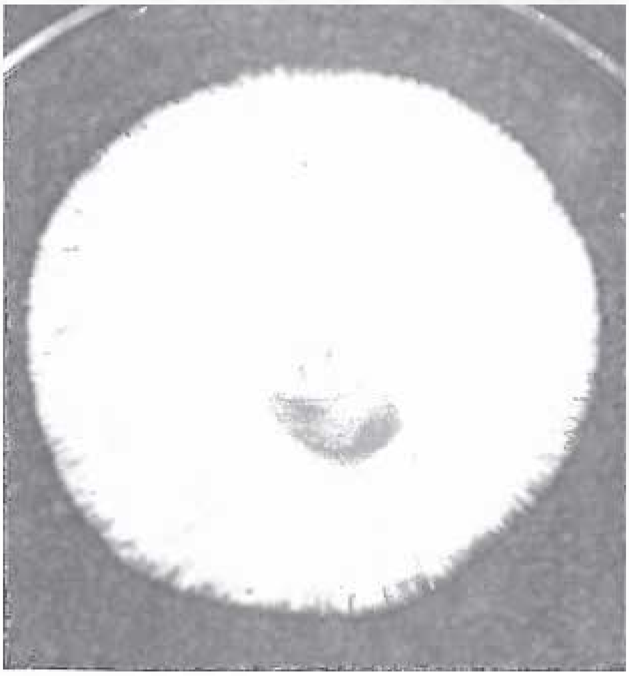

Figure 35 - Intermediate linear type mycelium. Note longitudinally radial fine strands (*Psilocybe cyanescens* mycelium).

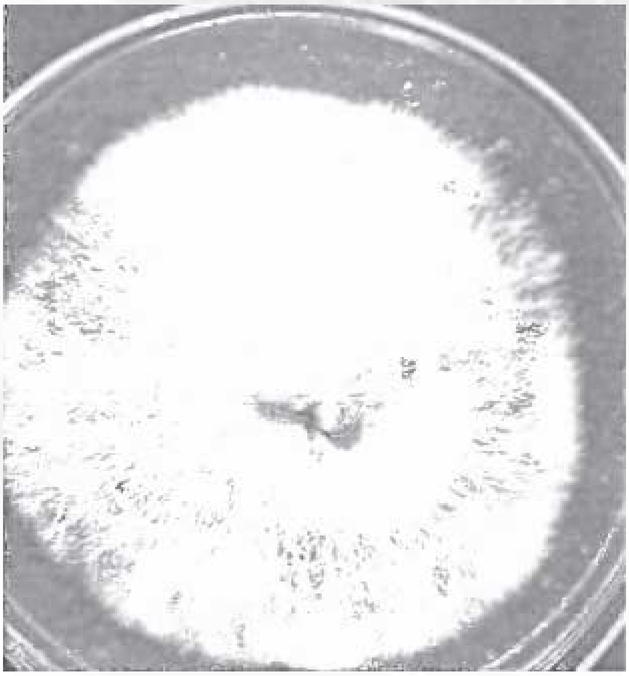

Figure 36 - Rhizomorphic mycelia with tomentose (cottony) sector (of *Agaricus brunnescens*).

In a dish that is largely covered with a cottony mycelia, a fan of strandy mycelia would be called a rhizomorphic sector, and vice versa. Sectors are common in mushroom culture and although little is known as to their cause or function, it is clear that genetics, nutrition and age of the mycelium play important roles.

According to Stoller (1962) the growth of fluffy sectors is encouraged by broken and exploded kernels which increase the availability of starch in the spawn media. Working with *Agaricus brunnescens*, Stoller noted that although mycelial growth is faster at high pH levels (7.5) than at slightly acid pH levels (6.5), sectoring is more frequent. He found that sectors on grain could be reduced by avoiding exploded grains (a consequence of excessive water) and buffering the pH to 6.5 using a combination of chalk (precipitated calcium carbonate) and gypsum (calcium sulfate).

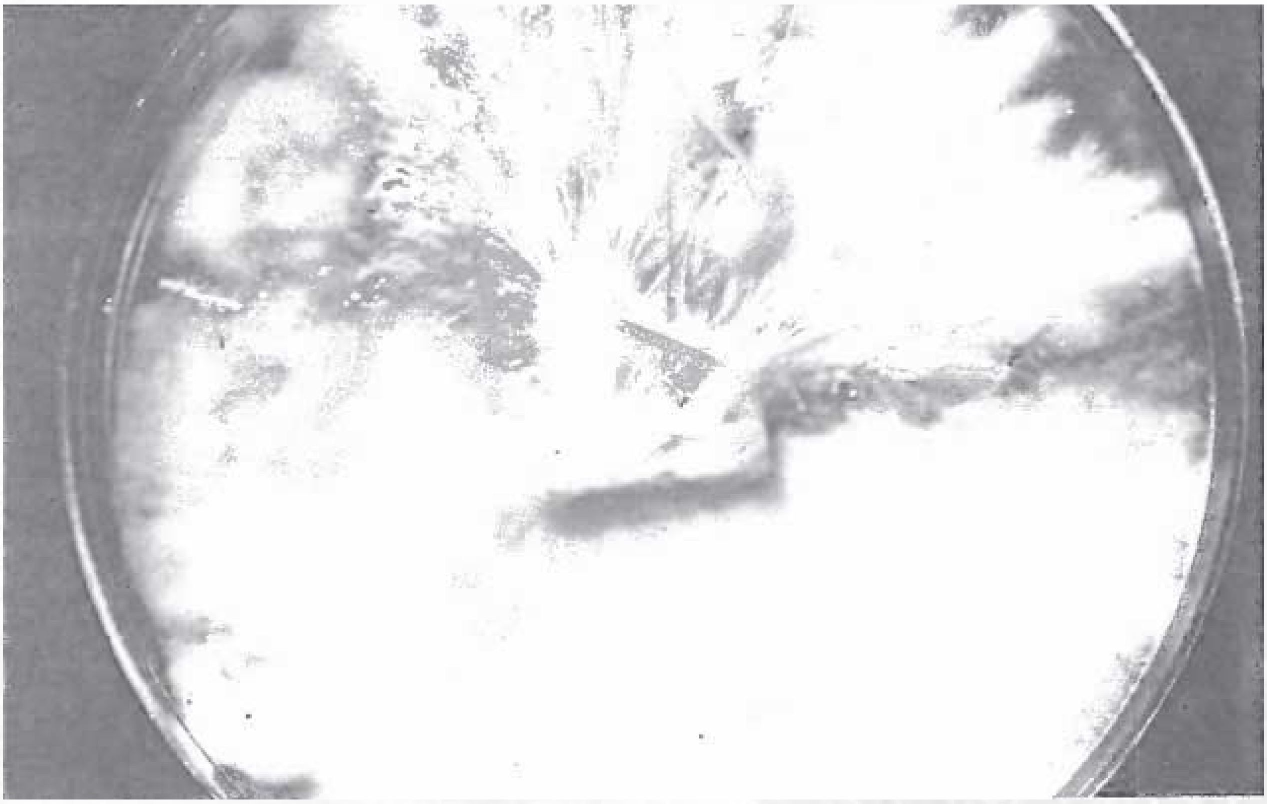

Figure 37 - *Psilocybe cubensis* mycelia with cottony and rhizomorphic sectors. Note that primordia form abundantly on rhizomorphic mycelium but not on the cottony type.

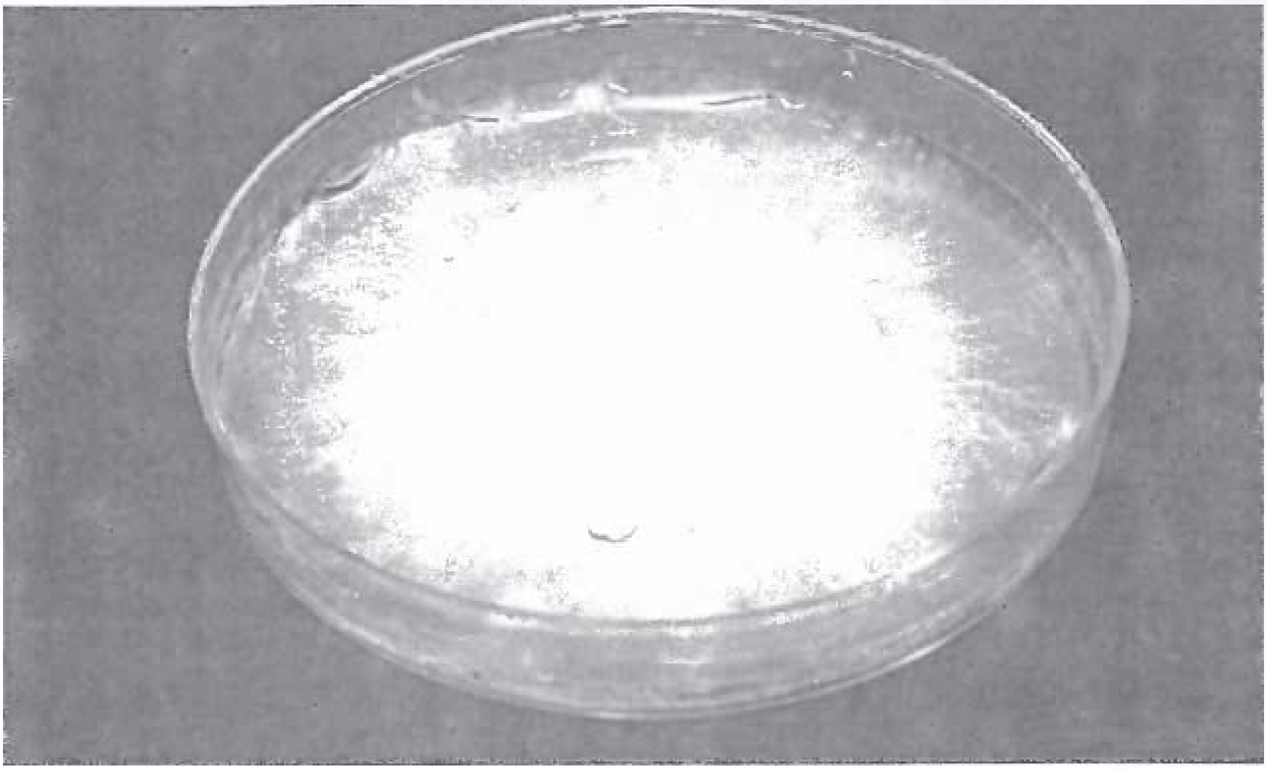

Figure 38 - Hyphal aggregates of *Agaricus bitorquis* forming on malt agar media.

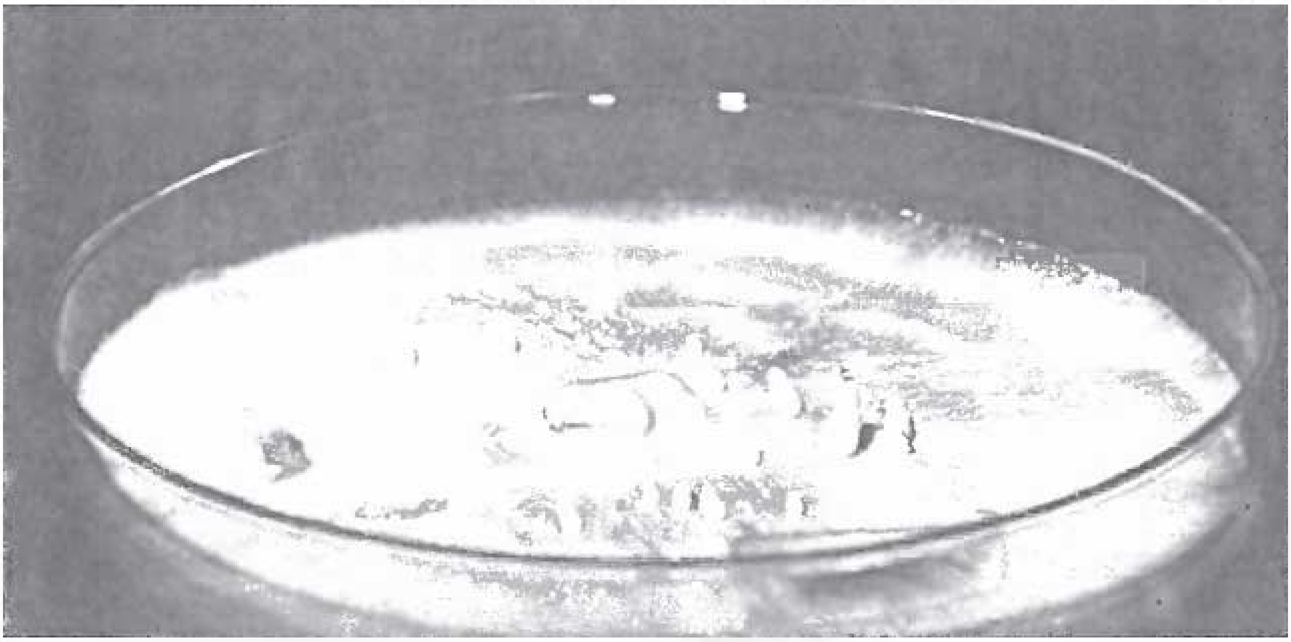

Figure 39 - Primordia of *Psilocybe cubensis* forming on malt agar media.

Commercial *Agaricus* cultivators have long noted that the slower growing cottony mycelium is inferior to the faster growing rhizomorphic mycelium. There is an apparent correlation between cottony mycelia on agar and the later occurrence of "stroma", a dense mat-like growth of mycelia on the casing which rarely produces mushrooms. Furthermore, primordia frequently form along generatively oriented rhizomorphs but rarely on somatically disposed cottony mycelia. It is of interest to mention that, under a microscope, the hyphae of a rhizomorphic mycelial network are larger and branch less frequently than those of the cottony network.

Rhizomorphic mycelia run faster, form more primordia and in the final analysis yield more mushrooms than cottony mycelia. One example of this is illustrated in Fig. 37. A single wedge of mycelium was transferred to a Petri dish and two distinct mycelial types grew from it. The stringy sector formed abundant primordia while the cottony sector did not, an event common in agar culture.

When a mycelium grows old it is said to be **senescing**. Senescent mycelium, like any aged plant or animal, is far less vigorous and fertile than its counterpart. In general, a change from rhizomorphic to cottony looking mycelium should be a warning that strain degeneration has begun.

If at first a culture is predominantly rhizomorphic, and then it begins to sector, there are several measures that can be undertaken to promote rhizomorphism and prevent the strain's degeneration.

1. Propagate only rhizomorphic sectors and avoid cottony ones.
2. Alter the media regularly using the formulas described herein. Growing a strain on the same agar formula is not recommended because the nutritional composition of the medium exerts an selective influence on the ability of the mushroom mycelium to produce digestive enzymes. By varying the media, the strain's enzyme system remains broadly based and the mycelium is better suited for survival. Species vary greatly in their preferences. Unless specific data is available, trial and error is the only recourse.
3. Only grow out the amount of mycelium needed for spawn production and return the strain to storage when not in use. Do not expect mycelium that has been grown over several years at optimum temperatures to resemble the primary culture from which it came. After so many cell divisions and continual transfers, a sub-strain is likely to have been selected out, one that may distantly resemble the original in both vitality, mycelial appearance and fruiting potential.
4. If efforts to preserve a vital strain fail, re-isolate new substrains from multispore germinations.
5. Another alternative is to continuously experiment with the creation of hybrid strains that are formed from the mating of dikaryotic mycelia of two genetically distinct parents. (Experiments with *Agaricus brunnescens* have shown, however, that most hybrids yield less than both or one of the contributing strains. A minority of the hybrids resulted in more productive strains.)

Home cultivators can selectively develop mushroom strains by rating mycelia according to several characteristics. These characteristics are:

1. Rhizomorphism - fast growing vegetative mycelium.
2. Purity of the strain - lack of cottony sectors.
3. Cleanliness of the mycelia - lack of associated competitor organisms (bacteria, molds and mites).
4. Response time to primodia formation conditions.
5. Number of primordia formed.
6. Proportion of primordia formed that grow to maturity.
7. Size, shape and/or color of fruitbodies.
8. Total yield.
9. Disease resistance.
10. CO_2 tolerance/sensitivity.
11. Temperature limits.
12. Ease of harvesting.

Using these characteristics, mushroom breeders can qualitatively judge strains and select ones over a period of time according to how well they conform to a grower's preferences.

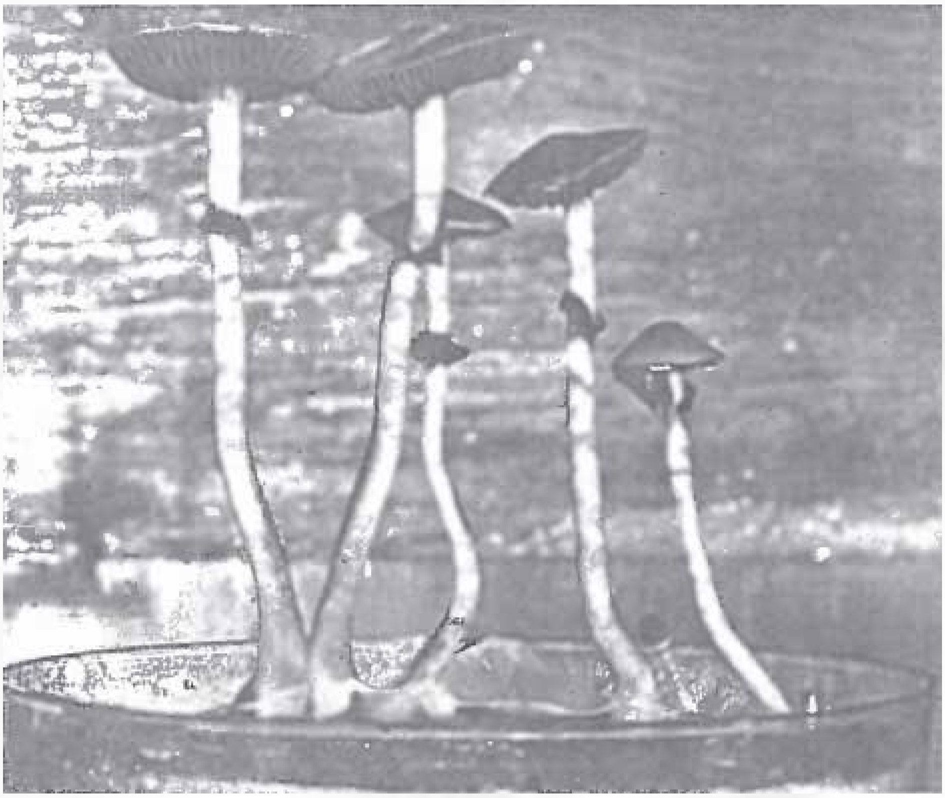

Figure 40 - Mature stand of *Psilocybe cubensis* on malt agar media.

Stock Cultures: Methods For Preserving Mushroom Strains

Once a pure strain has been created and isolated, saving it in the form of a "stock culture" is wise. Stock cultures - or "slants" as they are commonly called - are media filled glass test tubes which are sterilized and then inoculated with mushroom mycelium. A suitable size for a culture tube is 20 mm. x 100 mm. with a screw cap. Every experienced cultivator maintains a collection of stock cultures, known as a "species bank". The species bank is an integral part of the cultivation process. With it, a cultivator may preserve strains for years.

To prepare slants, first mix any of the agar media formulas discussed earlier in this chapter. Fill test tubes one third of the way, plug with cotton and cover with aluminum foil or simply screw on the cap if the tubes are of this type. Sterilize in a pressure cooker for 30 minutes at 15 psi. Allow the cooker to return to atmospheric pressure and then take it into the sterile room before opening. Remove the slants, gently shake them to distribute the liquified media and lay them at a 15-30 degree angle to cool and solidify.

When ready, inoculate the slants with a fragment of mushroom mycelium. Label each tube with the date, type of agar, species and strain. Make at least three slants per strain to insure against loss. Incubate for one week at 75°F. (24°C.). Once the mycelia has covered a major portion of the agar's surface and appears to be free of contamination, store at 35-40°F. (2-4°C.). At these temperatures, the metabolic activity of most mycelia is lowered to a level where growth and nutrient absorbtion virtually stops. Ideally one should check the vitality of stored cultures every six months by removing fragments of mycelium and inoculating more Petri dishes. Once the mycelium has colonized two-thirds of the media dish, select for strandy growth (rhizomorphism) and reinoculate more slants. Label and store until needed. Often, growing out minicultures is a good way to check a stored strain's vitality and fruiting ability.

An excellent method to save cultures is by the buddy system: passing duplicates of each species or of strains to a cultivator friend. Mushroom strains are more easily lost than one might expect. Once lost, they may never be recovered.

In most cases, the method described above safely preserves cultures. Avid cultivators, however, can easily acquire fifty to a hundred strains and having to regularly revitalize them becomes tedious and time consuming. When a library of cultures has expanded to this point, there are several additional measures that further extend the life span of stock cultures.

A simple method for preserving cultures over long periods of time calls for the application of a thin layer of sterile mineral oil over the live mycelium once it has been established in a test tube. The mineral oil is non-toxic to the mycelium, greatly reduces the mycelium's metabolism and inhibits water evaporation from the agar base. The culture is then stored at 37-41°F. until needed. In a recent study (Perrin, 1979), all of the 30 wood inhabiting species stored under mineral oil for 27 years produced a viable culture. To reactivate the strains, slants were first inverted upside down so the oil would drain off and then incubated at 77°F. Within three weeks each slant showed renewed signs of growth and when subcultured onto agar plates they yielded uncontaminated cultures.

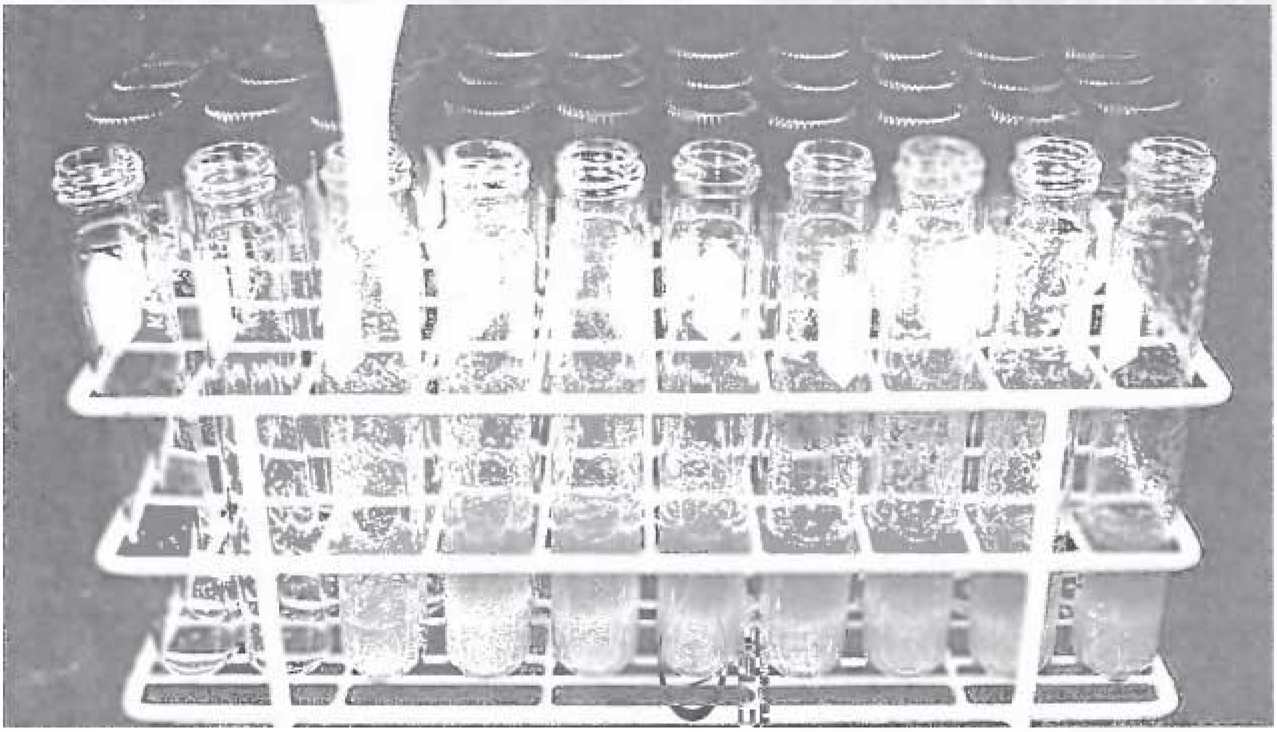

Figure 41 - Filling test tubes with liquid agar media prior to sterilization in a pressure cooker.

Although a strain may be preserved over the long term using this method, will it be as productive as when it was first stored? Other studies have concluded that strains saved for more than 5 years under mineral oil showed distinct signs of degeneration while these same strains were just as productive at 2½ years as the day they were preserved. Nevertheless, it is not unreasonable to presume, based on these studies, that cultures can be stored up to two years without serious impairment to their vitality.

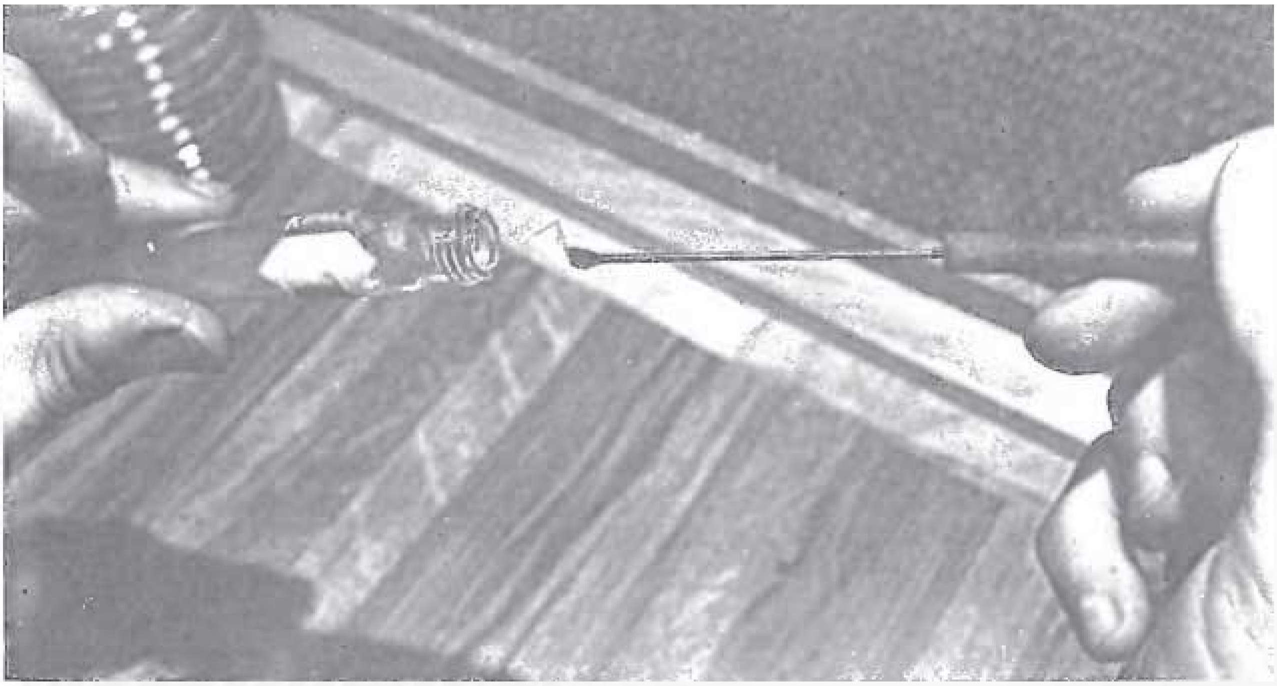

Figure 42 - Inoculating a test tube slant with a piece of mycelium.

Four other methods of preservation include: the immersion of slants into liquid nitrogen (an expensive procedure); the inoculation of washed sterilized horse manure/straw compost that is then kept at 36-38°F. (See Chapter V on compost preparation); the inoculation of sawdust/bran media for wood decomposers (see section in Chapter III on alternative spawn media); or saving spores aseptically under refrigerated conditions - perhaps the simplest method for home cultivators.

Whatever method is used, remember that the mushroom's nature is to fruit, sporulate and evolve. Cultivation techniques should evolve with the mushroom and the cultivator must selectively isolate and maintain promising strains as they develop. So don't be too surprised if five years down the line a stored strain poorly resembles the original in its fruiting potential or form.

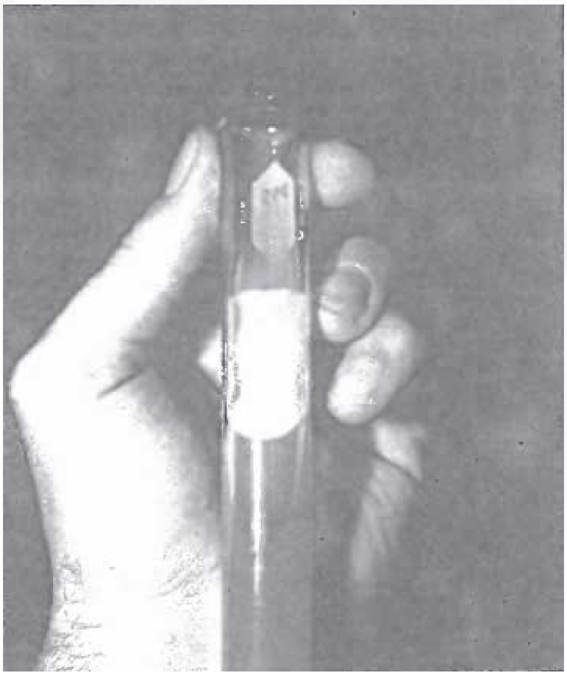

Figure 43 - Culture slant of healthy mycelium ready for cool storage.

III. GRAIN CULTURE

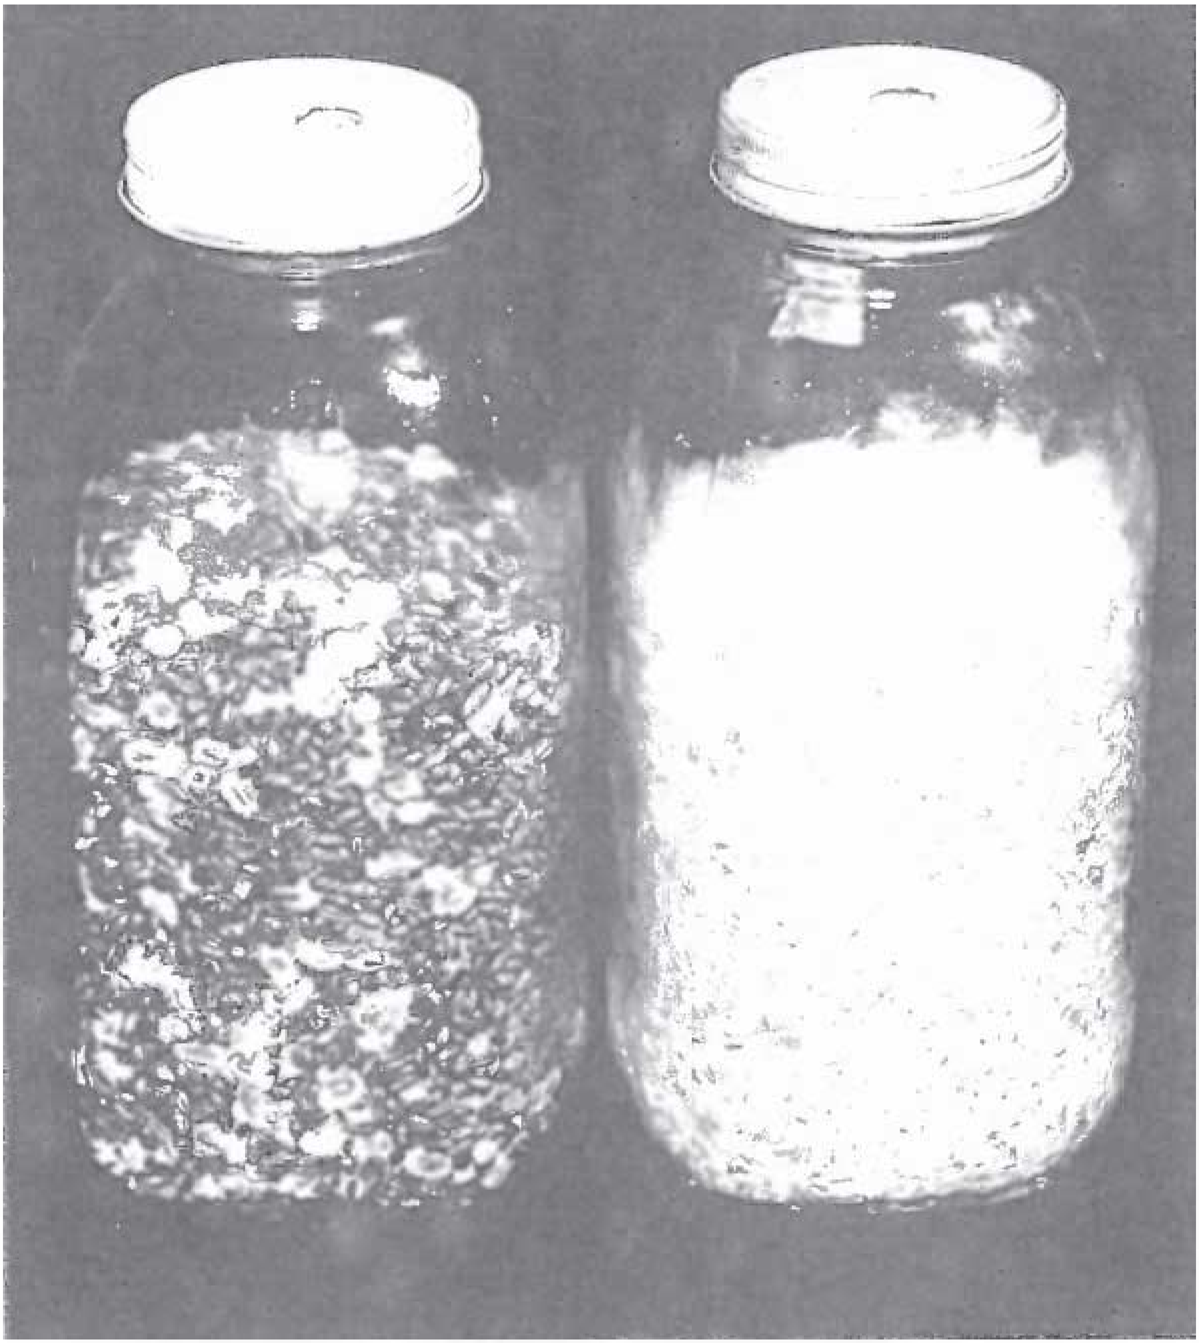

Figure 44 - Half gallon spawn jars at 3 and 8 days after inoculation.

The Development of Grain Spawn

Mushroom spawn is used to inoculate prepared substrates. This inoculum consists of a carrier material fully colonized by mushroom mycelium. The type of carrier varies according to the mushroom species cultivated, although rye grain is the choice of most spawn makers. The history of the development of mushroom spawn for *Agaricus brunnescens* culture illustrates how spawn production has progressed in the last hundred years.

During the 1800's *Agaricus* growers obtained spawn by gathering concentrations of mycelium from its natural habitat. To further encourage mycelial growth this "virgin spawn" was supplemented with materials similar to those occurring naturally, in this case horse manure. Spent compost from prior crops was also used as spawn. This kind of spawn, however, contained many contaminants and pests, and yielded few mushrooms. Before serious commercial cultivation could begin, methods guaranteeing the quality and mass production of the mushroom mycelium had to be developed.

With the advent of pure culture techniques, propagation of mushroom mycelium by spore germination or by living tissue completely superseded virgin spawn. Now the grower was assured of not only a clean inoculum but also a degree of certainty as to the strain itself. Strain selection and development was possible for the first time in the history of mushroom culture because high yielding strains could be preserved on a medium of precise composition. Sterilized, chopped, washed compost became the preferred medium for original pure culture spawn and was for years the standard of the *Agaricus* industry.

In 1932, Dr. James Sinden patented a new spawn making process using cereal grain as the mycelial carrier. Since then rye has been the most common grain employed although millet, milo and wheat have also been used. Sinden's novel approach set a new standard for spawn making and forms the basis for most modern spawn production. The distinct advantage of grain spawn is the increased number of inoculation sites. Each individual kernel becomes one such point from which mycelium can spread. Thus, a liter of rye grain spawn that contains approximately 25,000 kernels represents a vast improvement over inocula transmitted by coarser materials.

Listed below are cereal grains that can be used to produce spawn. Immediately following this list is a chart illustrating some of the physical properties important to the spawn maker.

RICE: Utilized by few cultivators. Even when it is balanced to recommended moisture levels, the kernels tend to clump together owing to the sticky nature of the outer coat.
MILLET: Although having a higher number of inoculation points than rye, it is more difficult to formulate as spawn. Amycel, a commercial spawn-making company, has successfully developed a formula and process utilizing millet as their primary spawn medium.
SORGHUM: Has spherical kernels and works relatively well as a spawn medium but it can be difficult to obtain. Milo, a type of sorghum, has been used for years by the Stoller Spawn Company.
WHEAT: Works equally well as rye for spawn making and fruitbody production.
WHEAT GRASS and **RYE GRASS SEED**: Both have many more kernels per gram than grain. The disadvantage of seed is the tendency to lose its moisture and its inability to separate into individual kernels, making it difficult to shake. (Rye grass and wheat grass seed are widely used to promote sclerotia formation in *Psilocybe tampanensis*, *Psilocybe mexicana* and *Psilocybe armandii*. Perennial or annual can be used although annual is far cheaper. See the species parameters for these species in Chapter XI.)
RYE: Its availability, low cost and ability to separate into individual kernels are all features recommending its use as a spawn and fruiting medium.

THE CEREAL GRAINS AND THEIR PHYSICAL PROPERTIES
(tests run by the authors)

TYPE	KERNELS/GRAM	GRAMS/100 ML	% MOISTURE
COMMERCIAL FEED RYE	30	75	15%
COMMERCIAL MUSHROOM RYE	40	72	13%
ORGANIC CO-OP RYE	55	76	11%
ORGANIC WHEAT	34	90	10%
SHORT GRAIN BROWN RICE	39	100	26%
LONG GRAIN BROWN RICE	45	86	15%
SORGHUM (MILO)	33	93	15%
PERENNIAL WHEAT GRASS SEED	450	43	16%
PERENNIAL RYE GRASS SEED	415	39	12%
MILLET	166	83	13%

In a single gram of commercial rye, *Secale cereale*, there is an estimated cell count of 50,000-100,000 bacteria, more than 200,000 actinomyces, 12,000 fungi and a large number of yeasts. To sterilize one gram of grain would require, in effect, the destruction of more than 300,000 contaminants! In a spawn jar containing in excess of a hundred grams of grain, and with the addition of water, the cell population soars to astronomical figures.

Of all the groups of these organisms, bacteria are the most pernicious. Bacteria can divide every twenty or so minutes at room temperature. At this rate, a single bacterium multiplies into more than a million cells in less than ten hours. In another ten hours, each one of these bacteria beget another million cells. If only a small fraction of one percent of these contaminants survive the sterilization process, they can render grain spawn useless within only a few days.

Most microorganisms are killed in the sterilization process. For liquids, the standard time and pressure for steam sterilization is 25 minutes at 15 psi (250°F). For solids such as rye, the sterilization time must be increased to insure that the steam sufficiently penetrates the small air pockets and structural cavities in the grain. Within these cavities bacteria and other thermo-resistant organisms, partially protected from the effects of steam, have a better chance of enduring a shorter sterilization period than a longer one. Hence, a full hour at 15 psi is the minimum time recommended to sterilize jars of rye grain.

Some shipments of grain contain extraordinarily high levels of bacteria and fungi. Correspondingly the contamination rate on these grains are higher, even after autoclaving and prior to inoculation. Such grain should be discarded outright and replaced with grain of known quality.

Once the grain has been sterilized, it is presumed all competitors have been neutralized. The next most probable source of contamination is the air immediately surrounding the jars. As hot jars cool, they suck in air along with airborne contaminants. If the external spore load is excessively high, many of these contaminants will be introduced into the grain even before conducting a single inoculation! In an average room, there are 10,000 particulates exceeding .3 microns (dust, spores, etc.) per cubic foot while in a "sterile" laboratory there are less than 100 per cubic foot. With these facts in mind, two procedures will lessen the chance of contamination after the spawn jars have been autoclaved.

1. If autoclaving grain media outside the laboratory in an unsterile environment (a kitchen, for instance), be sure to clean the outside of the pressure cooker before bringing it into the sterile inoculating room.
2. Inoculate the jars as soon as they have cooled to room temperature. Although many cultivators leave uninoculated jars sitting in pressure cookers overnight, this is not recommended.

The amount of water added to the grain is an important factor contributing to the reproduction of contaminants. Excessive water in a spawn jar favors the growth of bacteria and other competitors. In wet grain the mushroom mycelium grows denser and slower. Oversaturated grain kernels explode during the sterilization process, and with their interiors exposed, the grain is even more susceptible to contamination. In addition, wet grain permeated with mycelium is difficult to break up into individual kernels. When such grain comes in contact with a non-sterile medium such as casing soil or compost, it frequently becomes contaminated. Spawn made with a balanced moisture content has none of these problems. It easily breaks apart into individual mycelium covered kernels, insuring a maximum number of inoculation points from which mycelial strands can emerge.

Determining the exact moisture content of grain is not difficult. Once done, the cultivator can easily calculate a specific moisture content that is optimal for use as spawn. Commercial rye grain, available through co-ops and feed companies, is 11% water by mass, plus or minus 2%. The precise amount of water locked up in grain can be determined by weighing a sample of 100 grams. Then reweigh the same grain after it has been dried in an oven (250°F. for 3 hours) and subtract this new weight from the original 100 grams. The resultant figure is the percentage of moisture naturally bound within the grain.

Preparation of Grain Spawn

The optimum moisture content for grain in the production of spawn is between 49-54%. The following formulas are based on cereal rye grain, *Secale cereale*, which usually has a moisture content of 11%. Some variation should be expected depending on the brand, kernel size, geographical origin and the way the grain has been stored.

The standard spawn container for the home cultivator is the quart mason jar while the commercial spawn maker prefers the gallon jar. Wide mouth mason jars have been extensively used by home cultivators because of several books popularizing fruitbody production in these jars. Wide mouth jars have been preferred because mushrooms grown in them are easier to harvest than those in narrow mouth ones. Not only is this method of growing mushrooms outdated, but wide mouth jars have several disadvantages for spawn production and hence are not recommended. Narrow mouthed containers have less chance of contaminating from airborne spores because of their smaller openings and are more suited to use with synthetic filter discs. The purpose of the spawn container is to temporarily house the incubating mycelium before it is laid out in trays or used to inoculate bulk substrates. Jars are not well suited as a fruiting container.

Most commercial spawn makers cap their spawn bottles with synthetic filter discs which allow air penetration and gaseous exchange but not the free passage of contaminating spores. Home cultivators, on the other hand, have used inverted mason lids which imperfectly seal and allow some air exchange. This method works fine under sterile conditions although the degree of filtration is not guaranteed. The best combination uses filter discs in conjunction with one piece screw top lids having a ⅜-½ inch diameter hole drilled into its center and fitting a narrow mouthed autoclavable container. The authors personally find the regular mouthed ½ gallon mason jar to be ideal. (Note: These ½ gallon jars are inoculated from quart masters, a technique soon to be discussed). Using only filter discs on wide mouth jars is not recommended due to the excessive evaporation from the grain medium.

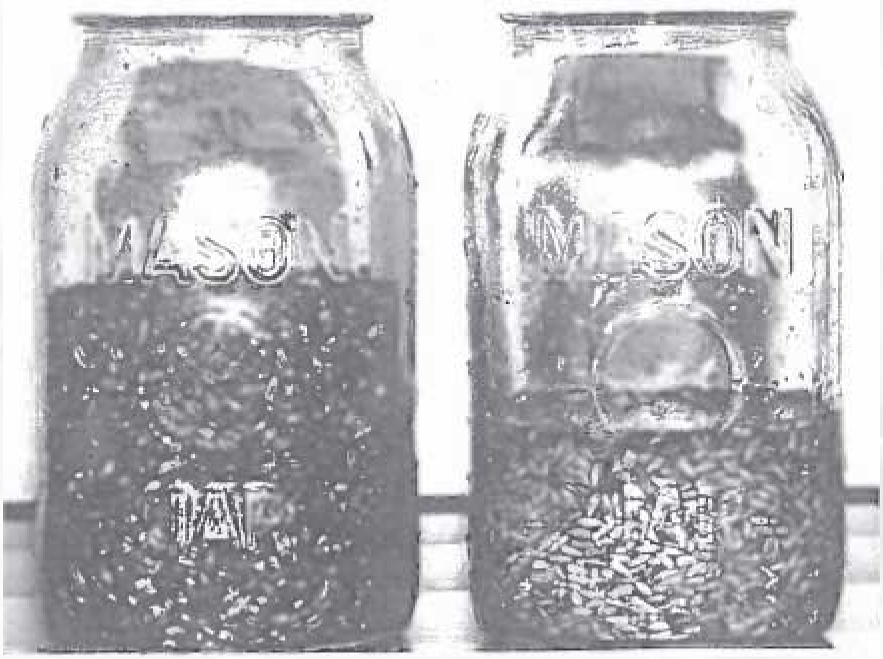

Figure 45 - Two jars of grain media, before and after autoclaving using the above formulas.

To produce grain spawn of 48-52% moisture use the formulas outlined below and autoclave in a pressure cooker for 1 hour at 15-18 psi. Note that considerable variation exists between measuring cups, differing as much as 10% in their volumes. Check the measuring cup with a graduated cylinder. Once standardized, fashion a "grain scoop" and a "water scoop" from a plastic container to the proportions specified below.

Spawn Formulas

QUART JARS	½ GALLON JARS
1 cup rye grain	3 cups rye grain
⅔-¾ cup water	1¾ cups water
or (approximately)	
240 ml. grain	600 ml. rye grain
170-200 ml. water	400-460 ml. water

The above formulas fill a quart or a half gallon jar to nearly ⅔ of its capacity after autoclaving. In all these formulas, chalk ($CaCO_3$) and gypsum ($CaSO_4$) can be added at a rate of 1-3 parts by weight per 100 parts of grain (dry weight). The ratio of chalk to gypsum is 1:4. The addition of these elements to spawn is optional for most species but necessary when growing *Agaricus brunnescens*. When these calcium buffers are used, add 10% more water than that listed above.

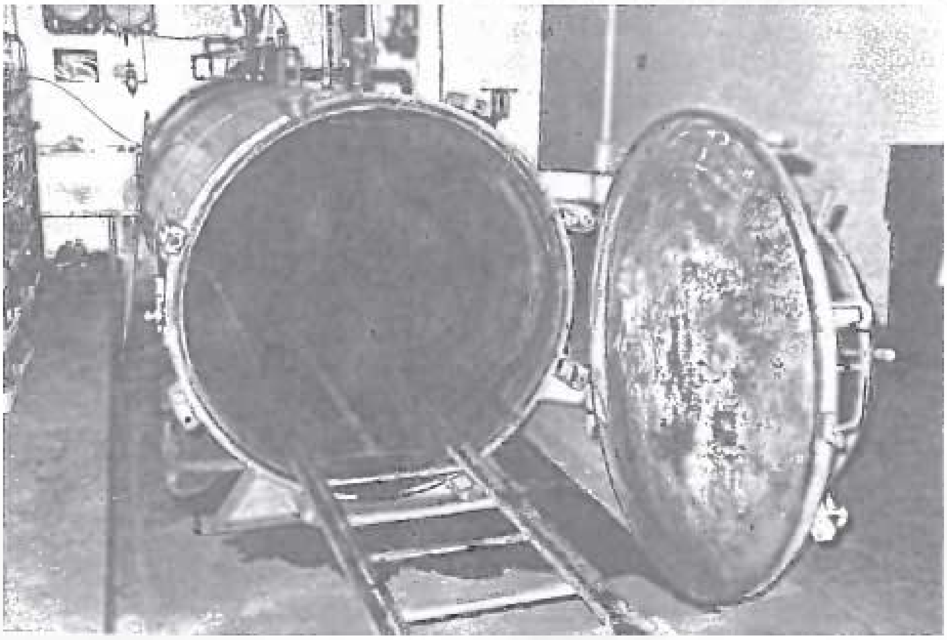

Figure 46 - Commercial spawn maker's autoclave.

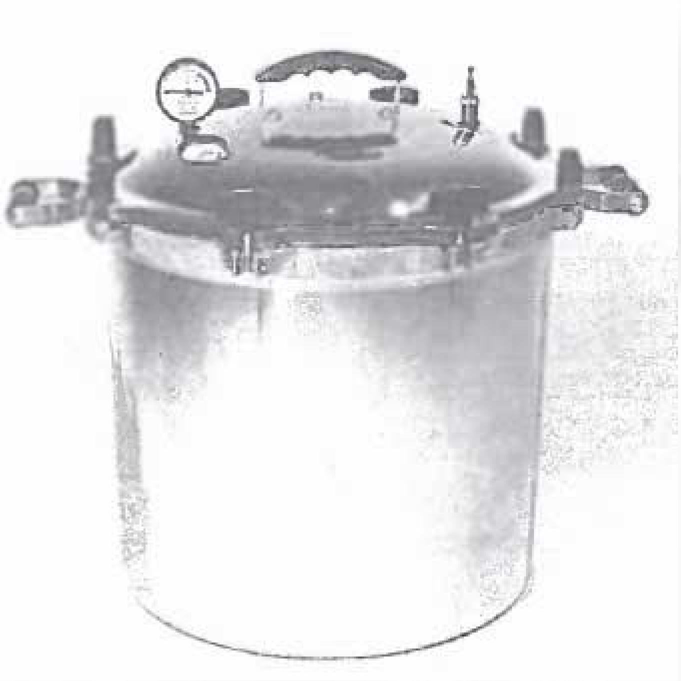

Figure 47 - Pressure cooker of home cultivator.

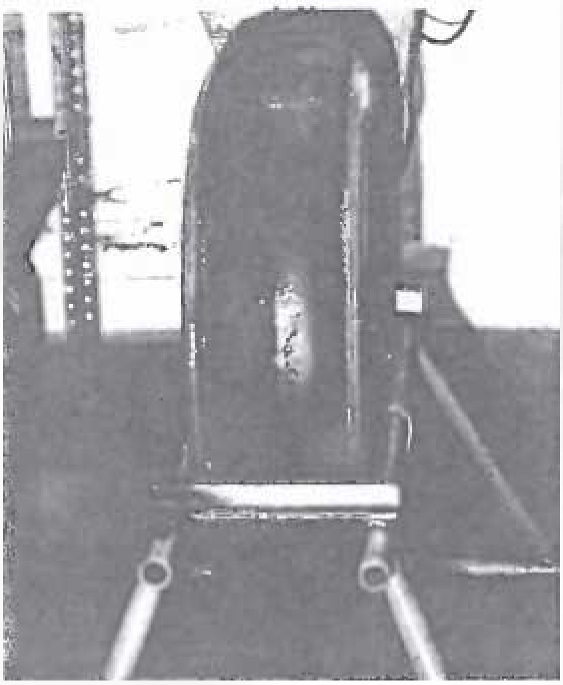

Figure 48 - The rubber tire is a helpful tool for the spawn laboratory. It is used to loosen grain spawn.

Once the grain filled jars have been autoclaved, they should be placed in the sterile room and allowed to cool. Prior to this point, the room and its air should be disinfected, either through the use of traditional cleaning methods, HEPA filters or both.

Upon removing the warm jars from the pressure cooker or autoclave, shake them to loosen the grain and to evenly distribute wet and dry kernels. Shaking also prevents the kernels at the bottom of the jar from clumping.

An excellent tool to help in this procedure is a bald car tire or padded chair. Having been carefully cleaned and disinfected, the tire should be mounted in an upright and stable position. The tire has a perfect surface against which to shake the jars, minimizing discomfort to the hands and reducing the risk of injury from breakage. The tire will be used at another stage in grain culture, so it should be cleaned regularly. Paint shakers are employed by commercial spawn makers for this same purpose but they are inappropriate for the home cultivator. **CAUTION**: ALWAYS INSPECT THE JARS FOR CRACKS BEFORE SHAKING.

When the grain jars have returned to room temperature, agar to grain inoculations can commence. Once again, good hygiene is of the upmost importance. When transferring mycelium from agar to grain, another dimension is added in which contaminants can replicate. In agar culture, the mycelium grows over a flat, two dimensional surface. If contamination is present, it is easily seen. In grain culture, however, the added dimension of depth comes into play and contaminants become more elusive, often escaping detection from the most discerning eye. If not noticed, contamination will be spread when this spawn is used to inoculate more sterilized grain.

Before conducting transfers, take precautions to insure the sterile quality of the inoculation environment. After cleaning the room, do not jeopardize its cleanliness by wearing soiled clothes. Few cultivators take into consideration that they are a major source of contamination. In fact, the human body is in itself a habitat crawling with bacteria, microscopic mites, and resplendent with spores of plants and fungi.

When satisfied that all these preparatory conditions are in force, the making of spawn can begin.

Inoculation of Sterilized Grain from Agar Media

Select a vigorously growing culture whose mycelium covers no more than ¾ of the agar's surface. Cultures that have entirely overrun the Petri dish should be avoided because contaminants often enter along the margin of the Petri dish. If that outer edge is grown over with mycelium, these invaders can go undetected. Since this peripheral mycelium can become laden with contaminant spores, any grain inoculated with it would become spoiled.

Flame sterilize a scalpel and cut out a triangular wedge of mycelium covered agar using the technique described for doing agar-to-agar transfers. With careful, deliberate movements quickly transfer the wedge to an awaiting jar, exposing the grain for a minimal amount of time. For each transfer, flame sterilize the scalpel and inoculate wedges of mycelium into as many jars as desired. A Petri dish two thirds covered with mycelium should amply inoculate 6-8 quart jars of grain. (A maximum of 10-12 jars is possible). The more mycelia transferred, the faster the colonization and the less chance of contamination. Since these jars become the "master cultures", do everything possible to guarantee the highest standard of purity.

The authors recommend a "double wedge" transfer technique whereby a single triangular wedge of mycelium is cut in half, both pieces are speared and then inserted into an awaiting jar of sterilized grain. Jars inoculated with this method grow out far faster than the single wedge transfer technique.

Loosening the lids prior to inoculation facilitates speedy transfers. As each agar-to-grain transfer is completed, replace the lid and continue to the next inoculation. Once the set is finished, tightly secure the lids and shake each jar thoroughly to evenly distribute the mycelial wedges. In the course of shaking, each wedge travels throughout the grain media leaving mycelial fragments adhering to the grain kernels. If a wedge sticks to the glass, distribution is hampered and spawn running is inhibited. This problem is usually an indication of agar media that has been too thinly poured or has been allowed to dehydrate. Once shaken, incubate the spawn jars at the appropriate temperature. (A second shaking may be necessary on Day 4 or Day 5). In general, the grain should be fully colonized with mycelium in seven to ten days.

Inoculation of Grain from Grain Masters

Once fully colonized, these grain masters are now used for the further production of grain spawn in quart or ½ gallon containers. Masters must be transferred within a few days of their full colonization; otherwise the myceliated kernels do not break apart easily. A step by step description of the grain-to-grain transfer technique follows.

1. Carefully scrutinize each jar for any signs of contamination. Look for such abnormalities as: heavy growth; regions of sparse, inhibited growth; slimy or wet looking kernels (an indication of bacteria); exploded kernels with pallid, irregular margins; and any unusual colorations. If in doubt lift the lid and smell the spawn - a sour "rotten apple" or otherwise pungent odor is usually an indication of contamination by bacteria. Jars having this scent should be discarded. (Sometimes spawn partially

contaminated with bacteria can be cased and fruited). Do NOT use any jar with a suspect appearance for subsequent inoculations.

2. After choosing the best looking spawn masters, break up the grain in each jar by shaking the jars against a tire or slamming them against the palm of the hand. The grain should break easily into individual kernels. Shake as many masters as needed knowing that each jar can amply inoculate ten to twelve quart jars or seven to nine half gallon jars.
   Once completed, SET THE SPAWN JARS ON A SEPARATE SHELF AND WAIT TWELVE TO TWENTY-FOUR HOURS BEFORE USING. This waiting period is important because some of the spawn may not recover, suffering usually from bacterial contamination. Had these jars been used, the contamination rate would have been multiplied by a factor of ten.
3. Inspect the jars again for signs of contamination. After twelve to twenty-four hours, the mycelium shows signs of renewed growth.
4. If the masters had been shaken the night before, the inoculations can begin the following morning or as soon as the receiving jars (G-2) have cooled. Again, wash the lab, be personally clean and wear newly laundered clothes.
   Place 10 sterilized grain-filled jars on the work-bench in the sterile room. Loosen each of the lids so they can be removed with one hand. Gently shake the master jar until the grain spawn separates into individual kernels. Hold the master in your preferred hand. Remove the master's lid and then with the other hand open the first jar to be inoculated. With a rolling of the wrist, pour one tenth of the master's contents into the first jar, replace its lid and continue to the second, third, fourth jars, until the set is completed. When this first set is done, firmly secure the lids. Replace the lid on the now empty spawn master jar and put it aside. Take each newly inoculated jar, and with a combination of rolling and shaking, distribute the mycelium covered kernels evenly throughout.
5. Incubate at the temperature appropriate for the species being cultivated. In a week the mycelium should totally permeate the grain. Designated G-2, these jars can be used for further inoculations, as spawn for the inoculation of bulk substrates, or as a fruiting medium.

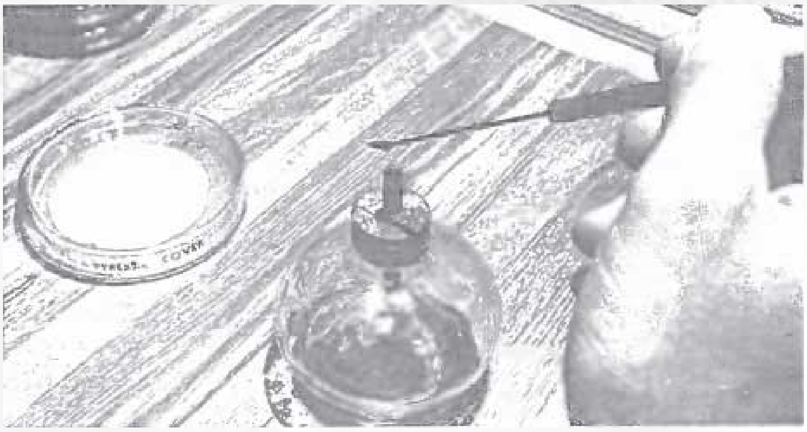

Figure 49 - Flaming the scalpel.

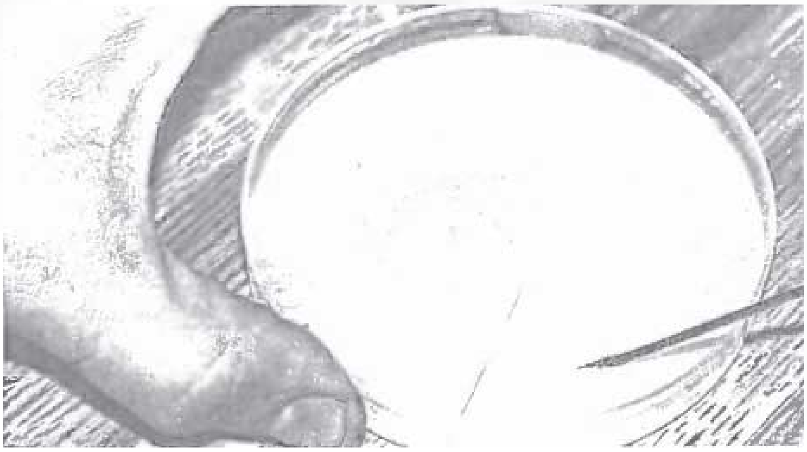

Figure 50 - Cutting two wedges of mycelium colonized agar.

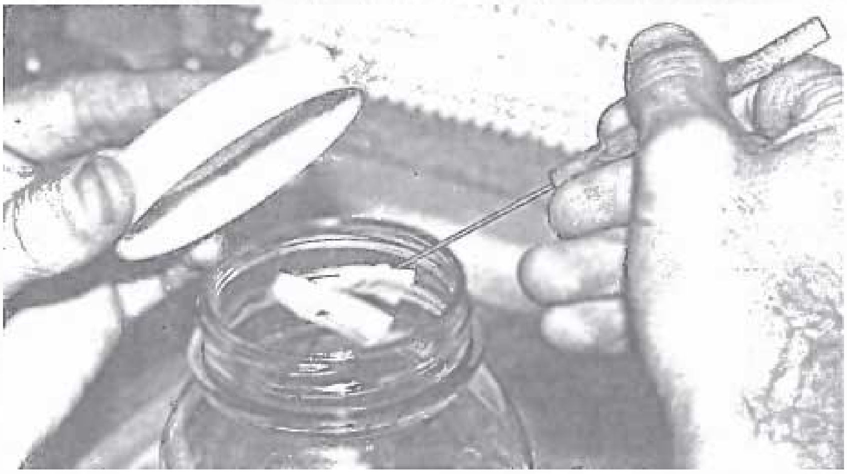

Figure 51 - Inoculating sterilized grain.

Some species are less aggressive than others. *Agaricus brunnescens*, for instance, can take up to two and a half weeks to colonize grain while *Psilocybe cubensis* grows through in a week to ten days. Here again, the use of the tire as a striking surface can be an aid to shaking. For slower growing species, a common shaking schedule is on the 5th and 9th days after inoculation. The cultures should be incubated in a semi-sterile environment at the temperature most appropriate for the species being cultivated. (See Chapter XI).

After transferring mycelium from agar to grain, further transfers can be conducted from these grain cultures to even more grain filled jars. A schedule of successive transfers from the first inoculated grain jar, designated G-1, through two more "generations" of transfers (G-2, G-3 respectively) will result in an exponential expansion of mycelial mass. If for instance, 10 jars were inoculated from an agar grown culture (G-1), they could further inoculate 100 jars (G-2) which in turn could go into 1000 jars (G-3). As one can see, it is of critical importance that the first set of spawn masters be absolutely pure for it may ultimately inoculate as many as 1,000 jars! Inoculations beyond the third generation of transfers are not recommended. Indeed, if a contamination rate above 10% is experienced at the second generation of transfers, then consider G-2 a terminal stage. These cultures can inoculate bulk substrates or be laid out in trays, cased and fruited.

Grain-to-grain transfers are one of the most efficient methods of spawn making. This method is preferred by most commercial spawn laboratories specializing in *Agaricus* culture. They in turn sell grain spawn that is a second or third transfer to *Agaricus* farmers who use this to impregnate their compost. For the creation of large quantities of spawn, the grain-to-grain technique is far superior to agar-to-grain for both its ease and speed. However, every cultivator must ultimately return to agar culture in order to maintain the purity of the strain.

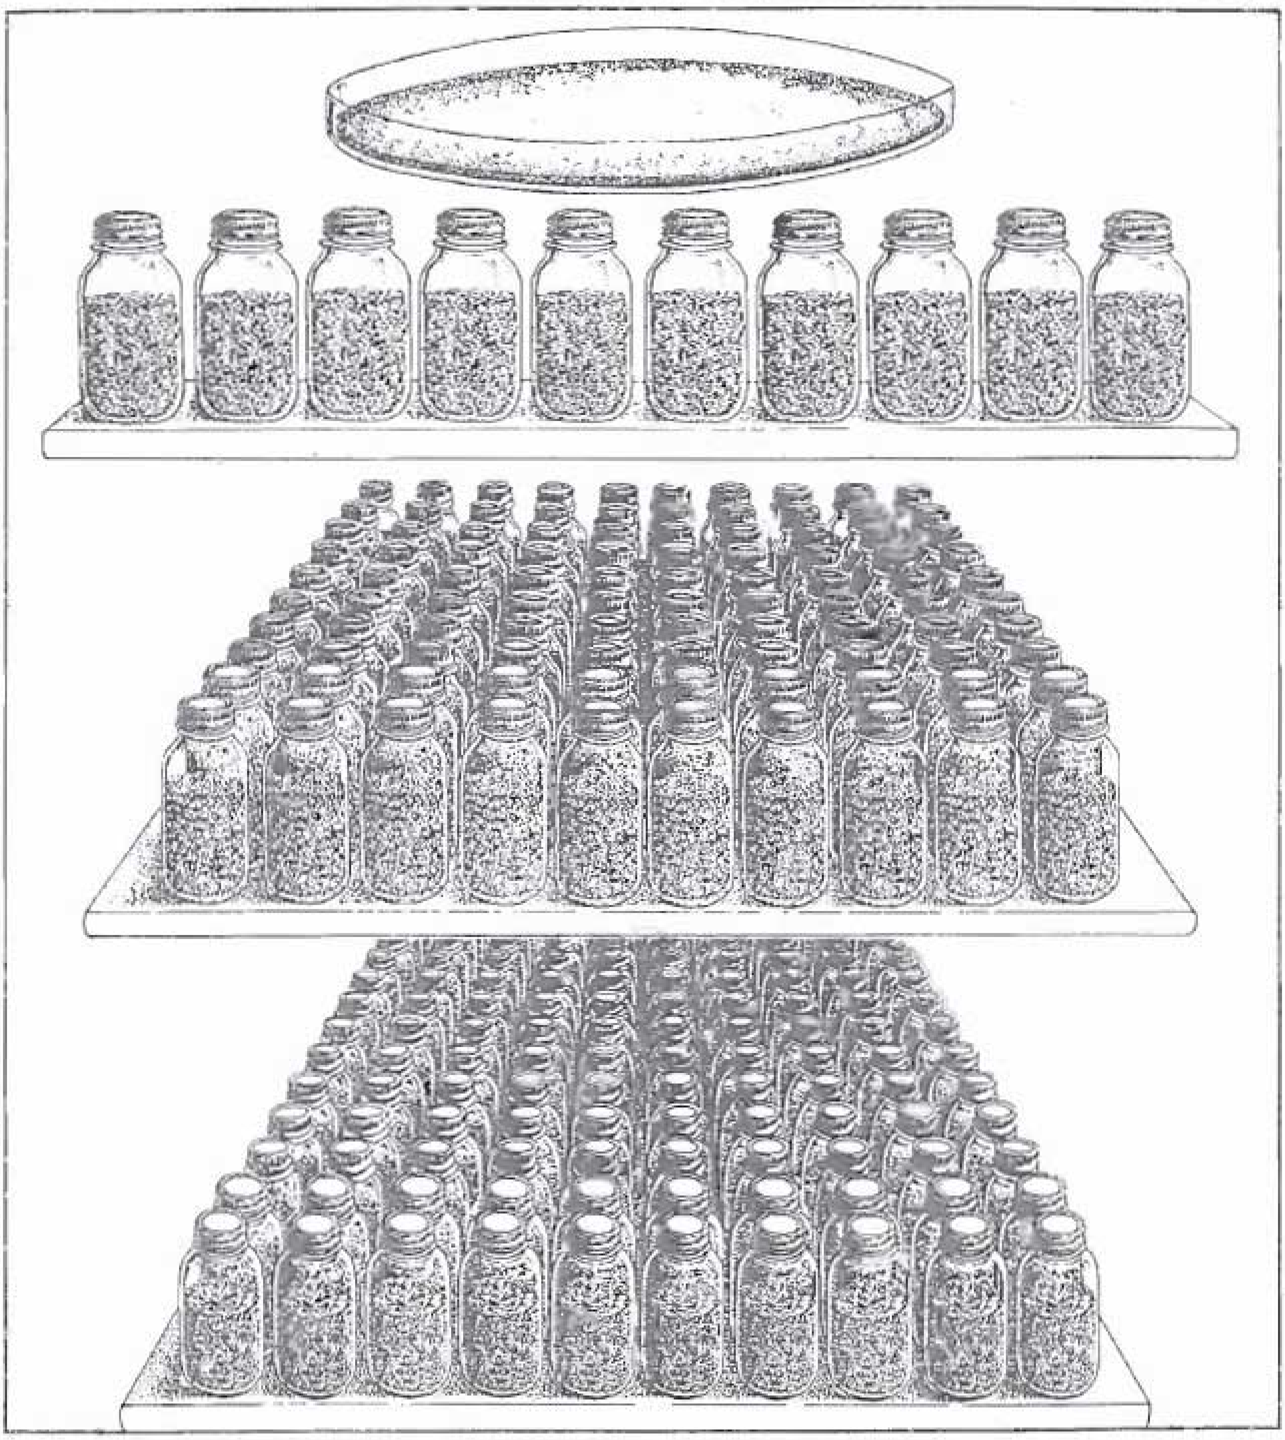

Figure 55 - Diagramatic expansion of mycelial mass using grain-to-grain transfer technique. One Petri dish can inoculate 10 spawn jars (G-1) which in turn can be used to inoculate 100 more jars (G-2) and eventually 1000 jars of spawn (G-3) provided the culture remains pure.

Alternative Spawn Media

Some mushroom species do not grow well on grain and are better suited to alternative spawn media. Other mushrooms are grown on substrates incompatible with grain spawn. For example, sawdust and bran are the preferred spawn materials for the cultivations of wood inhabitors such as *Lentinus edodes* and *Flammulina velutipes*. Another spawn media has a perlite bran base. Perlite is vitreous rock, heated to 1000°F. and exploded like popcorn. The thin flakes of bran are readily sterilized while the perlite gives the medium its structure. The recipes are:

Sawdust/Bran Spawn

4 parts sawdust (hardwood)
1 part bran (rice or wheat)
Soak the sawdust in water for a least twenty four hours, allow to drain and then thoroughly mix in the bran. If the mixture has the proper moisture content, a firm squeeze results in a few drops between the fingers. Fill the material firmly to the neck of the spawn container (wide mouth). Japanese spawn makers bore a ½ inch diameter hole down the center of the media into which they later insert their inoculum. Sterilize for 60-90 minutes at 15 psi. Once cooled, inoculate from agar media, liquid emulsion, or grain. A fully grown bottle of sawdust bran spawn can also be used for further inoculations.

Perlite Spawn

120 milliliters water
40 grams perlite
50 grams wheat bran
6 grams gypsum (calcium sulfate)
1.5 grams calcium carbonate
Screen the perlite to remove the fine powder and particulates. Fill the container (small mouth) with the dry ingredients and mix well. Add the water and continue mixing until the ingredients are thoroughly moistened. Sterilize for one hour at 15 psi. Inoculate from agar media or liquid emulsion.

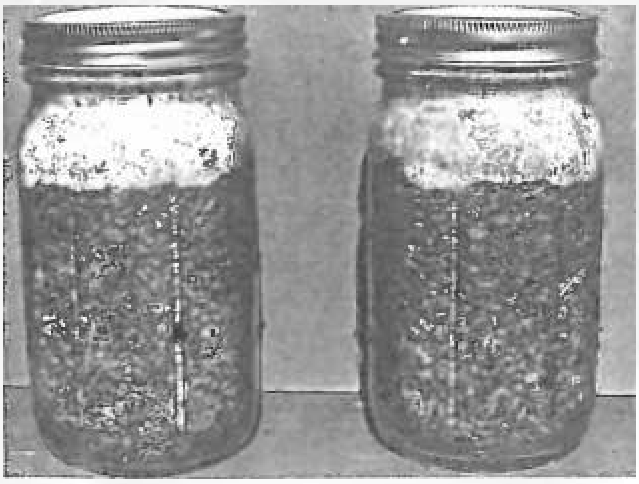

Figure 56 - Mycelium running through sawdust/bran spawn.

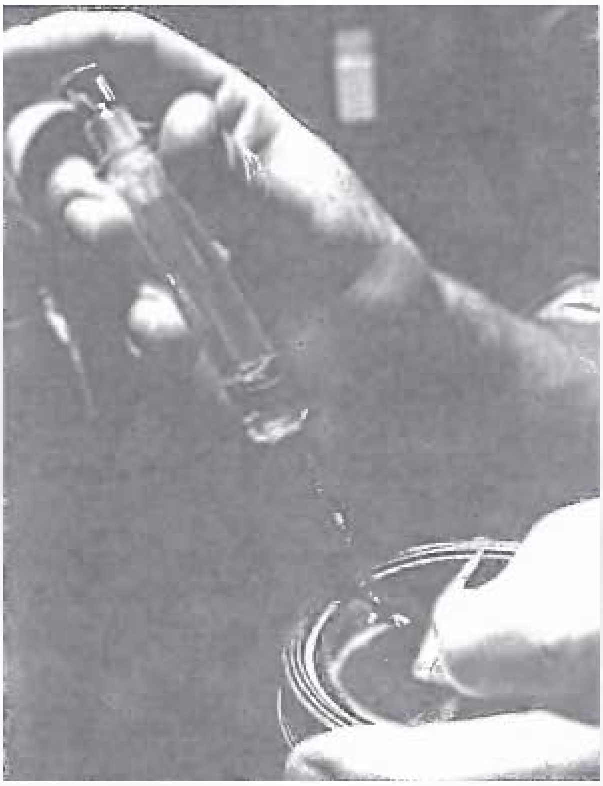
Liquid Inoculation Techniques

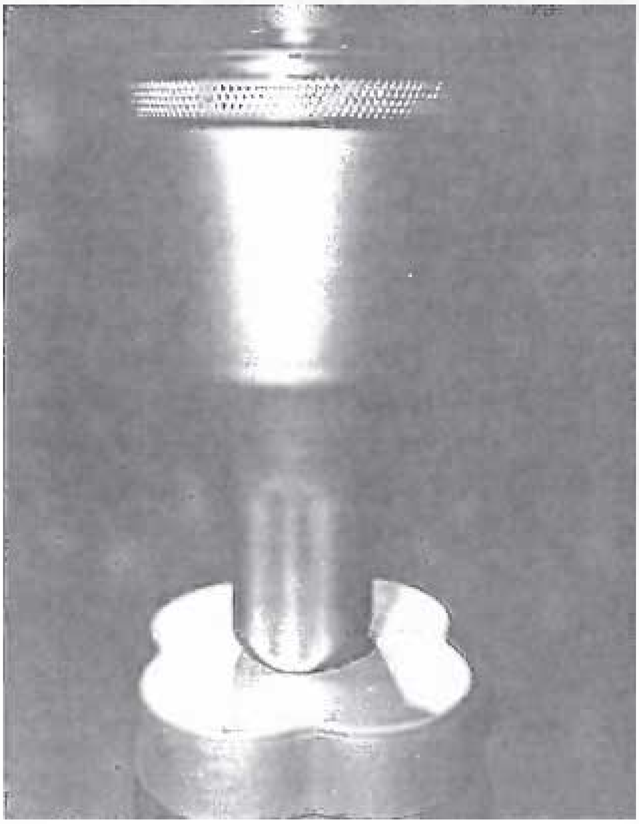
A highly effective technique for inoculating grain utilizes the suspension of fragmented mushroom mycelia in sterile water. This mycelium enriched solution, containing hundreds of minute cellular chains, is then injected into a jar of sterilized grain. As this water seeps down through the grain, mycelial fragments are evenly distributed, each one of which becomes a point of inoculation. For several days little or no sign of growth may be apparent. On the fourth to fifth day after injection, given optimum incubation temperatures, sites of actively growing mycelium become visible. In a matter of hours, these zones enlarge and the grain soon becomes engulfed with mycelium. Using the liquid inoculation technique eliminates the need for repeated shaking, and a single plate of mycelium can inoculate up to 100 jars, more than ten times the number inoculated by the traditional transfer method. There are several ways to suspend mycelium in water, two of which are described here.

The first method is quite simple. Using an autoclaved glass syringe, inject 30-50 ml. of sterilized water into a healthy culture. Then scrape the surface of the mycelial mat, drawing up as many fragments of mycelium as possible. As little as 5 ml. of mycelial suspension adequately inoculates a quart jar of grain.

The second method incorporates a blender with an autoclavable container-stirrer assembly. (Several companies sell aluminum and stainless steel units specifically manufactured for liquid culture techniques - refer to the sources listed in the Appendix). Fill with water until two thirds to three quarters full, cover with aluminum foil (if a tight fitting metal top is not handy), sterilize and allow to cool to room temperature.

Under aseptic conditions, insert an entire agar culture of vigorously grown mycelium into the sterilized stirrer by cutting it into four quadrants or into narrow strips. Because many contaminants appear along the outer periphery of a culture dish, it is recommended that these regions not be used. Place all four quadrants or mycelial strips into the liquid. Turn on the blender at high speed for no longer than 5 seconds. (Longer stirring times result not in the fragmentation of cell chains but in the fracturing of individual cells. Such suspensions are inviable). Draw up 5-10 ml. of the mycelium concentrate and inoculate an awaiting grain jar.





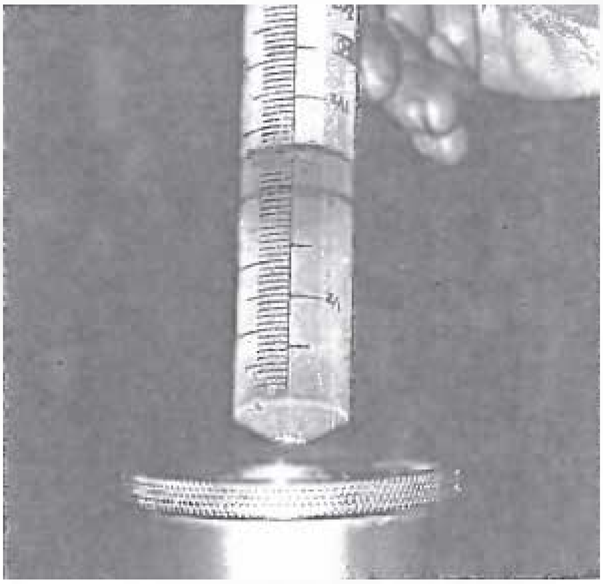


Figure 57 - Drawing up mycelium from culture dish with syringe.
Figure 58 - Syringe inoculation of sterilized grain.
Figure 59 - Eberbach container manufactured for liquid culture. Note bolt covering inoculation hole.
Figure 60 - Drawing up liquid inoculum.

A further improvement on this technique calls for a 10:1 dilution of the concentrated mycelial solution. Inject 50 ml. of mycelial suspension into four vessels containing 450 ml. of sterilized water. Narrow mouth quart mason jars are well suited to this technique. Gently shaking each jar will help evenly distribute the mycelium. Next inoculate the grain jars with 10-15 milliliters of the diluted solution. This method results in an exponential increase of liquid inoculum with the water acting as a vehicle for carrying the mycelial fragments deep into the grain filled jar. This is only one technique using water suspended fragments of mycelium. Undoubtedly, there will be further improvements as mycophiles experiment and develop their own techniques.

When using metal lids a small 1-2 mm. hole can be drilled and then covered with tape. When the sterilized containers are to be inoculated, remove the tape, insert the needle of syringe, inject the suspension of mycelia and replace the tape. In this way, the aperture through which the inoculation takes place is of minimal size and is exposed for a only second or two. The chance of airborne contamination is minimized.

The liquid inoculation technique works well provided the cultures selected are free from foreign spores; otherwise the entire set of jars inoculated from that dish will be lost. The disadvantage with this method is that there is no opportunity to avoid suspect zones on the culture dish - the water suspends contaminant spores and mycelia alike. If a culture dish is contaminated in one region, a few jars may be lost via the traditional inoculation method while with the liquid inoculation technique whole sets of up to one hundred spawn jars would be made useless.

Although mycelial suspensions created in this manner work for many species, the mycelia of some mushrooms do not survive the stirring process.

Incubation of Spawn

With each step in the cultivation process, the mycelial mass and its host substrate increases. In seven days to two weeks after inoculation, the spawn jars should be fully colonized with mushroom mycelia. The danger here is that, if contamination goes undetected, that mold or bacterium will likewise be produced in large quantities. Hence, as time goes by the importance of clean masters becomes paramount. By balancing environmental parameters during incubation, especially temperature, the mycelium is favored.

Once the jars have been inoculated, store them on shelves in a semisterile room whose temperature can be easily controlled. Light and humidity are not important at this time as a sealed jar should retain its moisture. Air circulation is important only if the incubating jars overheat. In packing a room tightly with spawn jars, overheating is a danger. Many thermophilic fungi that are inactive at room temperature flourish at temperatures too high for mushrooms. Herein lies one of the major problems with rooms having a high density of incubating spawn jars. If possible, some provisions should be made to prevent temperature stratification in the incubation environment.

The major factor influencing the rate of mycelial growth is temperature. For every species there is an optimum temperature at which the rate of mycelial growth is maximized. As a general rule, the best temperature for vegetative (spawn) growth is several degrees higher than the one most stimulatory for fruiting. In Chapter XI, these optimum temperatures and other parameters are listed for more than a dozen cultivated mushrooms. Yet another factor affecting both growth rate and susceptibility to contamination is moisture content, a subject covered in the previous chapter on grain culture.

Every day or so inspect the jars and check for the slightest sign of contamination. The most common are the green molds *Penicillium* and *Aspergillus*. If contamination is detected, seal the lid and remove the infected culture from the laboratory and growing facility. If a jar is suspected to be contaminated, mark it for future inspection.

Not all discolorations of the grain are *de facto* contaminants. Mushroom mycelium exudes a yellowish liquid metabolite that collects as droplets around the myceliated kernels of grain. As the culture ages and the kernels are digested, more metabolic wastes are secreted. Although this secretion is mostly composed of alcohols (ethanol and acetone), in time acids are produced that cause the lowering of the substrate's pH. These waste products are favorable to the propagation of bacteria that thrive in aqueous environments. Small amounts of this fluid do not endanger the culture; excessive waste fluids (where the culture takes on a yellowish hue) are definitely detrimental. If this fluid collects in quantities, the mycelium sickens and eventually dies in its own wastes. Such excessive "sweating" is indicative of one or a combination of the following conditions:

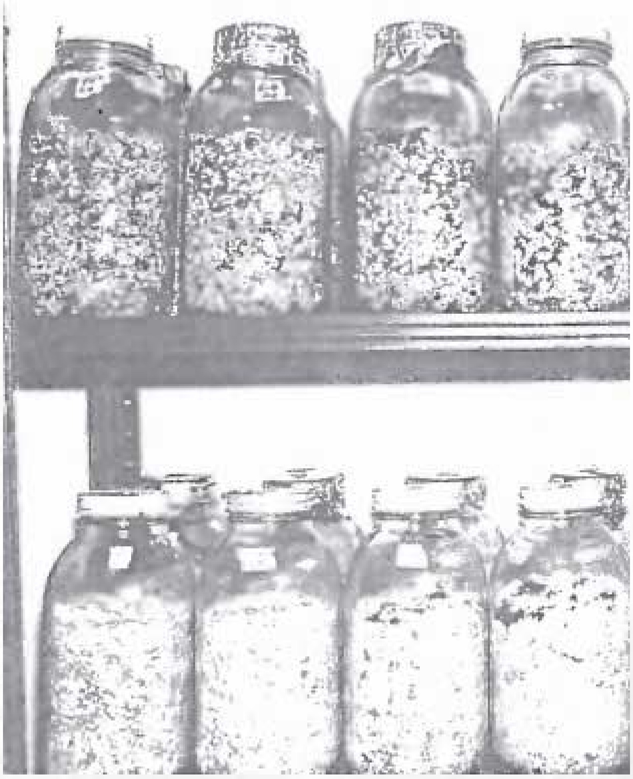

Figure 61 - Half gallon jars of spawn incubating in semisterile environment.

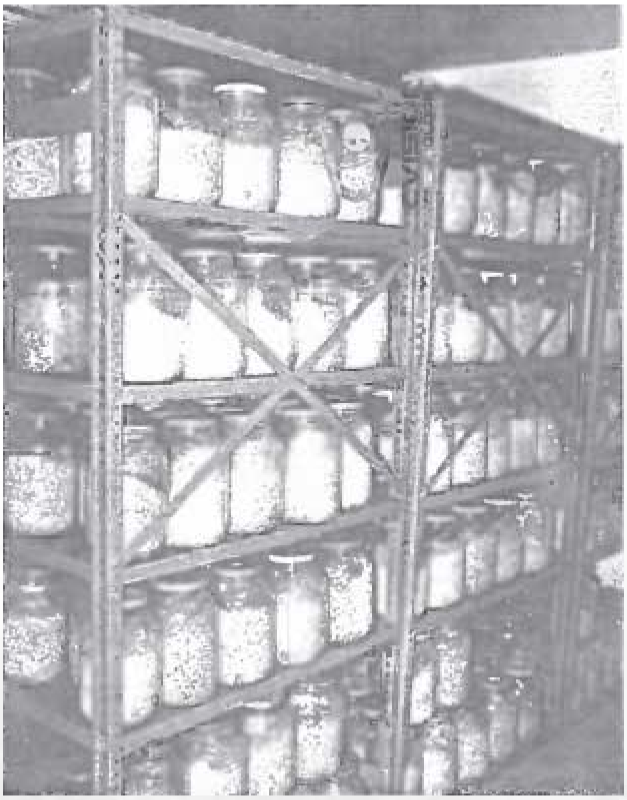

Figure 62 - Gallon jars incubating in semisterile environment.

1. Incubation at too high a temperature for the species being cultivated. Note that the temperature within a spawn jar is several degrees higher than the surrounding air temperature.
2. Over-aging of the cultures; too lengthy an incubation period.
3. Lack of gas exchange, encouraging anaerobic contamination.

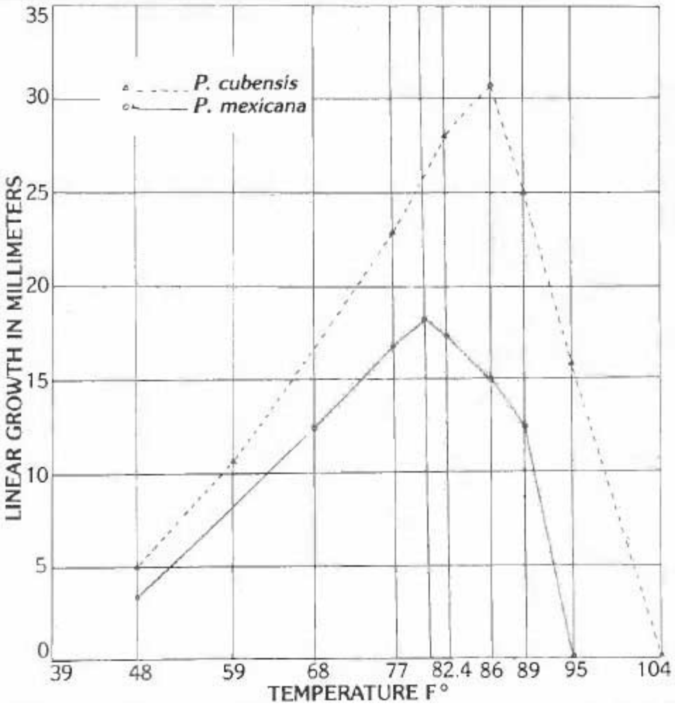

Figure 63 - Chart showing influence of temperature on the rate of mycelial growth in *Psilocybe cubensis* and *Psilocybe mexicana*. (Adapted from Ames *et al.*, 1958).

Contaminated jars should be sterilized on a weekly basis. Do not dig out moldy cultures unless they have been autoclaved or if the identity of the contaminant in question is known to be benign. Several contaminants in mushroom culture are pathogenic to humans, causing a variety of skin diseases and respiratory ailments. (See Chapter XIII on the contaminants of mushroom culture). Autoclave contaminated jars for 30 minutes at 15 psi and clean soon after. Many autoclaved jars, once contaminated, re-contaminate within only a few days if their contents have been not discarded.

If an exceptionally high contamination rate persists, review the possible sources of contamination, particularly the quality of the master spawn cultures (such as the moisture content of the grain) and the general hygiene of the immediate environment. Once the cultures have grown through with mycelium and are of known purity, this spawn can be used to inoculate bulk substrates or can be layed out in trays, cased and fruited.

IV. THE MUSHROOM GROWING ROOM

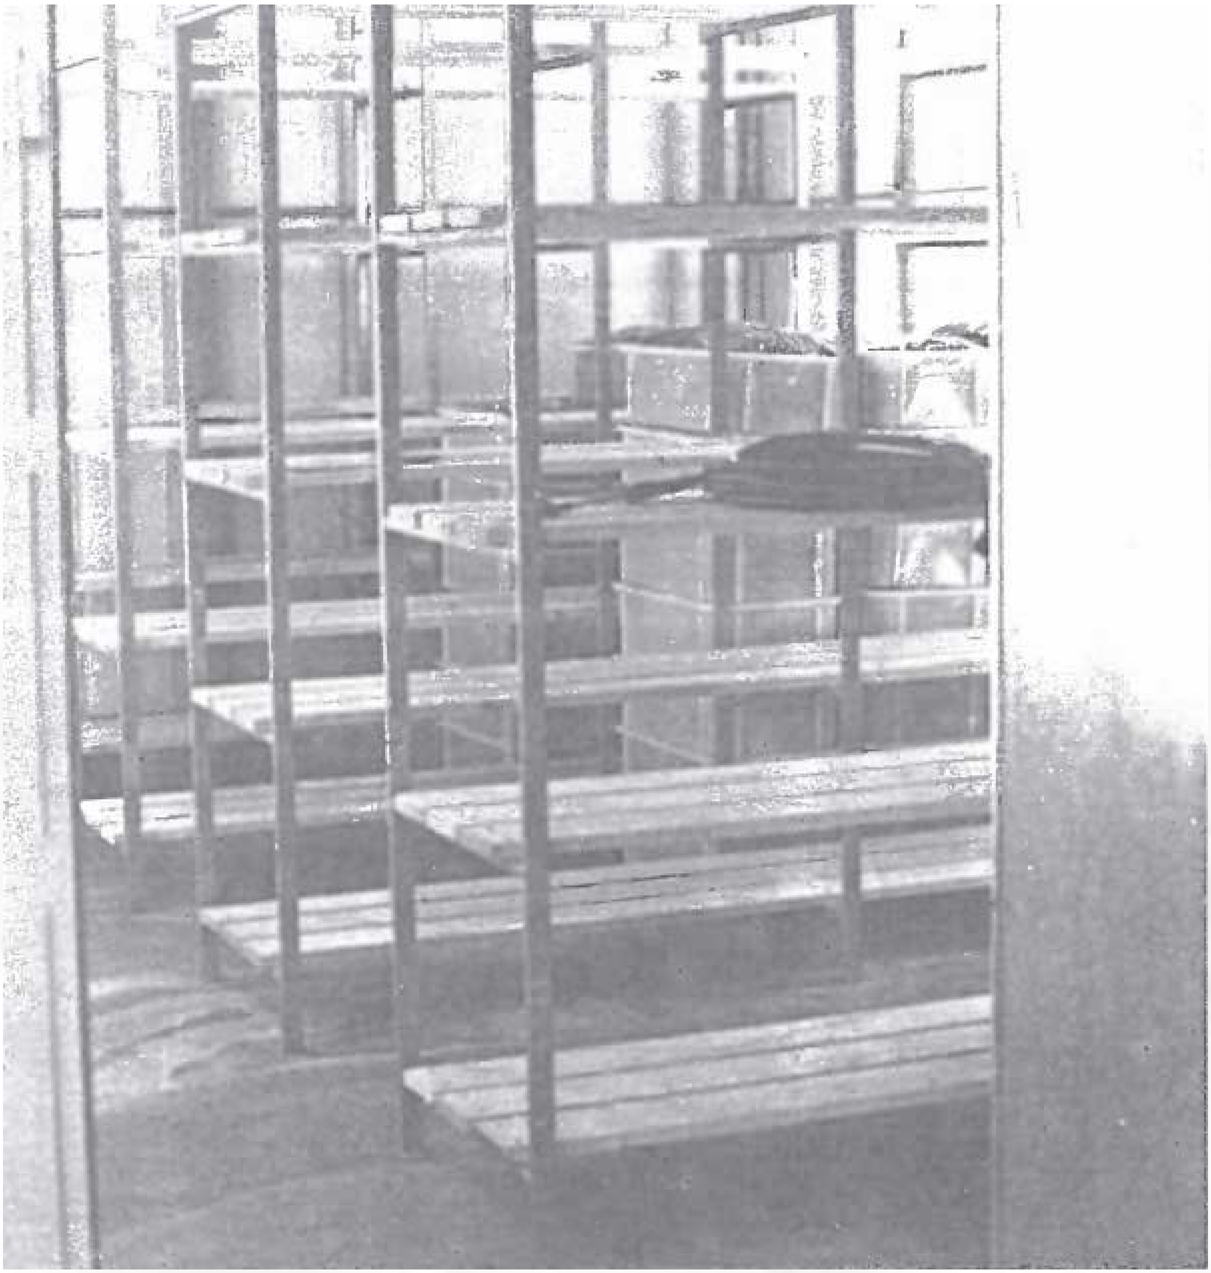

Figure 64 - Small growing room utilizing shelves.

Structure and Growing Systems

Mushroom cultivation was originally an outdoor activity dependent on seasonal conditions. Substrates were prepared and spawned when outside temperatures and humidify were favorable. This is still the case with many small scale growers of *Volvariella volvacea*, *Stropharia rugoso-annulata* and *Lentinus edodes*.

Agaricus cultivators grow solely indoors. Initially, *Agaricus* growers in France adapted the limestone mines near Paris and in the Loire valley to meet the necessary cultural requirements of that mushroom. These "caves" were well suited because of their constant temperature and high humidity, essential requirements for mushroom growing. When the first houses designed solely for mushrooms were built in the early 1900's, temperature and humidify control were the main factors guiding their construction.

For the home cultivator, a growing room should be scaled according to the scope of the project. The following guidelines supply the information to properly design and equip a growing chamber, basement growing room, outdoor shed or garage.

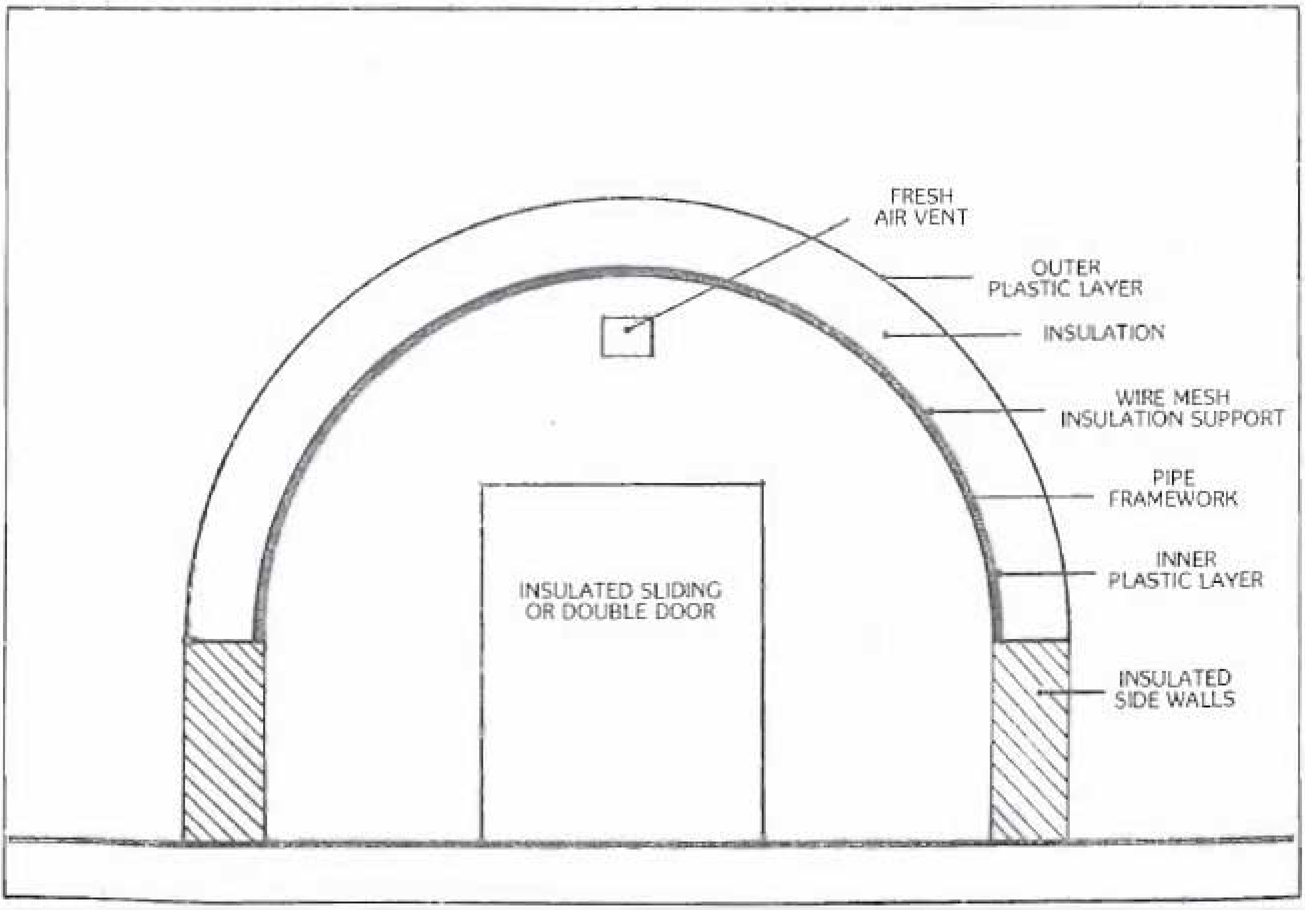

Figure 65 - An insulated plastic greenhouse suitable for mushroom growing.

Structure

The basic structure of a mushroom house is made of wood or concrete block with a cement floor. Because water collects on the floor during the cropping cycle, provisions should be made for drainage. A wood floor can be covered with a heavy gauge plastic. Interior walls, ceilings and exposed wood surfaces should be treated with a marine enamel or epoxy-plastic based paint. A white color enhances lighting and exposes any contaminating molds.

The most important feature of a growing room is the ability to maintain a constant temperature. In this respect, insulation is critical. The walls should be insulated with R=11 or R=9 and the ceiling with R=30 insulating materials. Fiberglass or styrofoam work well but should be protected from the high humidities of the growing room to prevent water from saturating them. For this purpose, a 2-4 mil. plastic vapor barrier is placed between the insulation and the interior wall.

An airtight room is an essential feature of the mushroom growing environment, preventing insects and spores from entering as well as giving the cultivator full control over the fresh air supply. During the construction or modification of the room, all cracks, seams and joints should be carefully sealed.

Many growers modify existing rooms in their own homes or basements. The main consideration for this approach is to protect the house structure (normally wood) from water damage and to make the growing chamber airtight. This is accomplished by plastic sheets stapled or taped to the walls, ceiling and floor, with the seams and adjoining pieces well sealed. If the room is adjacent to an exterior house wall where a wide temperature fluctuation occurs, condensation may form between the plastic and the wall. Within these larger structures, a plastic tent or envelope room can be constructed. Such a structure can be framed with 2" PVC pipe. The pipe forms a box frame to which the plastic is attached. This type of growing room should not need insulation because of the air buffer between it and the larger room.

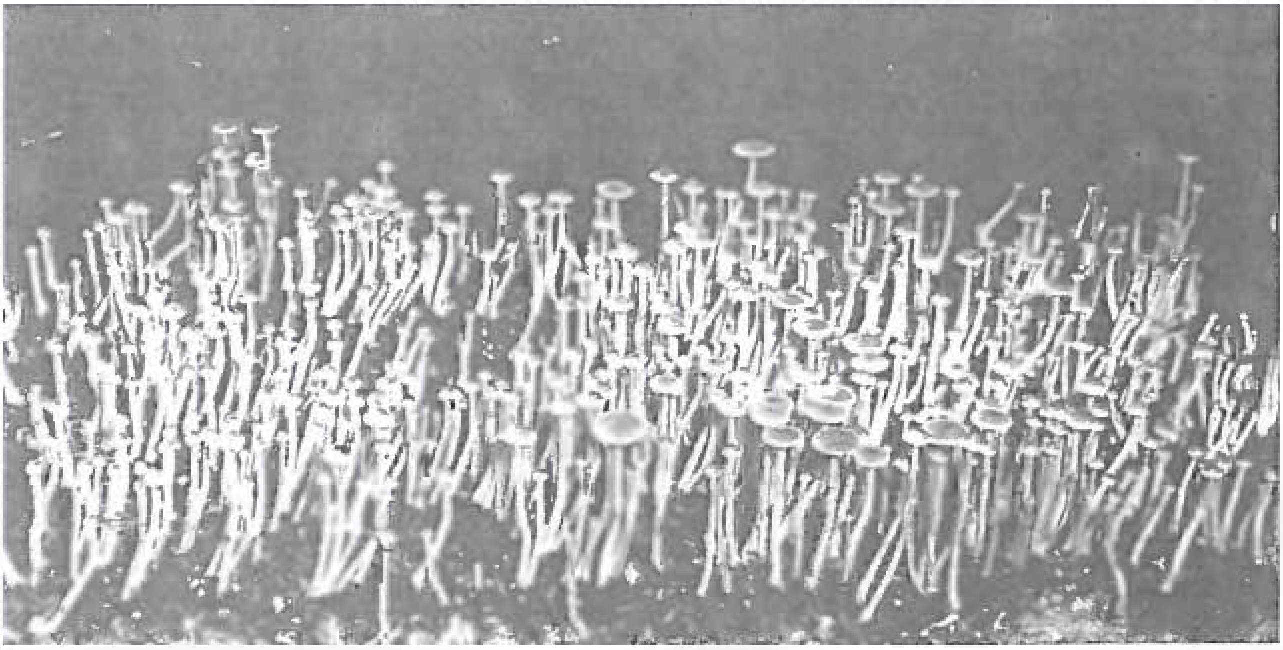

Figure 66 - Cultivation of mushrooms in an aquarium.

Porches, basements and garages can all be modified in the ways just mentioned. These areas can also be used with little additional change if the climate of the region is compatible with the mushroom species being grown. For example, *Lentinus edodes*, the shiitake mushroom, readily fruits at 50-60 degrees F. in a garage or basement environment.

The newest innovation in mushroom growing structures is the insulated plastic greenhouse. The framework is made of galvanized metal pipe bent into a semi-circular shape and mounted at ground level or on a 3.5 foot side wall. The ends of the walls and the doors are framed with wood. Heavy plastic (5-6 mil) is stretched over the metal framework to form the inner skin of the room. A layer of wire mesh is laid over the plastic and functions to hold 3-6 inches of fiberglass insulation in place. A second plastic sheet covers the insulation and protects it from the weather. The plastic should be stretched tight and anchored well. These layers are held in place by structural cable spanning the top and secured at each side. (See Figure 65). This type of structure, plastic coverings and plastic fasteners are all available at nursery supply companies. Remember, the design of a mushroom growing room strives to minimize heat gain and loss.

For people with little or no available space, "mini-culture" in small environmental chambers may be the most appropriate way to grow mushrooms. Styrofoam ice chests, aquariums and plastic lined wood or cardboard boxes can all be used successfully. Because of the small volume of substrates contained in one of these chambers, air exchange requirements are minimal. Usually, enough air is exchanged in opening the chamber for a daily or twice daily misting. Clear, perforated plastic covering the opening maintains the necessary humidity and the heat can be supplied by the outer room. Larger chambers can be equipped with heating coils or a light bulb on a rheostat. Both should be mounted at the base of the chamber. Mini-culture is an excellent and proven way to grow small quantities of mushrooms for those not having the time or resources to erect larger, more controlled environments.

Shelves

The most common indoor cultivation method is the shelf system. In this system, shelves form a platform upon which the mushroom growing substrate is placed. The shelf framework consists of upright posts with cross bars at each level to support the shelf boards. This fixed framework is constructed of wood or non-corrosive tubular metal. The shelves should be a preservative-treated softwood. The bottom boards are commonly six inches wide with one inch spaces between them. Side boards are 6-8 inches high depending on the depth of fill. A standardized design is shown in Figure 67. All shelf boards are placed unattached thereby allowing easy filling, emptying and cleaning. *Agaricus* growers fill the shelf house from the bottom up. The shelf boards are stacked at the side of the room and put into place after each level is completed.

The center pole design (shown in Figure 67) is a simple variation that is less restrictive and ideally suited for growing in plastic bags. Another alternative is to use metal storage shelves. These units come in a variety of widths and lengths and have the distinct advantage of being impervious to disease growth. Their use is particularly appropriate for cropping on sterilized substrates in small containers.

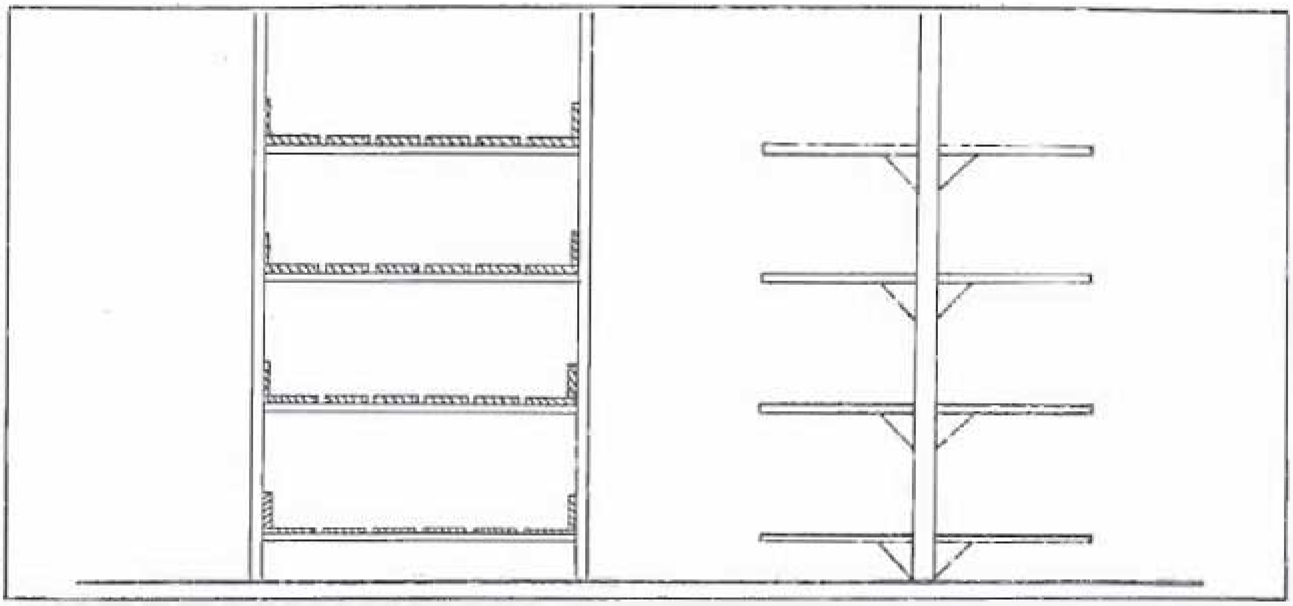

Figure 67 - Double support and centerpole design shelves. Both shelves are firmly attached to the floor and the ceiling.

Trays

The development of the tray system in *Agaricus* culture is largely due to the work of Dr. James Sinden. In direct contrast to anchored static shelves, trays are individual cropping units that have the distinct advantage of being mobile. This mobility has made mechanization of commercial cultivation possible. Automated tray lines are capable of filling, spawning and casing in less time, with fewer people and with better quality management.

Whereas in the shelf system all stages of the cultural cycle occur in the same room, the tray system utilizes a separate room for Phase II composting. On a commercial tray farm only the Phase II room is equipped for steaming and high velocity air movement.

A Sinden system tray design is shown in Figure 68. This tray has short legs in the up-position. During Phase II and spawn running these trays are stacked 15 cm. apart and tightly placed within the room to fully utilize compost heat. After casing, a wooden spacer is inserted between the trays for crop management, increasing the space to 25-35 cm. Other tray designs have longer legs in the down position and higher sideboards to accommodate more compost. These trays are similarly spaced throughout the cycle. In the growing room, trays can be stacked 3-6 high in evenly spaced rows. The main considerations for the home cultivator are that the trays can be easily handled and that they fit the floor space of the room.

The real advantage of the tray system is the ability to fill, spawn and case single units in an unrestricted environment outside the actual growing room. The tray system also gives the cultivator more control over hygiene and improves the efficiency of the operation. Moving trays from room to room does present contamination possibilities; therefore, the operations room must also be clean and fly tight for spawning and casing. Because there is no fixed framework in the growing room, it is easily cleaned and disinfected.

The tray method has many distinct advantages over the mason jar method for home cultivators preferring to fruit mushrooms on sterilized grain. These advantages are: fewer necessary spawn containers; fewer aborts due to uncontrolled primordia formation between the glass/grain interface; ease of picking and watering; better ratio of surface area to grain depth; and comparatively higher yields on the first and second flushes. An inexpensive tray is the 3-4 inch deep plant propagation flat commonly sold for staring seedlings. An example of such a tray is pictured in Fig. 69.

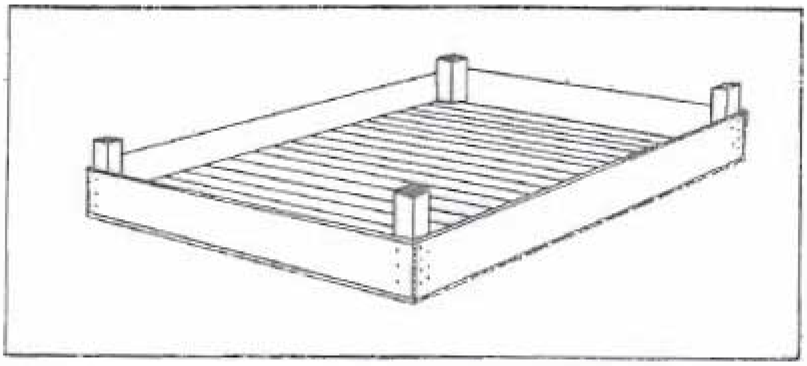

Figure 68 - Sinden system tray. The tray can be constructed of 1 x 6 or 2 x 6 inch lumber for bottom and side boards and 4 x 4 inch corner posts. (1 x 8 or 2 x 8 inch side boards are suggested for deep fills).

Environmental Control Systems

The mushroom growing room is designed to maintain a selected temperature range at high relative humidities. This is accomplished through adequate insulation and an environmental control system with provisions for heating, cooling, humidification and air handling.

In the original shelf houses the environment was controlled by a combination of active and passive means. Fresh air was introduced through adjustable vents running the length of the ceiling above the center aisle. Heat was supplied by a hot water pipe along the side walls, a foot above ground level. And humidity was controlled by similarly placed piping carrying live steam. The warm air rising up the walls in combination with the cool fresh air falling down the center aisle created convection currents for air circulation. Although no longer in general use by *Agaricus* growers, air movement based on convection can be similarly designed for small growth chambers where mechanical means are inappropriate.

Present day *Agaricus* farms integrate heating, cooling and humidification equipment into the air handling system and in this way are able to achieve balanced conditions throughout the growing room. Figure 73 shows an example of this type of system.

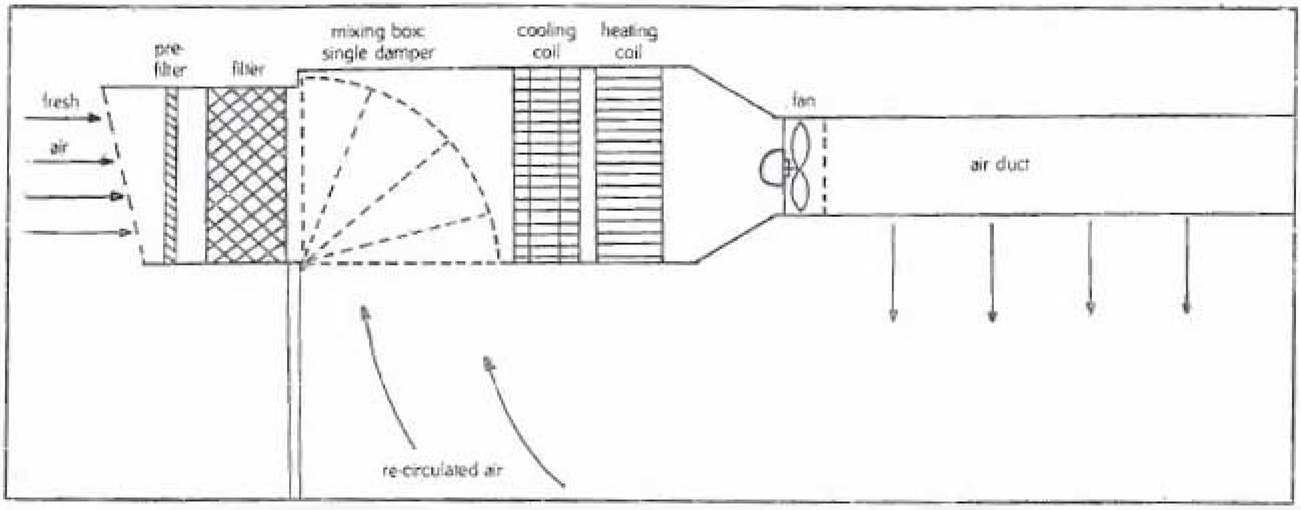

Figure 73 - Standard ventilation system used by *Agaricus* growers. (After Vedder)

Fresh Air

Filtered fresh air enters the room at the mixing box where it is proportionally regulated with recirculated air by a single damper. To prevent leakage during spawn running and pre-pinning, the damper fits tightly against the fresh air inlet. This allows full recirculation of room air to maintain even conditions, thereby counteracting temperature and CO_2 stratification. When fresh air is required, the damper can be adjusted to any setting, including complete closure of the recirculation inlet. As fresh air is introduced, room air is displaced and evacuated through an exhaust vent or cracks around the door. Because fresh air is generally at a different temperature than the one required for the growing room, it must be used judiciously in order to avoid disrupting the growing room environment or overworking the heating, cooling and humidication systems. By properly mixing the fresh outside air and the room air, a balance can be achieved and optimum conditions for mushroom growth prevail.

Fresh air serves many important functions in mushroom culture, primarily by supplying oxygen to the growing mushrooms and carrying away CO_2. Fresh air also facilitates moisture evaporation from the cropping surface. To determine the exact amount of air needed in a given situation, a knowledge of the CO_2 requirements for the species being grown is necessary. (See Chapter XI on growing parameters for various species). The fresh air can also be measured in terms of air changes per hour, a common way mushroom growers size the fan in the growing room.

Fans

Axial flow and centrifugal fans are the two most commonly used in mushroom houses. Both fans operate well against high static pressure, which is a measure of the resistance to forced air. Static pressure is measured in inches of water gauge - the height in inches to which the pressure lifts a column of water - and is caused by filters, heating and cooling coils or other obstructions to the free flow of air. Fans are rated in terms of their output, a measurement of cubic feet per minute (CFM) at varying static pressures (S.P.). When choosing a fan, these two factors must be considered for proper sizing.

Agaricus growers use fans capable of 4-6 changes per hour, or 0.5 CFM per square foot of cropping surface. For most small growing rooms, an axial flow fan, 6-10 inches in diameter and delivering between 100-500 CFM at up to 0.5 inches of static pressure, should meet general growing requirements. The addition of a variable speed motor control allows precise air velocity adjustment during different phases of the cultural cycle. This is especially important if the static pressure increases from spore build-up in the filter. A convenient method of testing air circulation is by blowing a small amount of cigarette smoke onto the cropping surface: the smoke should dissipate within twenty seconds.

The minimum fan output for a given room can be determined through knowledge of the air changes per hour required by the mushroom species. First calculate the volume of the room in cubic feet (height x width x length) and substract from this the volume occupied by trays, shelves, substrate and other fixtures. This figure is the free air space in the room. By dividing the CFM (cubic feet per minute) of the fan into the cubic feet of free air space, the time in minutes it takes for one air change is determined. This number is then divided into 60 minutes to calculate the air changes per hour. Another method to determine the CFM of the fan needed is described below.

Let X = the desired net CFM of a high pressure fan pushing through a filter.
Let Y = the total cubic feet of FREE air space in the growing room.
A maximum number of air exchanges/hour for *Agaricus brunnescens* is 4-6.
A maximum number of air exchanges/hour for *Psilocybe cubensis* is 2-3.

Therefore:

$$4 \text{ air exchanges/hour} * Y = 60 \text{ minutes} * X$$

$$\frac{4 * Y}{60 \text{ minutes}} = X = \text{necessary net CFM of fan}$$

$$\frac{Y}{15} = X$$

Example: If the growing environment measures 8 ft. x 8 ft. x 15 ft., the total volume would be 960 cu. ft. if the beds occupy 160 cu. ft. the net volume of free air space would be Y = 800 cu. ft. Therefore:

$$\frac{4 * 800 \text{ cu. ft.}}{60 \text{ min.}} = X$$

$$\frac{4 * 3200 \text{ cubic feet}}{60 \text{ min.}} = X$$

$$53.3 \text{ CFM} = X$$

Another factor of importance for proper ventilation is the air-to-bed ratio, which is the cubic feet of free air space divided by square feet of cropping surface. *Agaricus* growers have found a ratio of 5:1 to be optimum and this serves as a useful guideline when cropping other mushrooms on bulk substrates. The reason this ratio is so important is that increased amounts of substrate can generate heat and carbon dioxide beyond the handling capacity of the ventilation system. A large free air space acts to buffer these changes. Ostensibly, a ventilation system could be matched with a room having a 3:1 air-to-bed ratio, but it would have to move such a volume of air that evaporation off the sensitive cropping surface would be uncontrollable and excessive. Growing mushrooms on thin layers of grain (1-3 inches), however, produces less CO_2 than growing on 8 inches of compost and consequently would emit a lower air-to-bed ratio.

Air Ducting

Ducting for the air system is standard inflatable polyethylene tubing, sized to conform to the fan diameter. If ducting is not available in the correct size, PVC pipe can be substituted. Figures 74, 75 and 76 show different air distribution arrangements and their flow patterns. The ducts run the length of the room at ceiling level. One is centrally mounted and discharges towards both walls or directly down the center aisle, whereas the other is wall mounted and is directed across the width of the room.

The outlet holes in the duct are designed to discharge air at such a velocity that the airstream reaches the walls and passes down to the floor without directly hitting the top containers. The holes are spaced so that the boundaries of the adjacent jets meet just before reaching the wall or floor. This effectively eliminates dead-air pockets. To size and space the outlet holes exactly, two guidelines are used:

1. The total surface area of the holes is equal to the cross section of the duct. (The area of a circle is $^{22}/_{7}$ times the radius squared, $A = \prod(r)^2$).
2. The space between the holes is equal to a quarter of the distance between the duct and the wall or floor.

The discharge of air at velocities sufficient to draw in surrounding room air is called entrainment, a phenomenon that enhances the capacity of the air circulation system. A flow pattern of even air is then reached that directly benefits the growing mushrooms. The entrainment of air is the goal of air management in the growing room.

Filters

Fresh air filters are an important part of the ventilation system and contribute to the health of the crop. Their function is to screen out atmospheric dust particles like smoke, silica, soot and decayed biological matter. Atmospheric dust also contains spores, bacteria and plant pollen, some of which are detrimental to mushroom culture. Furthermore, spores and microorganisms originating within the cropping room can also be spread by air movement. To counteract this danger, some mushroom farms filter recirculated air as well.

Agaricus growers commonly use high efficiency, extended surface, dry filters. These filters are of pleated or deep fold design which gives them much more surface area than their frame opening. They filter out 0.3 micron particles with 90-95% efficiency and 5.0 micron particles with an efficiency of 99% at an initial resistance of 0.10 to 0.50 inches of static pressure.

High efficiency particulate air (HEPA) filters are even more efficient than those just described and are cost effective for the home cultivator. They screen out particulates down to 0.1-0.3 microns with a rated 99.96% to 99.99% efficiency and have a resistance of .75-1.00 inches of static pressure. HEPA filters are made of a variety of materials, depending on their intended application. Most HEPA filters operate in environments of up to 80% humidity without disintegration. Special "waterproof" filters operable in 100% humidify environments can also be purchased at little or no extra expense. These "waterproof" filters are especially appropriate for use with systems that push recirculated air through the filter. This type of system is illustrated in Figure 77. To protect the filters and prolong their usefulness, a one inch prefilter of open celled foam or fiberglass (of the furnace type) is installed to remove large particulates.

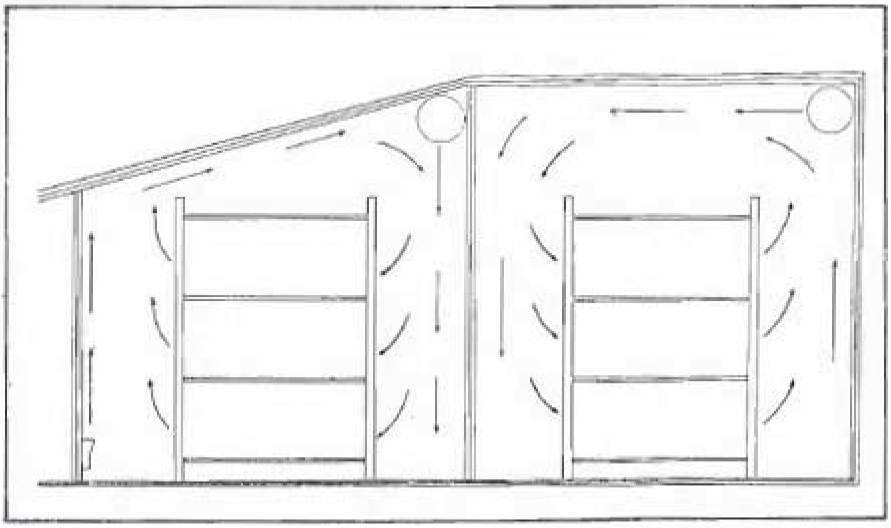

Figure 76 - Wall mounted duct directing airflow across the width or down the sidewall of the room.

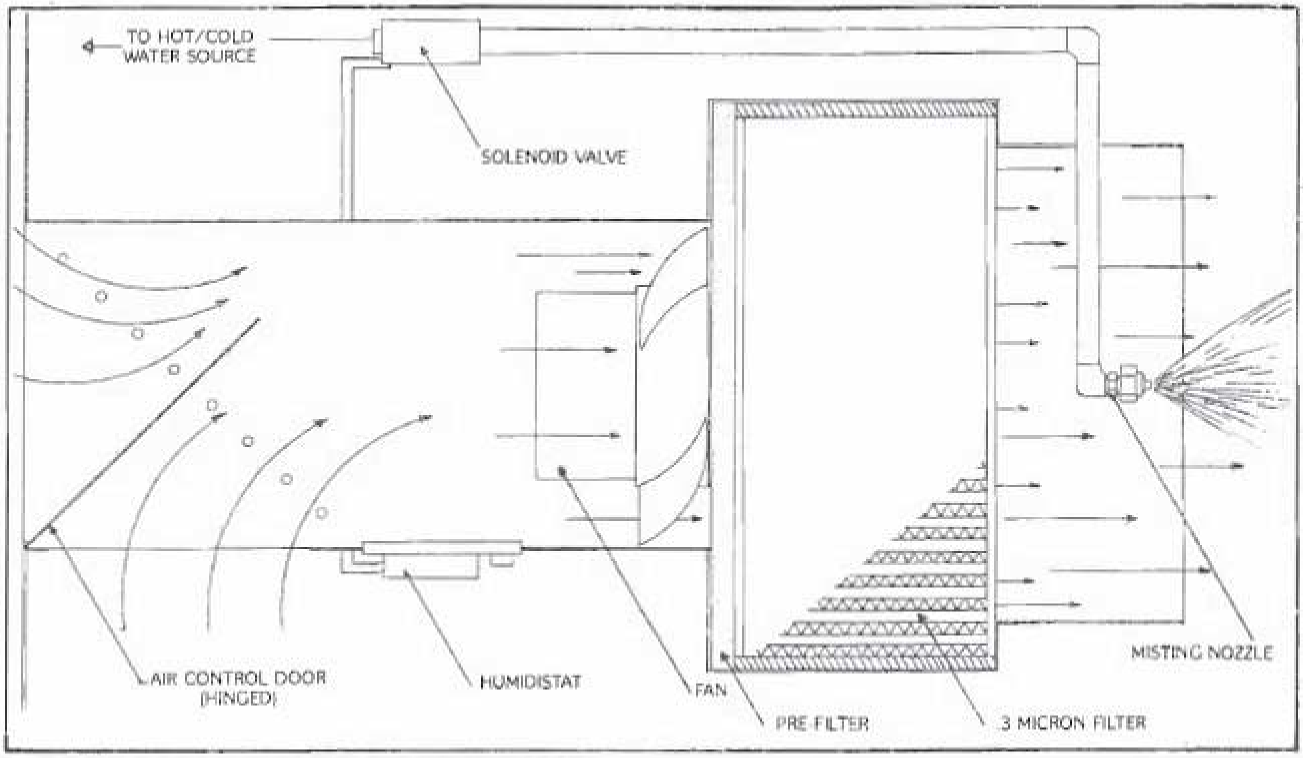

Figure 77 - Schematic of mixing box and controlled recirculation system in the growing room.

Exhaust Vents

Exhaust vents are designed to relieve overpressure within the growing room caused by the introduction of fresh air. Without an exit for the air, a back pressure is created that increases resistance and reduces the CFM of the fan. Small rooms operating with low fresh air requirements can forgo special exhaust vents and allow the air to escape around the seals of the room entrance, in effect creating a positive pressure environment. Positive pressure within a room can also be created by undersizing the exhaust vent, which should be no larger than half the size of the fresh air inlet. Free swinging dampers operating on overpressure are widely employed in the mushroom growing industry. The outlet should be screened from the inside to prevent the entry of flies.

Heating

Heating systems for cropping rooms can be based on either dry heat or live steam. Dry heat refers to a heating source that lowers the moisture content of the air as it raises the temperature. These systems utilize either hot water or steam circulating through a closed system of pipes or radiator coils. Heating systems can also be simple resistance coils or baseboard electric heaters. Heat coils are placed in the air circulation system ahead of the fan as shown in Figure 73. Small portable space heaters can also be attached to the mixing box or placed on the wall under it. Otherwise, baseboard heaters can be installed along the length of the side walls and matched with the air circulation design shown in Figure 75.

Heat supplied by live steam has the advantage of keeping the humidity high while raising the temperature of the room. If regulated correctly, steam can maintain the temperature and relative humidity within the required ranges without drawing upon other sources. Nevertheless, a backup heat source is advantageous in the event humidity levels become too high. For steam heat to function properly it should be controlled volumetrically by adjusting a hand valve (rather than simply on and off). Vaporizers well suited for small growing rooms are available in varying capacities, and can be fitted with a duct that connects with the air system downstream from the fan and filter.

To avoid high energy consumption and the expense associated with equipment purchase, operation and maintenance, the growing room should be designed to take full advantage of the heat generating capabilities of the substrate. This is done by matching the air-to-bed ratio to the type of substrate. Growing on thin layers of grain can be done with a ratio of 4:1 (or less) whereas compost demands 5:1. The influence of the outside climate and its capacity for cooling the growing room should also be considered. All these factors must be evaluated before a growing environment with efficient temperature control can be constructed.

Cooling

Commercial farms use cooling coils with cold water or glycol circulating through them. The coils are placed before the fan as shown in Figure 73 and are supplied by a central chiller or underground tank and well. Other systems use home or industrial refrigeration or air conditioning units that operate with a compressor and liquid coolant filled coils. These units are positioned to draw in recirculated as well as fresh air. All these systems share the common trait of drawing warm air over a colder surface. In doing so, moisture condenses out of the air and in effect dehumidifies the room.

The oldest and most widely practiced method of cooling is through the use of fresh air. Cooling with fresh air depends upon the weather and the temperature requirements of the species being cultivated. However, its use is the most practical means available to the home cultivator. In climates with high daily temperatures, fresh air can be shut off or reduced to a minimum during the day and then fully opened at night when temperatures are at their lowest.

Humidification

Most mushroom growers use steam as the principal means of humidification. The steam is injected into the air system duct on the downstream side of the fan and filter. Household vaporizers are well suited for small growing rooms. They are available in various capacities and can be fitted with a duct running to the air system. The vaporizer can also be positioned under the mixing box for steam uptake with the recirculated air. Keep in mind that cold fresh air has much less capacity for moisture absorption and therefore does not mix well with large volumes of steam.

Another method of humidification uses atomizing nozzles to project a fine mist into the air stream. Large systems have a separate mixing chamber with nozzles mounted to spray the passing air. In a small room, a single nozzle can be mounted in the center of the duct and aimed to flow with the air as it exits the fan. (See Figure 77). An appropriately sized nozzle emits 0.5-1.0 gallons per hour at 20-30 psi. To prevent the nozzle from plugging up, filters should be incorporated in the water supply line.

In a third method, air passes through a coarse mesh absorbant material that is saturated with water. This system is widely used for cooling at nurseries. It is similar in principle to a "swamp cooler". In this system (and the water atomizing system), the temperature of the supply water can be regulated to provide a measure of heating and cooling. Both systems also produce some free water so provisions must be made for drainage.

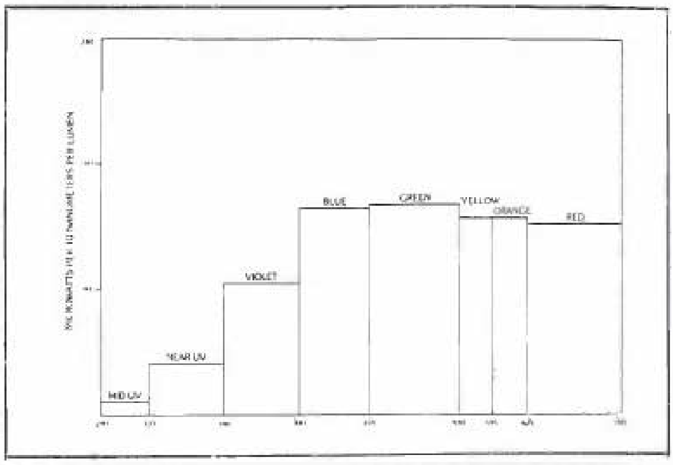
Thermostats and Humidistats

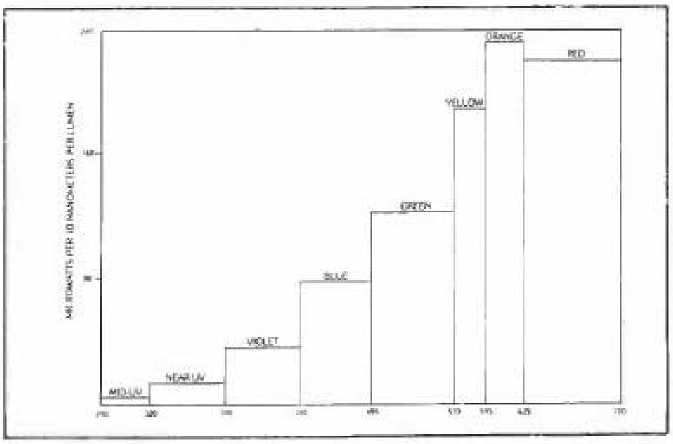
In general, thermostats and humidistats are designed to open and close valves in response to pre-set temperature or humidity limits. The instrument sensors are placed in a moving air stream representative of room conditions, usually in or near the recirculation inlet. Because these instruments are programmed for either on or off, heat and humidity come in surges. Often this results in uneven and fluctuating conditions within the room.

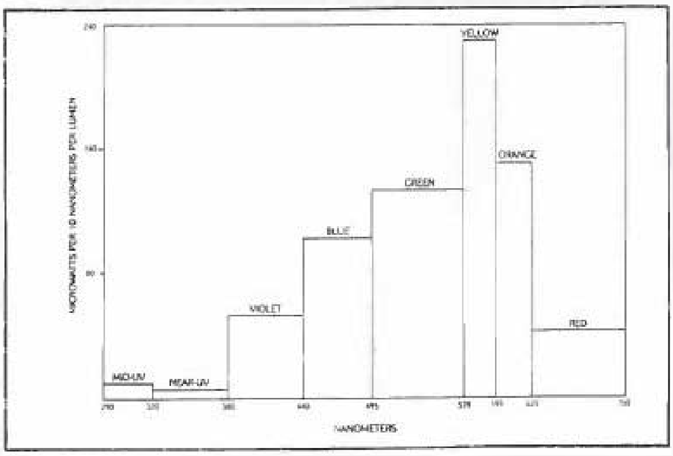
The ideal in environmental control is to supply just enough heat and humidity to make up for losses from the room and to compensate for differences in the fresh air. Modulating thermostats do this by supplying heat continuously in proportion to the deviation from the desired temperature. Positive control of this sort can also be accomplished by hand valves, alone or in conjunction with on/off instruments. Supply line volume is thereby regulated in order to attain an equilibrium. With a thermostat, this means keeping the supply volume just below the cut-off point.

Lighting

Many cultivated mushrooms require light for pinhead initiation and proper development of the fruitbody. In fact, such phototropic mushrooms actually twist and turn towards a light source, especially if it is dim and distant in an otherwise darkened room. Consequently, it is important to equip the growing room with a lighting system that provides even illumination to all areas and levels.







Figures 78, 79 & 80 - Charts showing the proportions of spectra in incandescent, fluorescent and natural lighting.

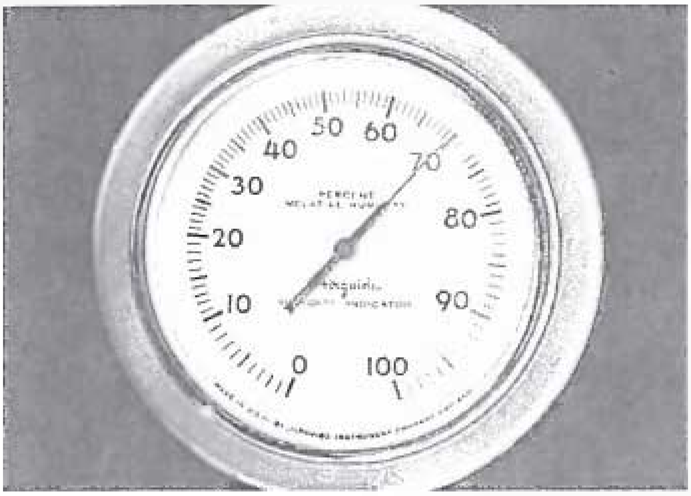


Figure 81 - An inexpensive hygrometer for measuring relative humidity.

Flourescent light fixtures are the most practical and give the broadest coverage. These fixtures should be evenly spaced and mounted vertically on the side walls of the room or horizontally on the ceiling above the center isle. An alternative is to mount the lights on the underside of each tier of shelf or tray, at least 18 inches above the cropping surface. To eliminate the heat and consequent drying action caused by the fixture ballasts, these can be removed and placed outside the room.

The best type of light tube is one which most closely resembles natural outdoor light: i.e. one that has at least 140 microwatts per 10 nanometer per lumen of blue spectra (440-495 nm). In contrast, warm-white fluorescent light has only 40-50 microwatts/nm/lum. and cool-white has 100-110 microwatts/nm/lum. Commercial lights meeting the photo-requirements of species mentioned in this book are the "Daylite 65" kind manufactured by the Durotest Corporation and having a "color temperature" of 6500°K and the "Vita-Lite" fluorescent at 5500°K. These color temperatures provide the proper amount of blue light for promoting primordia formation in *Pleurotus ostreatus*, *Psilocybe cubensis* and in other photosensitive species.

Environmental Monitoring Equipment

Few organisms are as sensitive to fluctuations in the environment as mushrooms. A matter of a few degrees in temperature or humidity can dramatically influence the progression of fruiting and affect overall yields. To adequately monitor the growing environment, quality equipment is essential for accurate readings. This equipment should include maximum-minimum thermometers to gauge temperature fluctuations and a hygrometer or a sling psychrometer for measuring humidity. Hygrometers should be periodically calibrated with a sling psychrometer to insure accuracy. Thermometers also should be checked as there are occasional irregularities. Other more advanced, expensive but not absolutely essential equipment helpful to mushroom growers include: CO_2 detectors; moisture meters; anemometers; and light measuring devices.

V. COMPOST PREPARATION

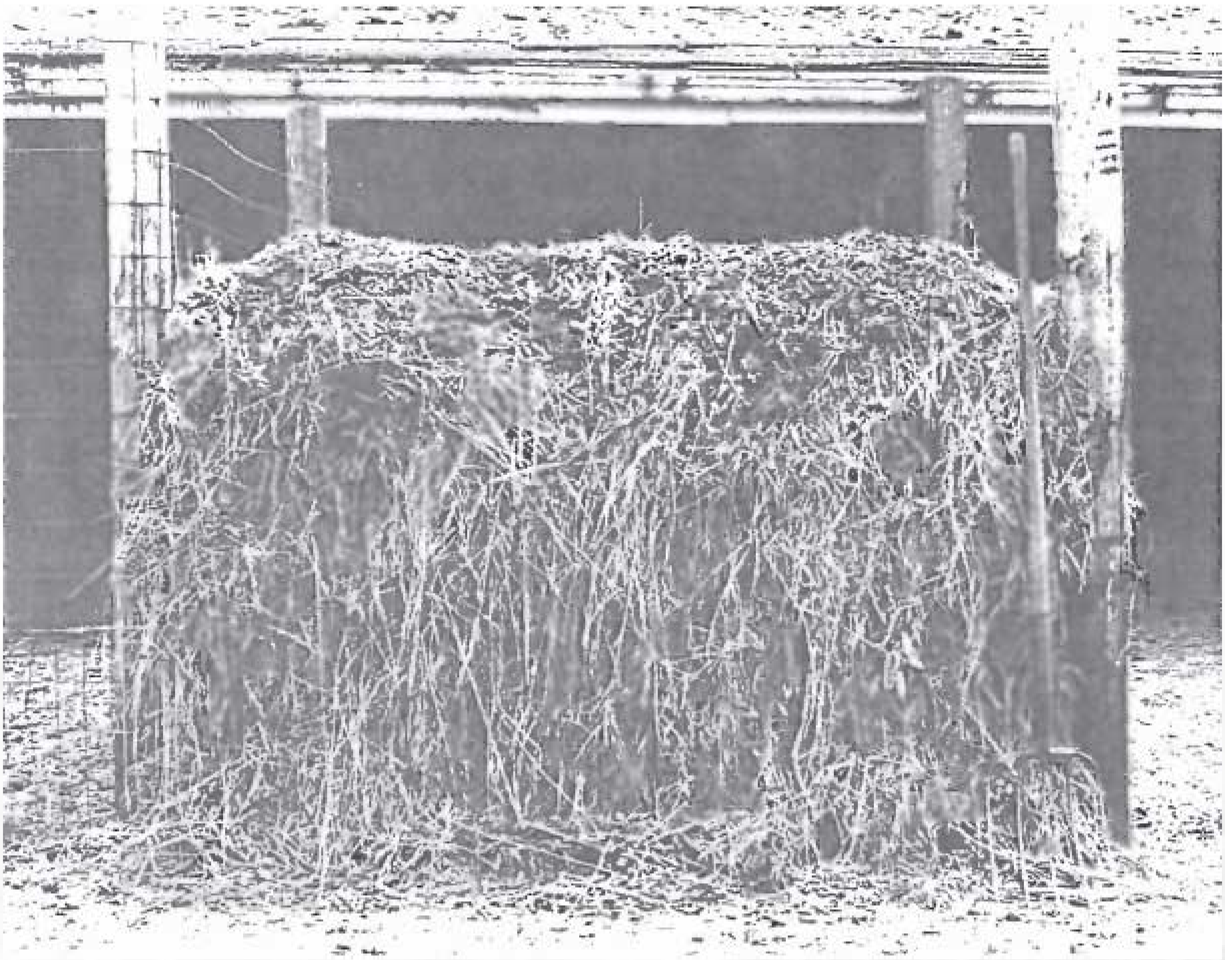

Figure 82 - Compost pile in a standard configuration.

The purpose of composting is to prepare a nutritious medium of such characteristics that the growth of mushroom mycelium is promoted to the practical exclusion of competitor organisms. Specifically this means:

1. To create a physically and chemically homogeneous substrate.
2. To create a selective substrate, one in which the mushroom mycelium thrives better than competitor microorganisms.
3. To concentrate nutrients for use by the mushroom plant and to exhaust nutrients favored by competitors.
4. To remove the heat generating capabilities of the substrate.

Mushroom mycelium grows on a wide variety of plant matter and animal manures. These materials occur naturally in various combinations and in varying stages of decomposition. Physically and chemically they are a heterogeneous mixture containing a wide variety of insects, microorganisms and nematodes. Many of these organisms directly compete with the mushroom mycelium for the available nutrients and inhibit its growth. By composting, nutrients favored by competitors gradually diminish while nutrients available to the mushroom mycelium are accumulated. With time, the substrate becomes specific for the growth of mushrooms.

The composting process is divided into two stages, commonly called Phase I and Phase II. Each stage is designed to accomplish specific ends, these being:

> **Phase I:** Termed outdoor composting, this stage involves the mixing and primary decomposition of the raw materials.
> **Phase II:** Carried out indoors in specially designed rooms, the compost is pasteurized and conditioned within strict temperature zones.

Phase I Composting

Basic Raw Materials

The basic raw material used for composting is cereal straw from wheat, rye, oat, barley and rye grass. Of these, wheat straw is preferred due to its more resilient nature. This characteristic helps provide structure to the compost. Other straw types, oat and barley in particular, tend to flatten out and waterlog, leading to anaerobic conditions within a compost pile. Rye grass straw is more resistant to decomposition, taking longer to compost. Given these factors and with proper management, all straw types can be used successfully.

Straw provides a compost with carbohydrates, the basic food stuffs of mushroom nutrition. Wheat straw is 36% cellulose, 25% pentosan and 16% lignin. Cellulose and pentosan are carbohydrates which upon break down yield simple sugars. These sugars supply the energy for microbial growth. Lignin, a highly resistant material also found in the heartwood of trees, is changed during composting to a "Nitrogen-rich-lignin-humus-complex", a source of protein. In essence, straw is a material with the structural and chemical properties ideal for making a mushroom compost.

When cereal straw is gathered from horse stables, it is called "horse manure". Although cultivators call it by this name, the material is actually 90% straw and 10% manure. This "horse manure" includes the droppings, urine and straw that has been bedding material. The quality of this material depends on the proportions of urine and droppings present, the essential elements nitrogen, phosphorous and potassium being contained therein. The reason horse manure is favored for making compost is the fact that fully 30-40% of the droppings are comprised of living microorganisms. These microorganisms accelerate the composting process, thereby giving horse manure a decided advantage over other raw materials.

Horse manure used by commercial mushroom farms generally comes from race tracks. The bedding straw is changed frequently, producing a material that is light in urine and droppings. On the other hand, boarding stables change the bedding less, generating a heavier material. If sawdust or shavings are used in place of straw for bedding, the material should be regarded as a supplement and not as a basic starting ingredient.

When horse manure is used as the basic starting ingredient, the compost is considered a "horse manure compost" whereas "synthetic compost" refers to a compost using no horse manure. Straw, sometimes mixed with hay, is the base ingredient in synthetic composts. Because straw is low in potassium and phosphorus, these elements must be provided by supplementation and for this reason chicken manure is the standard additive for synthetic composts. No composts are made exclusively of hay because of its high cost and small fiber. In fact, mushroom growers have traditionally used waste products because they are both cheap and readily available.

By themselves horse manure or straw are insufficient for producing a nutritious compost. Nor do they decompose rapidly. They must be fortified by specific materials called supplements. In order to determine how much supplementation is necessary for a given amount of horse manure or straw based synthetic, a special formula is used. This formula insures the correct proportion of initial ingredients, which largely determines the course of the composting process. The formula is based on the total nitrogen present in each ingredient as determined by the Kjeldahl method. By using this formula and certain composting principles, the carbon:nitrogen ratio for optimum microbial decompositions is assured. In turn, maximum nutritional value will be achieved.

Supplements

Composting is a process of microbial decomposition. The microbes are already present in large numbers in the compost ingredients and need only the addition of water to become active. To stimulate microbial activity and enhance their growth, nutrient supplements are added to the bulk starting materials. These supplements are designed to provide protein (nitrogen) and carbohydrates to feed the ever increasing microbial populations. Microbes can use almost any nitrogen source as long as sufficient carbohydrates are readily available to supply energy for the nitrogen utilization. Because of the tough nature of cellulose, the carbohydrates in straw are not initially usable and must come from another source. A balanced supplement is therefore highly desirable. It should contain not only nitrogen but also sufficient organic matter to supply these essential carbohydrates. For this reason certain manures and animal feed meals are widely used for composting.

The following is a list of possible compost ingredients or supplements, grouped according to nitrogen content. Their use by commercial growers is largely determined by availability and cost. This list is not all inclusive and similar materials can be substituted. (See Appendix).

Group I: High nitrogen, no organic matter

Ammonium sulfate - 21 % N
Ammonium nitrate - 26% N
Urea - 46% N
Maximum rate - 25 lbs/dry ton of starting materials

These are inorganic compounds that supply a rapid burst of ammonia. They are frequently used for initial straw softening in synthetic composts. When used, care should be taken that they are applied evenly. If ammonium sulfate is used, calcium carbonate must also be added at a rate of 3 parts $CaCO_3$ to 1, to neutralize sulfuric acid groups. These supplements are not recommended for horse manure composts.

Group II: 10-14% N

Blood Meal - 13.5% N
Fish Meal - 10.5% N

These materials consist mainly of proteins but because of their high cost are rarely used.

Group III: 3-7% N

Malt sprouts - 4% N
Brewers' grains - 3-5% N
Cottonseed meal - 6.5% N
Peanut meal - 6.5% N
Chicken manure - 3-6% N

This group contains the materials most widely used by commercial growers and is characterized by a favorable carbon:nitrogen balance. Dried chicken manure from broilers mixed with sawdust is commonly used and easy to handle.

Group IV: Low nitrogen, high carbohydrate

Grape pomace - 1.5% N
Sugar beet pulp - l.5% N
Potato pulp - 1% N
Apple pomace - 0.7% N
Molasses - 0.5% N
Cottonseed hulls - 1 % N

These materials are excellent temperature boosters and for this reason are a recommended additive to all composts. They can be added to any compost formula at a rate of 250 lbs per dry to of ingredients. Cottonseed hulls are an excellent structural additive.

Group V: Animal manures

Cow manure - 0.5 % N

Pig manure - 0.3-0.8% N

These manures are rarely used for composting, except in areas without horses or chickens. They have been used with success and should be considered supplements to a synthetic blend.

Group VI: Hay

Alfalfa - 2.0-2.5% N
Clover - 2% N

Hay is useful for boosting initial temperatures in synthetic composts. Hay contains substantial quantities of carbohydrates which help build the microbial population. Yet another advantage is the relatively high nitrogen content in alfalfa and clover. Use at a rate of 20% of the basic starting material (dry weight).

Group VII: Minerals

Gypsum - Calcium sulfate

Gypsum is an essential element for all composts. Its action, largely chemical in nature, facilitates proper composting. Its effects are:

1. To improve the physical structure of the compost by causing aggregation of colloidal particles. This produces a more granular, open structure which results in larger air spaces and improved aeration.
2. To increase the water holding capacity, while decreasing the danger of over-wetting. Loose water is bound to the straw by colloidal particles.
3. To counteract harmfully high concentrations of the elements K, Mg, P and Na should they occur, thereby preventing a greasy condition in the compost.
4. To supply the calcium necessary for mushroom metabolism.

Gypsum should be added at a rate of 50-100 lbs per dry ton of ingredients. When supplementing with chicken manure, it is advisable to use the high rate.

Limestone flour - Calcium carbonate

Limestone is used when one or more supplements are very acidic and need to be buffered. A good example of this is grape pomace, which has a pH of 4. Because it is added in large quantities, grape pomace could affect the composting process which normally occurs under alkaline conditions.

Group VIII: Starting materials

Horse manure - 0.9-1.2% N
Straw, all types - 0.5-0.7% N

Compost Formulas

The following formulas for high yield compost are commercially proven. If an ingredient is not available locally, substitute one that is. The aim of the formula is to achieve a nitrogen content of 1.5-1.7% at the initial make-up of the compost pile.

In order for these formulas to be effective, the moisture content and nitrogen content must be correct. Moisture level is determined by weighing 100 grams of the material, drying it in an oven at 200°F. for several hours, and then reweighing it. The difference is the percent moisture. Be sure the sample is representative. The nitrogen content (protein divided by 6.25) is always listed with commercial materials because they are priced according to percentage of protein. On the other hand, barnyard materials vary considerably with age. The more a material breaks down, the more nitrogen it loses. Most compost supplements are purchased dry and added dry, helping even distribution as well as enabling easy storage. It is also important that the raw materials used for composting be as fresh as possible. This insures maximum utilization of their properties. Baled straw stored for a year and kept dry is fine. If the straw has gotten wet, moldy or otherwise started to decompose, it should not be used.

Formula I

Ingredient	Wet wt.	% H_2O	Dry wt.	% N	lbs.
Horse manure	2,000	50	1,000	1.0	10
Cottonseed meal	30	10	117	6.5	8
Gypsum	50	-	50	-	-
			1,167		18
(18)÷(1,167)=1.54% N This formula makes approximately 2800 pounds of compost at a 70% moisture content.					

Formula II

Ingredient	Wet wt.	% H_2O	Dry wt.	% N	lbs.
Wheat straw	2,000	10	1,800	0.5	9
Chicken manure	2,000	20	1,600	3.00	48
Gypsum	125	-	125	-	-
			3,525		57
(57)÷(3,525)=1.62% N This formula make approximately 7,000 pounds of compost at a 71% moisture content.					

Although 7,000 pounds of compost seems like a large quantity, at a fill level of 20 pounds per sq. ft., this will fill only 350 sq. ft. of beds or trays. Keep in mind that during the composting process there is a gradual reduction in the the total volume of raw materials. Fully 20-30% of the dry matter is consumed during Phase I and another 10-15% during Phase II. **In total, approximately 40% of the dry matter is reduced by microbial and chemical processes**. This loss of potential nutrients can not be avoided and demonstrates the importance of composting no longer than necessary.

Ammonia

The production of ammonia is essential to the composting process. Just as the carbohydrates must be in a form that microbes can utilize, so must the nitrogen.

1. Ammonia supplies nitrogen for microbial use.
2. Ammonia is produced by microbes acting upon the protein contained in the supplements.

With the energy supplied by readily available carbohydrates, microbes use the ammonia to form body tissues. A microbial succession of generations is established, with each new generation decomposing the remains of the previous one. Microbial action also fixes a certain amount of the ammonia, forming the "nitrogen-rich-lignin-humus-complex". Unused ammonia volatilizes into the atmosphere. The smell of ammonia should be evident throughout Phase I, reaching a peak at filling.

Carbon:Nitrogen Ratio

The importance of a carbon:nitrogen balance cannot be underestimated. A well balanced compost holds an optimum nutritional level for microbial growth. An imbalance slows and impedes this growth. It is the compost formula that enables the grower to achieve the correct C:N balance. Because organic matter is reduced during composting, the C:N ratio gradually decreases. Approximate values are: 30:1 at make-up; 20:1 at filling; and 17:1 at spawning.

1. Over-supplementation with nitrogen results in prolonged ammonia release.

2. Over-supplementation with carbohydrates results in residual carbon compounds.

Prolonged ammonia release from an over-supplemented compost necessitates longer composting times. If composting continues too long, the physical structure and nutritional qualities are negatively affected. If the ammonia persists, the compost becomes unsuitable for mycelial growth.

Readily available carbohydrates which are not consumed by the microbes during composting can become food for competitors. It is therefore important that these compounds are no longer present when composting is finished.

Water and Air

Water is the most important component in the composting process. To a large degree water governs the level of microbial activity. In turn, this activity determines the amount of heat generated within the compost pile because the microorganisms can only take up nutrients in solution. Not only do the microorganisms need water to thrive, but they also need oxygen. Years of practice and research have established a basic relationship between the amount of water added and the aeration of the compost. **An inverse relationship exists between the amount of water and the amount of oxygen in a compost pile**.

1. Too much water = too little air
   Moisture content 75% or above.
2. Too little water = too much air
   Moisture content 67% or below.

Overwetting a compost causes the air spaces to fill with water. Oxygen is unable to penetrate, causing an anaerobic condition. In contrast, insufficient water results in a compost that is too airy. Beneficial high temperatures are never reached because the heat generated is quickly convected away.

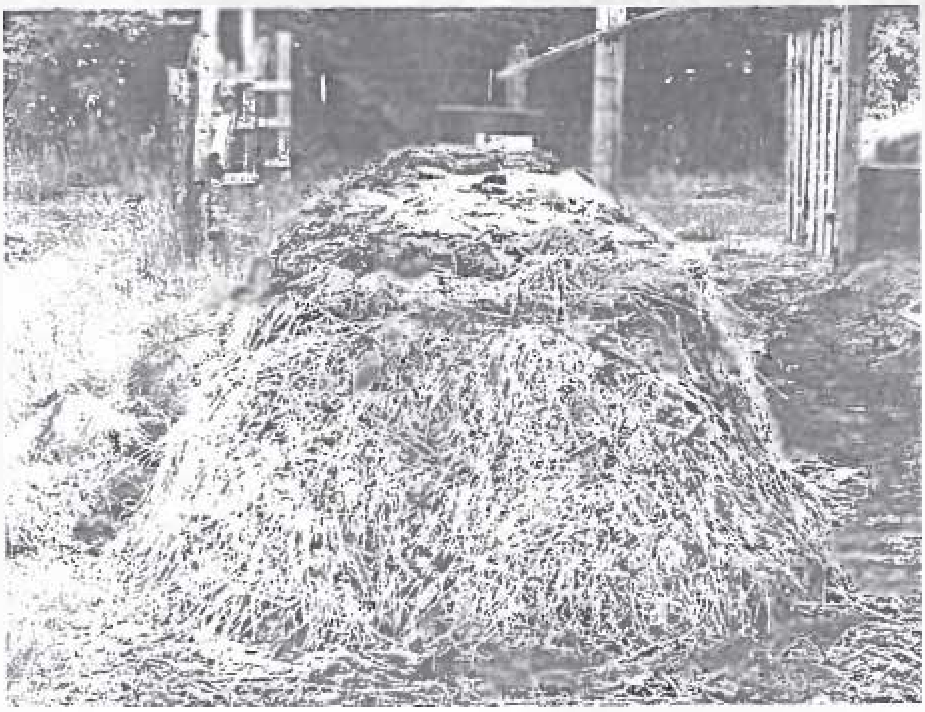

Figure 83 - Pre-wetted raw materials in a windrow.

Compost microorganisms can be divided into two classes according to their oxygen requirements. Those needing oxygen to live and grow are called **Aerobes** while those living in the absence of oxygen are called **Anaerobes**. Each class has well defined characteristics.

1. Aerobes decompose organic matter rapidly and completely with a corresponding production of CO_2, water and heat. This heat generation is called **Thermogenesis**.

2. Anaerobes partially decompose organic matter, producing not only CO_2 and water, but also certain organic acids and several types of gases such as hydrogen sulfide and methane. Anaerobes generate less heat than aerobes.

Examination of anaerobic areas of the compost reveals a yellowish, under-composted material that smells like rotten eggs. These areas in a compost pile are noticeably cooler and generally waterlogged. Anaerobic compost is unsuitable for mushroom growth.

Since neither fresh horse manure nor straw based synthetics have the correct moisture content, water must be added to these materials. The recommended levels for optimum composting are:

Horse manure: 69-71%
Synthetic: 71-73%

Pre-wetting

As long as the composting ingredients remain dry, the microorganisms lie dormant and composting does not take place. The first step in the composting process is the initial watering of the starting materials. The purpose of this pre-composting or pre-wetting is to activate the microbes. Once activated, the microbes begin to attack the straw and decompose the waxy film which encases the straw fibers. Until this film is degraded, water will not penetrate the straw and its nutrients will remain unavailable. As the process progresses, the fibers become increasingly receptive to water, which rather than being free or on the surface, penetrates and is absorbed into the straw.

There are many methods for pre-wetting. These include: dipping or dunking the material into a tank of water; spraying it with a hose; or spreading it out in a flat pile 2-3 feet high and running a sprinkler over it. Regardless of the method used, the result should be the same - a homogeneous evenly wetted pile.

Horse manure needs less time for pre-wetting due to the nature of the bedding straw. This straw has been trampled upon, opening the straw fiber and damaging the waxy film. The urine and droppings have also begun to soften it. This is not the case with a synthetic compost in which the baled straw is still fresh and tough. To stimulate microbial action in synthetics, some supplements are added at pre-wetting. Suitable supplements include any from group 1, 4, 5 or chicken manure.

The length of time needed for pre-wetting varies according to the condition of the starting materials. Generally 3 days for horse manure and 5-12 days for a synthetic compost is sufficient. The pre-wetting time for a synthetic compost can be shortened if the straw is mechanically chopped, but care should be taken that the fibers do not become too short.

The wetted materials are then piled in a large rounded heap called a windrow. During this period the windrow can be turned and re-wetted as needed, usually 1-3 times.

Building the Pile

Building the compost pile is called stacking, ricking or "make-up". At this time the pre-wetted starting materials and the nitrogenous supplements are evenly mixed, watered and assembled into a pile. The size, shape and specific physical properties of this pile are very important for optimum composting. These are:

1. Pile dimensions should be 5-6 feet wide by 4-6 feet high. The shape should be rectangular or square.
2. The side of the pile should be vertical and compressed from the outside by 3-6 inches. The internal section should be less dense than the outer section.
3. The pile is such that any further increase in size would result in an anaerobic core.

Throughout the composting process, the size of the pile varies depending on the physical condition of the straw, which provides the pile's basic structure. The structure of the compost refers to the physical interaction of raw materials, especially the straw fibers. As the straw degrades and the fibers flatten out, the structure becomes more dense and the airflow is restricted. The pile becomes more compact and its size is reduced accordingly. Initially the fresh straw allows for generous air penetration which convects away heat and slows microbial action. To counteract this heat loss, the pile should be of maximum size and optimum moisture content at make-up.

Figure 85 illustrates air penetration of a compost pile. Air enters the pile from the sides. As the oxygen is used by microorganisms, heat is set free and the air temperature rises. The warm air current created rises to the top of the pile. This is called the chimney effect. The factors that affect the rate of internal air flow are pile size and structure, moisture content and the differential between ambient air and internal pile temperatures.

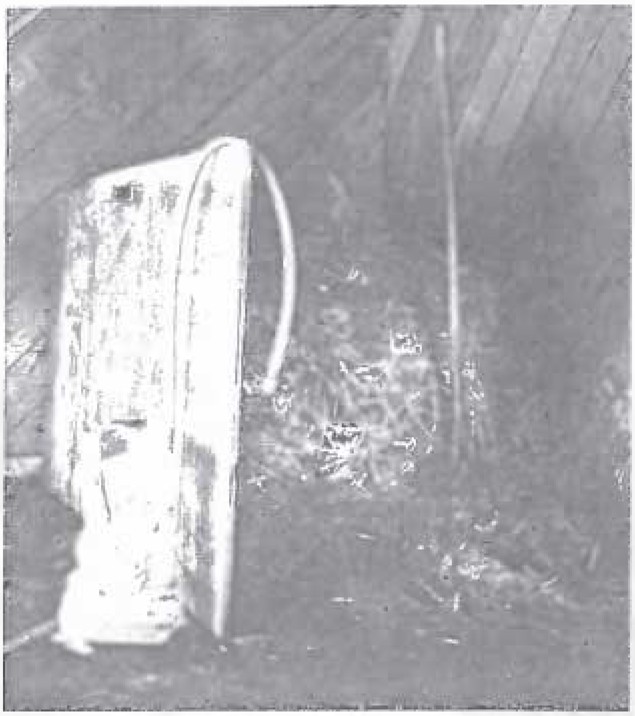

Figure 84 - Ricking the compost pile.

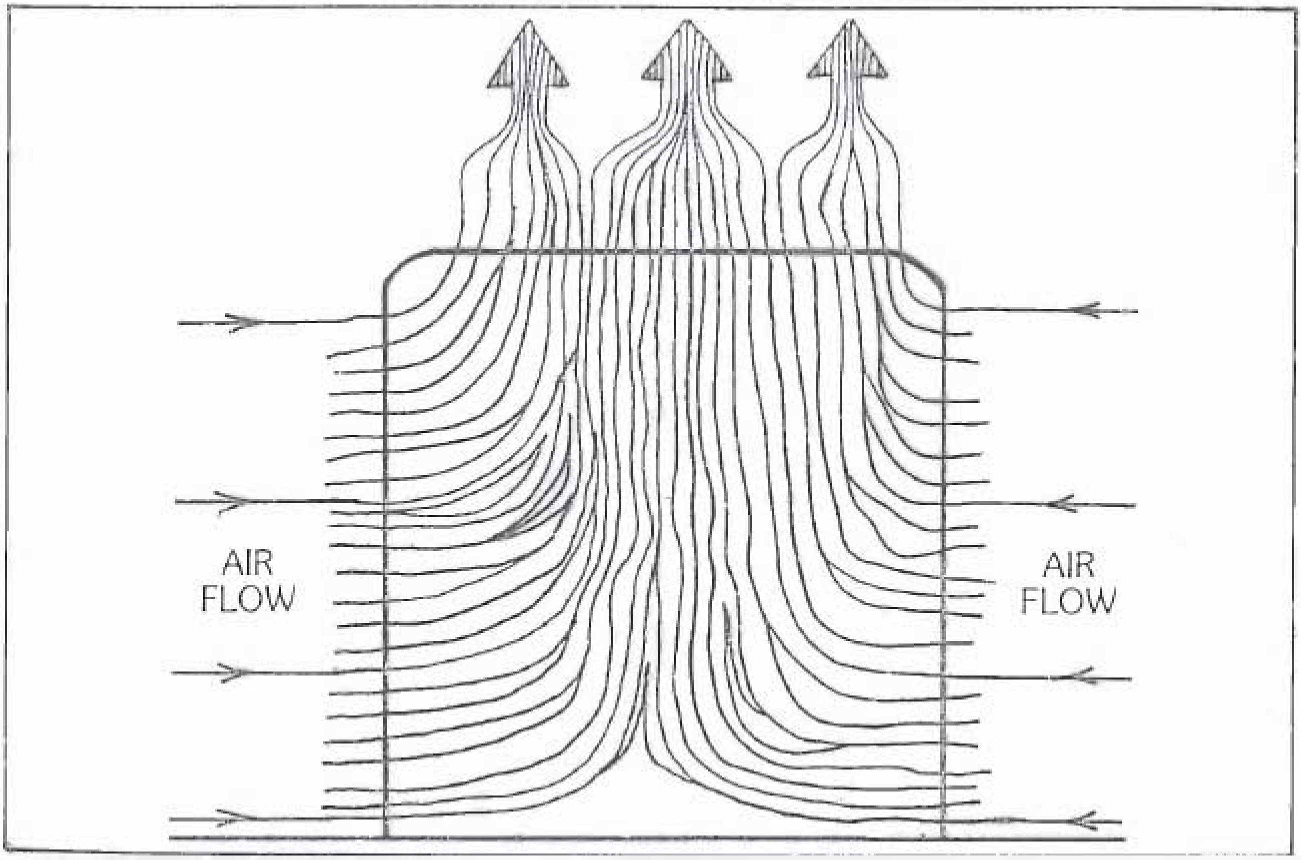

Figure 85 - Chimney effect in a compost pile.

Turning

A well built compost pile runs out of oxygen in 48 to 96 hours and then enters an anaerobic state. To prevent this, the pile should be disassembled and then reassembled. The purposes of this turning procedure are:

1. To aerate the pile, preventing anaerobic composting.
2. To add water lost through evaporation.
3. To mix in supplements as required.
4. To fully mix the compost, preventing uneven decomposition.

As a consequence of microbial decomposition, the compost pile begins to shrink and becomes more compact. Coupled with loose water gravitating downward and water generated by microbes in the inner active areas, this compaction closes the air spaces and stifles aerobic action, particularly in the core at the bottom center. Through the use of a long stemmed thermometer reaching to the center of the pile, the time of oxygen depletion can be monitored by watching temperature. When the temperature begins to drop, indicating a slowing of microbial action, it is time to turn the compost.

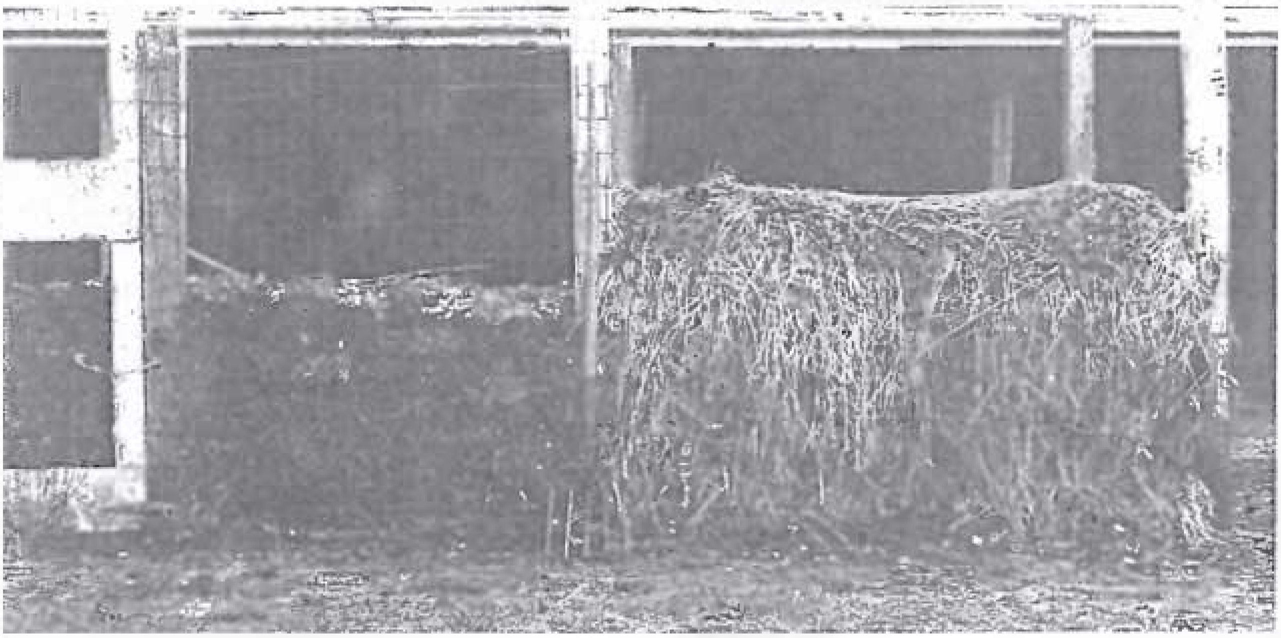

Figure 86 - Turning the compost pile using wire mesh pile formers.

In the early stages the temperature stratification in the pile is quite pronounced. Outer areas are cool and dry from the air flowing inward and the accompanying evaporation. These outer areas are watered during turning and moved to the center of the newly built pile and the center areas are relocated to the outside. Being aware of the varied rate of decomposition in a stratified pile and compensating during turning maintains the important homogeneous character of the pile.

Supplements deleted at make-up should be added during the turning cycle. Gypsum is normally added at the second turn. Adding gypsum any earlier is believed to depress ammonia production. Until some decomposition has occurred, the beneficial action of gypsum will not be realized. As with other supplements, gypsum is mixed in as evenly as possible.

Temperature

Environmental conditions in the compost are specifically designed to facilitate growth of beneficial aerobic microorganisms. Given the proper balance of raw materials, air and water, a continuous succession of microbial populations produces temperatures up to 180°F. These microbes can be divided into two groups according to their temperature requirements. Mesophiles are active under 90°F. and thermophiles are active from 90-160°F. The action of these microbial groups during the composting process is summarized in the following paragraphs.

During pre-composting mesophilic bacteria and fungi, utilizing available carbohydrates, attack the nitrogenous compounds thereby releasing ammonia. This ammonia is then utilized by successive microbial populations and the temperature rises.

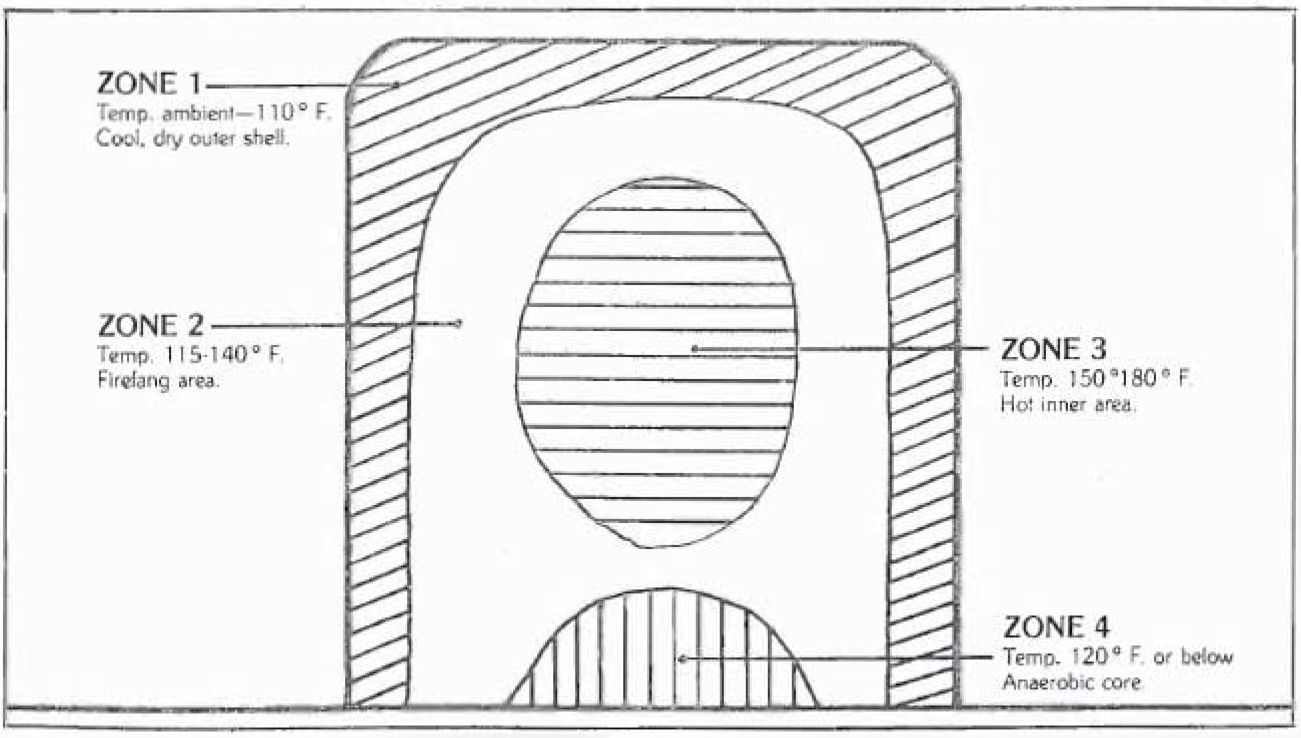

Figure 87 - Standard temperature zonation in a compost pile.

After make-up, the mesophiles remain in the cool outer zones while the thermophilic fungi, actinomycetes and bacteria dominate the inside of the pile. The actinomycetes are clearly visible as whitish flecks forming a distinct ring around the hot center. Bacteria dominate this center area and continue to decompose the nitrogenous supplements, liberating more ammonia. At this point the carbohydrates in the straw are ready for microbial use.

At temperatures over 150°F., microbial action slows and chemical processes begin. Between 150-165°F. microbial and chemical actions occur simultaneously. From 165-180°F. decomposition is mainly due to the chemical reactions of humification and caramellization, the latter taking place under conditions of high temperature, high pH (8.5) and in the presence of ammonia and oxygen. Many of the dark compounds produced during composting are believed to result from these chemical reactions. Decomposition proceeds rapidly at these high temperatures, and if they can be maintained throughout the process, composting time will be greatly reduced.

Figure 87 shows the temperature zonation commonly found in a compost pile. Studies by Dr. E.B. Lambert in the 1930's showed that compost taken from zone 2 produced the highest yielding crops. Based on this research, growers always subject their compost to zone 2 conditions prior to spawning. This normally occurs during Phase II in specially designed rooms. However, if a Phase II room can not be built, zone 2 conditions can be achieved by an alternate method known as Long Composting, developed by C. Riber Rasmussen of Denmark.

Long Composting

Long composting is designed to carry out the complete composting process outdoors (excluding pasteurization). The method is characterized by the avoidance of high temperature chemical decomposition and a reliance on purely microbial action. Specifically this procedure is designed to promote the growth of actinomycetes and rid the compost of all ammonia by the time of filling. The temperature zonation desired in this method is illustrated in Figure 88. An outline of the Long Composting procedure follows.

DAY	LONG COMPOSTING PROCEDURE
-10	**For synthetic composts**: Break the straw bales and water them thoroughly. Mix in group 1, 4 or 5 supplements or chicken manure. Windrow. Start at day -5 if straw is short or has been chopped.
-5	**For synthetic composts**: Turn and add more water. Break up any concentrations of supplements. Windrow.

-2	**For horse manure or synthetic composts**: Thoroughly wet and mix all raw materials and supplements (except gypsum). Windrow.
0	**Make up the pile**. Dimensions should be 6 feet wide and 4 feet high. The vertical sides should be tightly compressed with the middle of the pile remaining loose. Use the pile formers to make the stack and stomp the sides from the top to achieve ample compression. Water dry areas.
6	**First turn**: Water as needed. Move the center anaerobic zone to the outside of the new pile and the outside zone to the center. Keep the pile height and length constant by reducing the width as decomposition proceeds.
10-12	**Second turn**: Add the gypsum and water as needed. Distribute the zone of actinomycetes evenly throughout.
13-15	**Third turn**: The actinomycete zone should be evident throughout. Strong actinomycete growth may cause excessive drying, so be sure to check moisture content and water as needed. The smell of ammonia should be slight. Build the new pile only 24 inches high and 4-5 feet wide. Distribute the actinomycetes evenly throughout.
15-17	**Fourth turn**: The compost should now appear dark brown and well flecked with actinomycetes. All traces of ammonia should be gone. Moisture content should be approximately 67-70% and the pH 7.0-7.5. If this is not the case, continue the process turning at 2 day intervals until this condition is reached. The pile height may vary between 16-24 inches and is designed solely to promote optimum conditions for the growth of the actinomycetes - temperatures of 120-135°F.

Once finished, this compost is normally pasteurized at 135°F. for four hours. If pasteurization is impossible, discard the cool outer shell and utilize the areas showing strong actinomycete activity. Although these areas will not be free from all pests and competitors, they should provide a reasonably productive substrate. The aspect and characteristics of a properly prepared Long Compost should conform to the guidelines for compost after Phase II. (See Aspect of the Finished Compost on page 105 and Color Plate 8.)

Short Composting

Commercial *Agaricus* growers uniformly base their composting procedures on the methodology developed by Dr. James Sinden, who called his technique "Short Composting" in reference to the short period of time involved. Dr. Sinden's process is centered around the fast acting chemical reactions occurring in zone 3. Besides the shorter preparation time, this process also results in a greater preservation of dry matter, thus retaining valuable nutrients. Figure 89 illustrates the zonation during short composting.

Without commercial composting equipment, approximating the temperature conditions of Short Composting is very difficult. However, it does provide a model for optimum composting and can be approached by adhering to the basic principles discussed in this chapter. The Short Composting procedure is outlined below.

Short Compost Procedure

DAY	SHORT COMPOSTING PROCEDURE: Formula 1
-1	**For horse manure**: Wet the starting materials thoroughly. Windrow.
0	**Make up the pile**. Add all supplements except gypsum. Mix and water thoroughly. Pile should be 6 feet wide by 5-6 feet high. The sides should be vertical and compressed tightly.
2,3	**First turn**: Add gypsum and water as needed. Keep the pile height constant and vary the width only in relation to the amount of anaerobic material.
5	**Second turn**: Add water as needed.
7	**Third turn**: Add water as needed. Compost should be ready to fill.

The procedures for making a synthetic compost by the short composting method are outlined below, with minor modifications for the home cultivator. Note the longer period of pre-composting to condition the straw.

Synthetic Compost Procedure

DAY	SYNTHETIC COMPOSTING PROCEDURE: Formula 2
-10	Break straw bales and wet thoroughly. Windrow or spread out in a low flat pile, 2-3 feet high. Water daily.
-7	Mix the chicken manure together with the straw, wetting both well. Avoid water run-off. Windrow.

-3	Re-mix the windrow, adding water as necessary. Start here if chopped straw is used - wet the straw and chicken manure. Mix well and windrow.
0	**Make up the pile**. Dimensions should be 6 feet wide by 5 feet high. Add as much water as possible without run-off. Use pile formers to insure vertical sides and stomp down the sides from the top to achieve adequate compression. The pile should be tight and compact.
4	**First turn**: Add the gypsum. Water as needed. Keep the pile dimensions constant, varying the width as indicated by the amount of anaerobic material in the center. Maintain pile compaction.
7	**Second turn**: Water as needed and redistribute outer and inner areas. Redistribution should occur during each turn to keep the material in an even state of decomposition.
10	**Third turn**: Mix well and add water as needed. Reduce width to 5 feet. Fill if ready.
13	Fill if ready, or continue composting, turning at two day intervals.

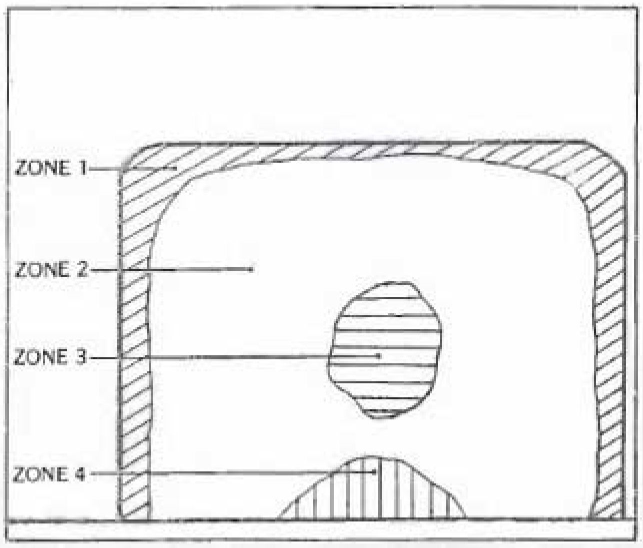

Figure 88 - Temperature zonation during Long Composting.

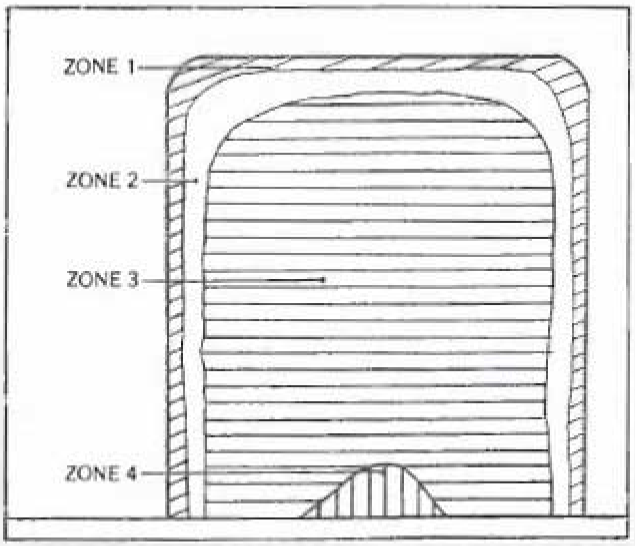

Figure 89 - Temperature zonation during Short Composting.

Composting Tools

Since commercial growers work with many tons of compost, a bucket loader is essential. They also use a specially designed machine for turning the piles. This compost turner can travel through a 200 foot pile in a little over one hour, mixing in supplements and adding water. Small scale cultivators can make compost without these machines. The following is a list of tools and facilities that are basic to compost preparation.

1. **A cement floor**. Not absolutely necessary but highly desirable, a cement floor is easy to work on, prevents migration of water to the earth and prevents soil and unwanted soil organisms from contaminating the pile. Water leaching from the pile, a good indicator of compost moistures, is quite evident on a cement floor. If a cement floor is not available, a sheet of heavy plastic can be used.
2. **Bobcat or small tractor loader with ¾-1 yard bucket with fork**. If producing large amounts of compost, one of these machines saves time and labor. Not only do they make pre-wetting, supplementing and pile building easier, they can be used to turn the pile.
3. **Pile formers**. These are constructed from 2 x 4's and plywood or planks to the dimensions desired for the compost pile. One for each side is necessary. Standard size would be 4-5 feet high by 8 feet long. An alternative to pile formers is a three sided bin.
4. **Long handled pitchfork with 4 or 5 prongs**. The basic tool in a compost yard, all compost piles were turned with pitchforks before the advent of compost turners and bucket loaders.
5. **Flat bladed shovel**. Used for handling supplements.
6. **Hose with spray nozzle, or sprinkler**.
7. **Thermometers**. Although pile temperatures can be guaged by touch, a long stemmed thermometer gives accurate readings.

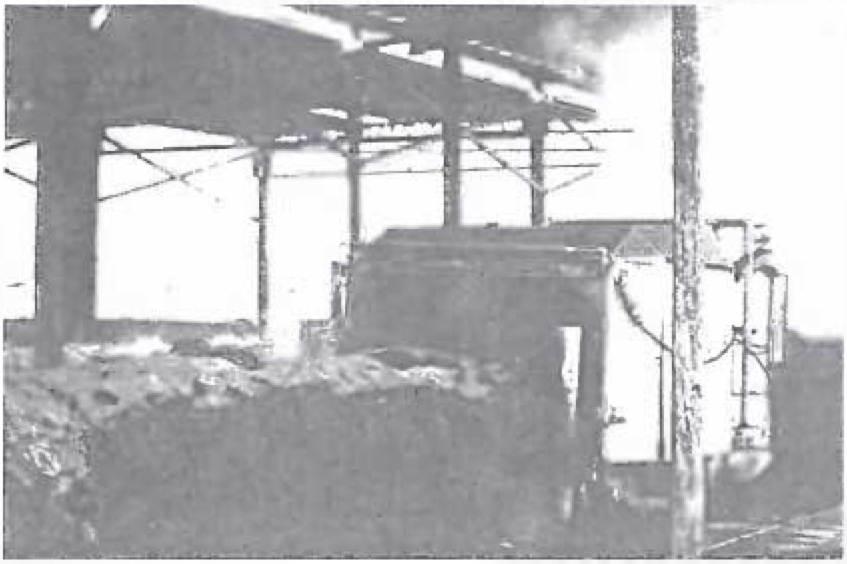

Figure 90 - Commercial compost turning machine.

Figure 91 - Pile Formers in use.

Characteristics of the Compost at Filling

The composting materials undergo very distinct changes during Phase I. A judgment as to the suitability of the compost for filling is based on color, texture and odor. Gradual darkening of the straw and the pronounced scent of ammonia are the most obvious features. These and other characteristics provide important guidelines for judging the right time for filling the compost. (Note: these guidelines do not apply for a compost prepared by the Long Composting methods.)

The compost is ready for filling if:

1. Compost is uniformly deep brown.
2. Straw is still long and fibrous, but can be sheared with some resistance.
3. When the compost is firmly squeezed, liquid appears between the fingers.
4. Compost has a strong smell of ammonia, pH of 8.0-8.5.
5. Compost is lightly flecked with whitish colonies of actinomycetes.
6. Kjeldahl nitrogen is 1.5% for horse manure and 1.7% for synthetic composts.

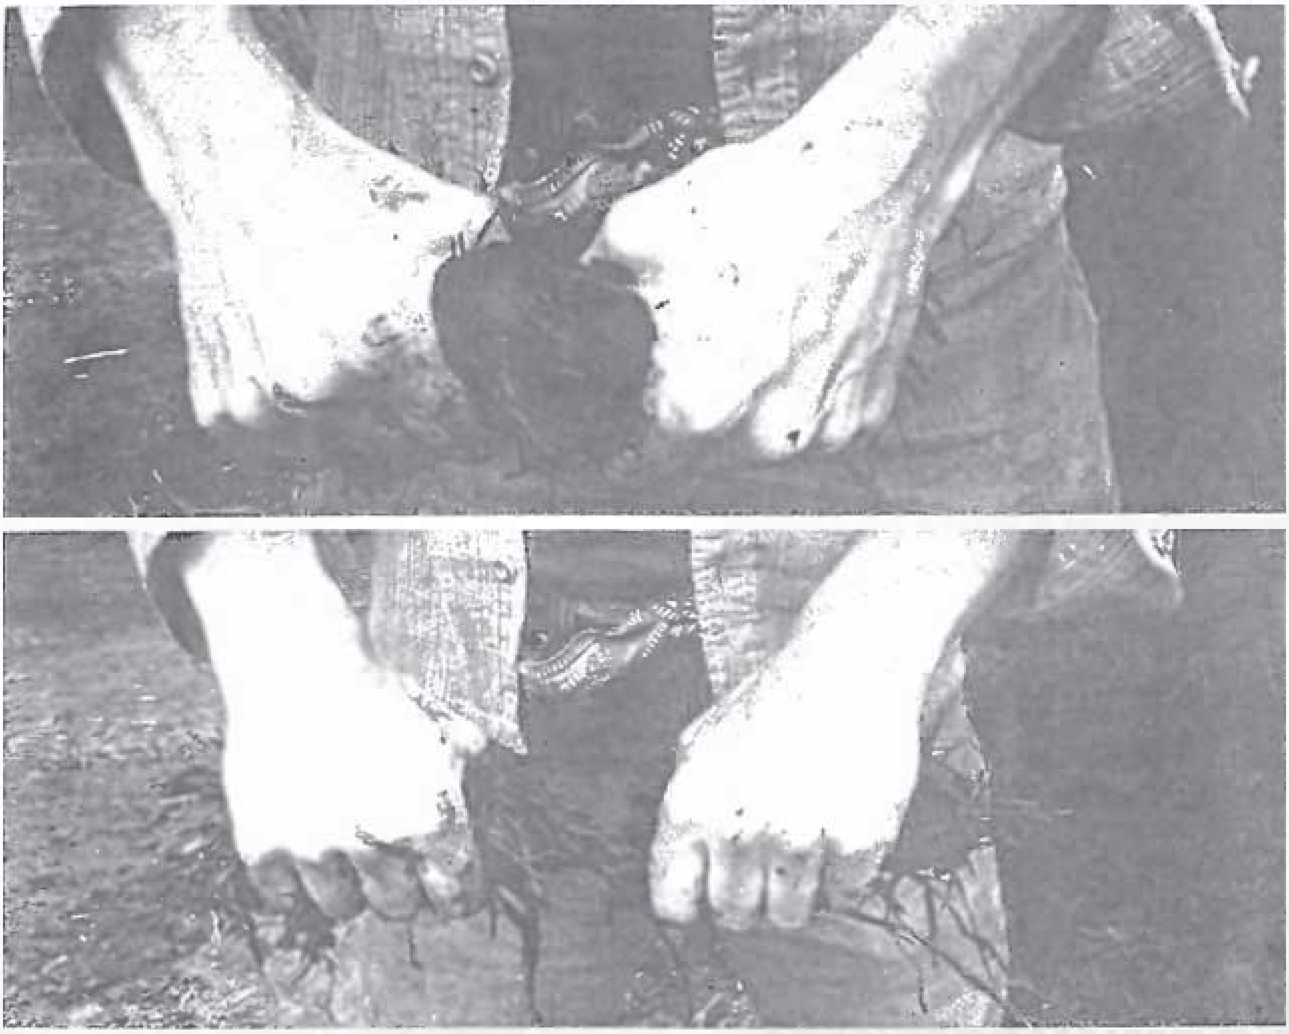

Figure 92, 93 - Compost at filling can be sheared with moderate resistance.

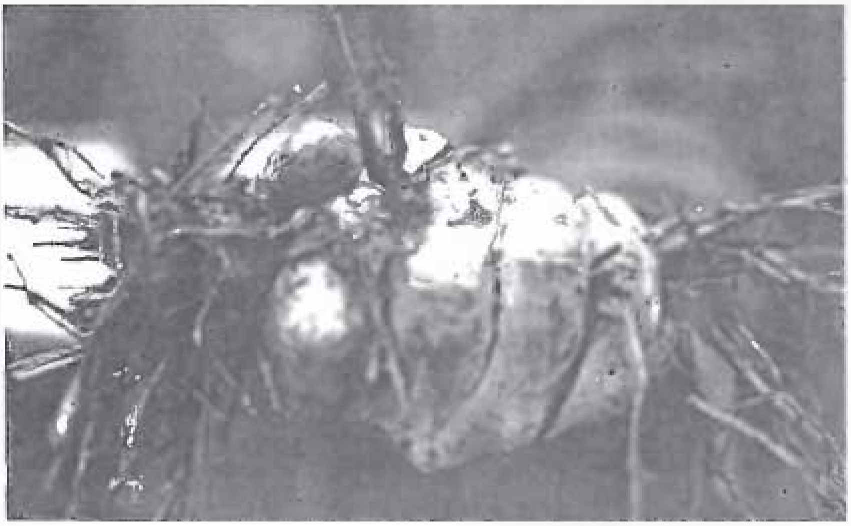

Figure 94 - Compost at filling should release some moisture when firmly squeezed.

Supplementation at Filling

The key to a successful Phase II, whether in trays, shelves or a bulk room, lies in the heat generating capabilities of the completed Phase I compost. To this end the compost should be biologically "active," a term that describes a compost with sufficient food reserves to sustain a high level of microbial activity. Whereas the Sinden Short Compost is a model of a vitally active compost, the Rasmussen Long Compost is considered biologically "dead" because these food reserves have been deliberately exhausted during Phase I. In this same sense, a compost having completed the Phase II is also considered a dead compost.

A method that insures a high level of microbial activity during the Phase II is supplementation with highly soluble carbohydrates during Phase I or with vegetable oils (fats) at filling. The purpose of these supplements is to provide readily available nutrients which stimulate the growth of the microbial populations. The effect of carbohydrates or oil supplementation on the Phase II is:

1. Accelerated thermogenesis - The nutrients provided by the supplements act as a "supercharger" for the microbial populations. Consequently their increased activity generates more heat. Specifically, supplementation with vegetable oil (cottonseed oil) increased populations of actinomycetes and thermophilic fungi (Schisler and Patton, 1970) while soluble carbohydrates (molasses) enhanced bacterial populations (Hayes and Randle, 1968).
2. Better compost ventilation - Heightened thermogenesis within the compost requires lower air temperatures within the Phase II room. The greater the compost to air temperature differential, the better the air movement through the compost. In this respect a dead compost requires a high room temperature and is difficult to condition because of its low microbial activity.
3. Rapid reduction of free ammonia - The increased ventilation and microbial activity give rise to a rapid fixation of ammonia. As a result, the Phase II period is reduced by as much as three days. The advantage of this reduced time period is that dry matter and hence nutrients for mushroom growth are conserved.
4. Reduced spawn running period - Oil supplemented composts show increased mycelial activity and therefore higher temperatures during the spawn running period. As a result the colonization period is shortened by three to five days.
5. Increased yields - Yield increases of 0.4-0.5 lbs/ft^2 are common for *Agaricus* growers using vegetable oil at filling. Similar increases are reported for molasses.

Compost supplementation with soluble carbohydrates is an effective way to prepare an active compost. These materials are listed earlier in the chapter as Group IV supplements. They are added to a synthetic compost during pre-composting (50%) and at third turn (50%) and to a horse manure compost at make-up and at third turn. Molasses is added at make-up at a rate of 10 ml per pound of compost wet weight and is diluted 1:2 with water for easy application. Vegetable oil is sprayed onto the compost the day of fill at a rate of 10 ml per pound of compost wet weight. Even application is important to avoid creating hot spots.

Compost supplementation with soluble carbohydrates or vegetable oils is highly recommended, especially for those planning a Phase II without steam or with only limited supplemental heating. Hence, this type of supplementation is particularly appropriate for the home cultivator.

Phase II Composting

While Phase I is a combination of biological and chemical processes, Phase II is purely biological. In fact, Phase II can be considered a process of microbial husbandry. By bringing the compost indoors into specially designed rooms, the environmental factors of temperature, humidity and fresh air can be controlled to such a degree that conditions for growth of select microbial groups can be maximized. These thermophilic and thermotolerant groups and their temperature ranges are:

Bacteria: 100-170°F. Different species of bacteria are active throughout this range so an optimum can not be given. At temperatures above 130°F. bacteria dominate and are responsible for the ammonification that occurs at these temperatures. The most common bacteria found by researchers are *Pseudomonas* species.

Actinomycetes: 115-140°F. with an optimum temperature range of 125-132°F. The most common species are found in the genera *Streptomyces* and *Thermomonospora*. Work done by Stanek (1971) has shown that actinomycetes and bacteria are mutually stimulatory, resulting in greater efficiency when working together.

Fungi: 110-130°F. with an optimum temperature of 118-122°F. Common genera are *Humicola* and *Torula*. Recent research indicates that these fungi are the most efficient de-ammonifiers, which has led to a more general use of their temperature range for Phase II conditioning.

The basic function of these microorganisms is to utilize and thereby exhaust the readily available carbohydrates and the free ammonia. Ammonia in particular must be completely removed because of its inhibitory effect on the growth of mushroom mycelium. The result of this microbial action is a build-up of cell substance or "biomass" which contains vitamins, fats and proteins. What the mushroom mycelium uses for a large portion of its nutrition then, is the concentrated bodies forming the microbial biomass. This biomass constitutes part of the brown layer coating the partially decomposed straw fibers.

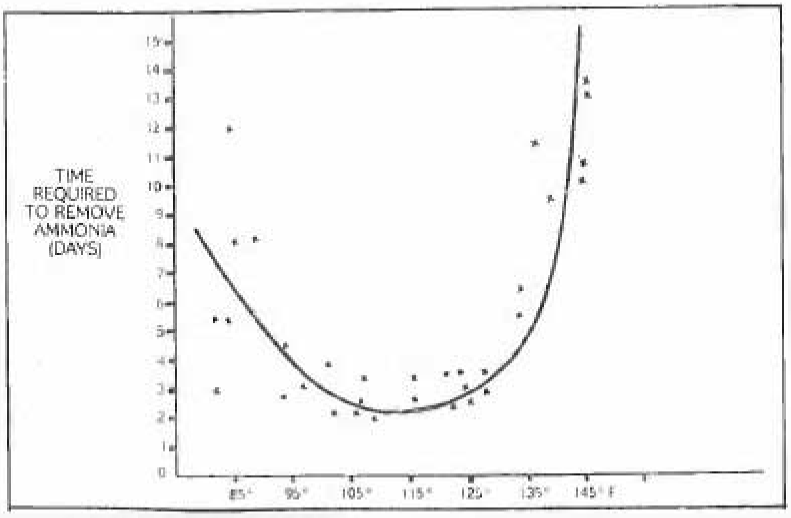

Figure 95 - Temperature vs. ammonia utilization by microbial populations. (After Ross, 1978)

Many growers consider Phase II to be the most important stage in the growing cycle and rightly so. An improperly prepared substrate yields few if any mushrooms. It is critical, therefore, that the environmental conditions required during Phase II be carefully maintained. Phase II can be separated into two distinct parts, each serving a specific function. These are:

1. **PASTEURIZATION**: The air and compost temperature are held at 135-140°F. for 2-6 hours. The purpose of pasteurization is to kill or neutralize all harmful organisms in the compost, compost container and the room. These are mainly nematodes, eggs and larvae of flies, mites, harmful fungi and their spores. The length of time needed generally depends on the depth of fill. Deeper compost layers require more time than shallow ones. In general, two hours at 140°F. is sufficient. Compost temperatures above 140°F. must be avoided because they inactivate fungi and actinomycetes while at the same time stimulating the ammonifying bacteria. If temperatures do go above 140°F., be sure there is a generous supply of fresh air.
2. **CONDITIONING**: The compost temperature is held at 118-130°F. Once the pasteurization is completed, the compost temperature should be lowered gradually over 24 hours to the temperature zone favored by actinomycetes and fungi. The exact temperature varies according to the depth of fill. At depths up to 8 inches, 122°F. as measured in the center of the compost is most frequently used. At depths over 8 inches, temperature stratification becomes more pronounced, making a higher core temperature of 128°F. advantageous. A common procedure is to bring the compost temperature down in steps, dropping the core temperature 2° per day, from 130° to 122°F. This temperature is then held until all traces of ammonia are gone.

Basic Air Requirements

Phase II is purely a process of aerobic fermentation and as such a constant supply of fresh air is essential. To insure this supply, a minimum fresh air setting is established on the air intake damper. A standard minimum setting is 8-10% of the intake opening. The oxygen level can be checked in a practical manner by lighting a match in the Phase II room. If a flame can be maintained, the oxygen level is sufficient. Lack of oxygen stimulates the growth of *Chaetomium*, the Olive Green Mold, which will spoil the compost. (See Chapter XIII).

Compost temperatures follow the air temperature of the room. Fresh air not only supplies oxygen, but is also used to keep the compost within the correct temperature zone. To drop the compost temperature, more fresh air is introduced and vice versa. Oversupply of fresh air is only a problem if it leads to rapid cooling of the compost. In this regard, changes in the fresh air setting should be slow and deliberate. Only when the compost threatens to overheat should maximum fresh air be introduced. This is particularly common directly after pasteurization.

Peak microbial activity normally occurs 24-48 hours after pasteurization. As Phase II progresses and the food supply diminishes, this activity begins to slow. Compost temperatures should begin to drop on their own. As they drop, the fresh air supply should be decreased, thus slowly raising the air temperature as the compost reaches the required temperature zones. If the fresh air minimum is reached and the compost temperatures are still dropping, a supplemental heat source must be installed.

Phase II Room Design

The Phase II room can be a special room set aside solely for this purpose (the norm on tray farms) or it can be in the same room where cropping occurs. Design features are critical for its success and should be strictly adhered to. These features are:

1. Adequate insulation: Insulate to a R value of 19 for walls and a minimum of 30 for the ceiling. A vapor barrier is needed to protect the insulation. (A layer of polyethylene is cheap and effective.)
2. The room must be functionally airtight. The door should form a tight seal. Any cracks or openings allow the passage of flies.
3. The ventilation system uses a backward-curved centrifugal fan driven by pulleys and belts, and whose speed can be varied. The fan should be capable of moving air at 1 cubic foot per minute (CFM) per square foot of compost surface area. A perforated polythene duct runs the length of the room and directs the air either straight down the center aisle or across the ceiling to the side walls. High velocity airflow is necessary to maintain even temperatures throughout as well as to keep the room under positive pressure.
4. A fresh air vent is located before the fan. This damper also regulates recirculated air. (See Fig. 73).
5. Filters are placed before the fresh air inlet. These filters are important as protection against flies, dust and spores. High efficiency spore filters are commonly used for the incoming fresh air. A pre-filter placed upstream of the main filter will increase its life. Recirculated air should never be filtered during Phase II because of its high moisture content.
6. At the opposite end of the room from the fresh air vent are exhaust louvers operating on air pressure. This exhaust air outlet must be screened from the inside.
7. If steam is used for boosting temperature, pipes can be run the length of the floor along the side walls discharging outwards. Steam can also be discharged directly into the air duct after the fan. High output electric space heaters can also be used.

Filling Procedures

Depending on the growing system chosen, the compost is loaded into trays, shelves or a bulk room. Certain basic principles should be adhered to when filling. These are:

1. Fill the room as quickly as possible to minimize heat loss from the compost.
2. Compress a long strawy compost and fill loosely a short dense compost.
3. If the compost appears dry, water lightly and evenly during filling. If water streams out when a handful is squeezed, don't fill. Add again as much gypsum, turn and wait a few days.
4. Fill all shelves and trays evenly and to the same depth. Avoid creating pockets of compact compost. Keep all compost within the container. No compost should hang over the sides.
5. Once finished, the floor should be cleaned of all loose compost, then washed with water.

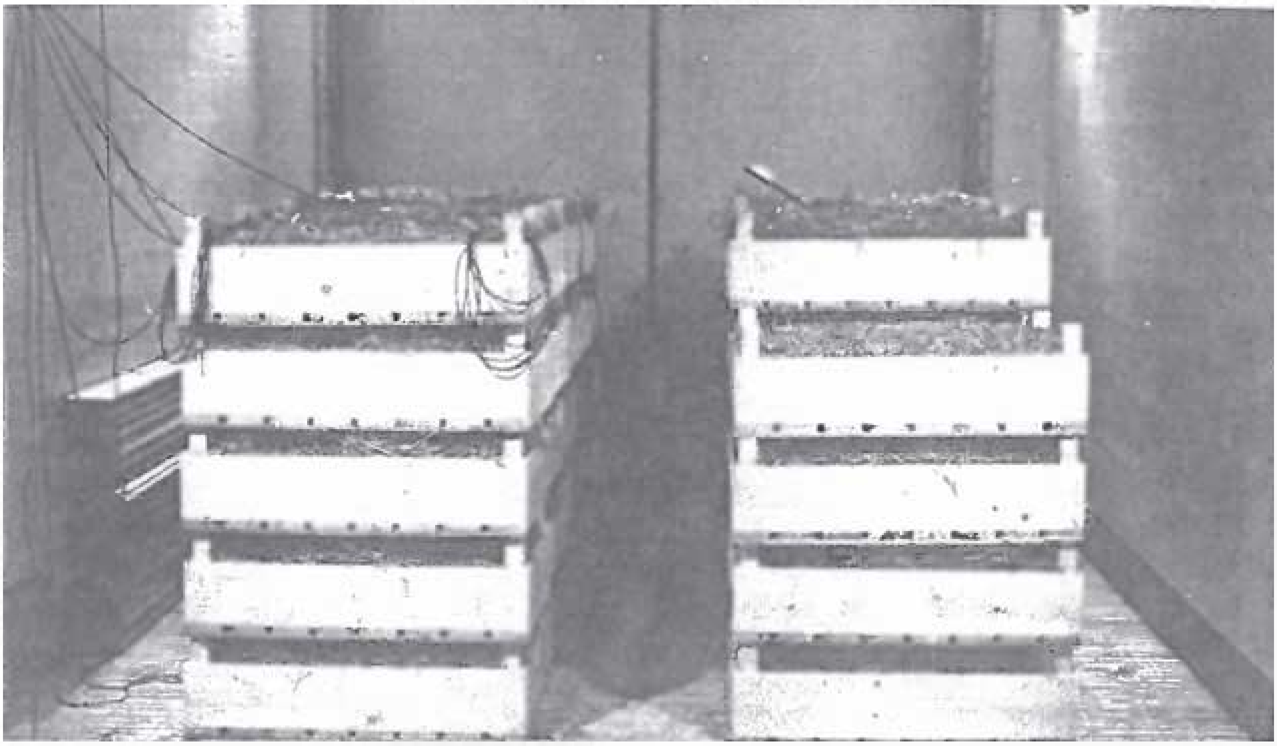

Figure 96 - Small Phase II room designed for trays or bulk fill.

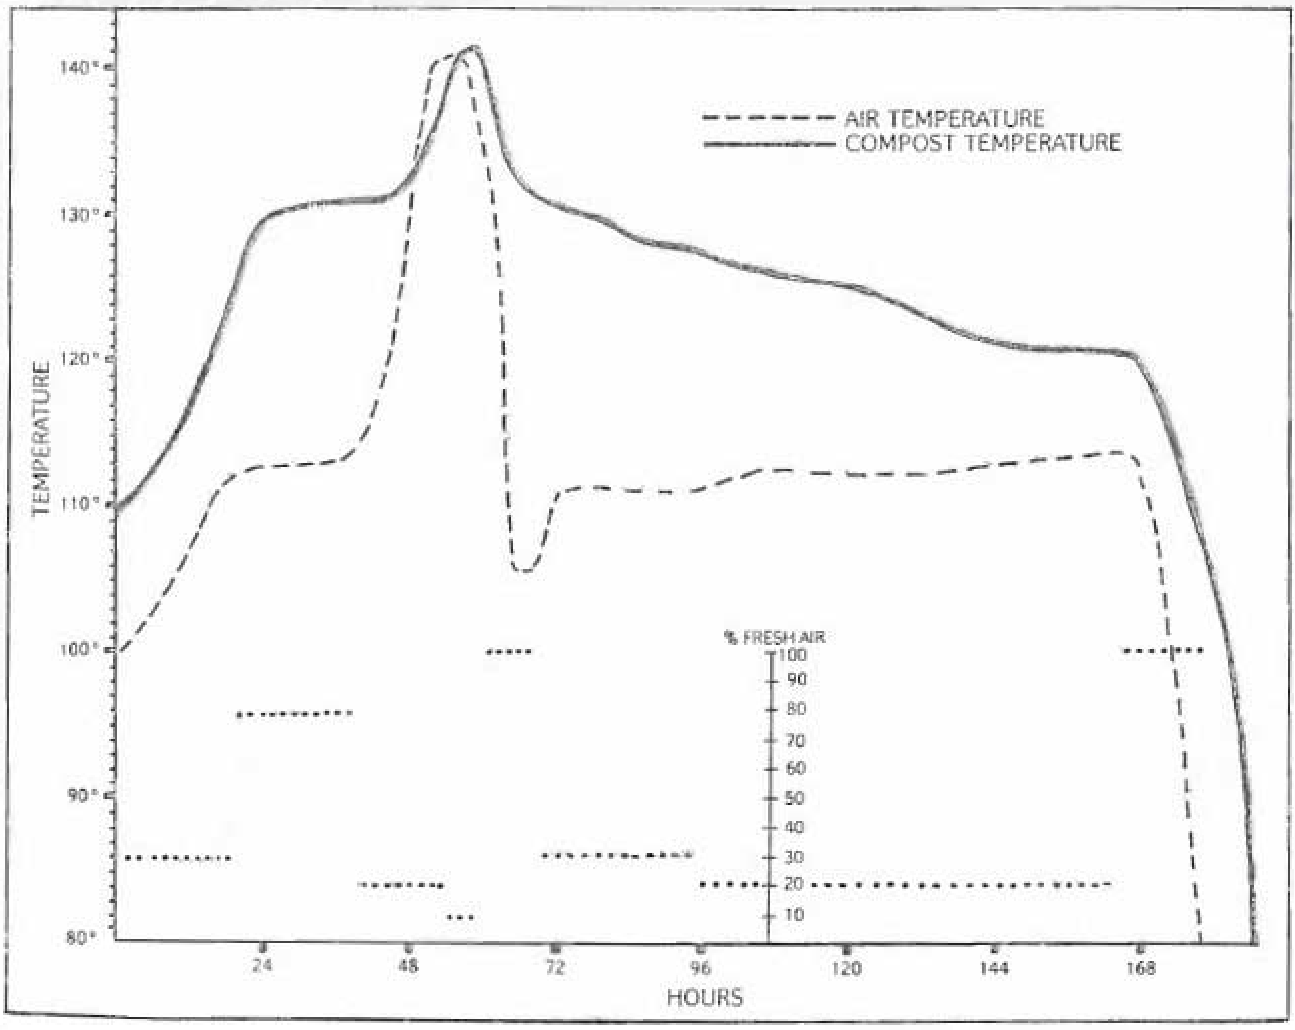

Figure 97 - Phase II temperature profile for trays or shelves.

Depth of Fill

Up to a point there exists a direct relationship between the amount of compost filled per square foot and yield. In a fixed shelf system, the amount of compost filled is usually the amount available for cropping. This normally holds true for trays, although some systems empty the trays at spawning and then refill 25% fewer trays than the number that was originally filled. This results in high dry weight efficiencies without the complications of deep compost layers during Phase II. As a general rule, a fill depth of 8 inches will provide sufficient nutrients as well as contribute to the ease of Phase II. At depths over 8 inches temperature stratification will lead to varying conditions within the compost, complicating the Phase II program. At depths under 5 inches there is insufficient mass for proper heat generation and large quantities of steam may be needed.

An important consideration is the ratio of cubic feet of compost filled to cubic feet of air space in the room. This ratio largely determines whether a supplementary heating source is necessary. Clearly, greater volumes of compost require less additional heating. To maximize compost heat generation, some tray systems stack trays no more than 3-4 inches apart during Phase II. These trays are later distributed to two cropping rooms with a spacer inserted between the trays to facilitate picking.

Phase II Procedures: Trays or Shelves

Day	Phase II Procedure: Trays or Shelves
0	The house is filled and cleaned. Thermometers are placed in the center of at least four containers, and one in the middle of the room for reading air temperature. Shut the door, turn on the fan and close the fresh air vent. Air and compost temperatures should rise from microbial activity. If not, additional heat should be supplied. Once the compost reaches 120°F., the fresh air vent should be opened and regulated to maintain compost temperatures in the 125-130°F. range. From this point on, the fresh air vent should never be less than the minimum setting of 10%.
1-2	A temperature chart should be kept, noting air and compost as well as fresh air and steam settings. Temperatures should be read every 4-6 hours. Compost temperatures should be in the 125-130°F. range for the first 48 hours after fill. After this period, pasteurization should commence. The air temperature is boosted to 140°F. and held long enough to subject the compost to 140°F. for 2 hours. If 140° can not be reached, a compost and air temperature of 135° for four hours is sufficient. The temperatures should be monitored closely to be sure pasteurization is complete. A long stemmed thermometer can be pushed through a drilled opening in the door, or a remote reading thermocouple can be used. After pasteurization, full fresh air is introduced to stop rising compost temperatures. Once the compost temperature begins to drop, adjust the fresh air setting to stop the compost in the temperature zone required, 128-130°F.
2-10	Starting at 128°F., use fresh air to lower the compost temperature gradually, 2° per day, until 122° is reached. Hold the compost at that temperature until it is free of ammonia. Throughout this conditioning process, a compost to air differential of 10-30°F. is normal. This differential is important for the passage of air through the compost. Little or no differential is undesirable and indicates over-composting or under-supplementation. During the conditioning period definite changes in the compost become apparent. The compost becomes well flecked with whitish actinomycetes, and on the surface whitish grey aerial mycelia of *Humicola* species appear. Both are indicators of proper microbial conversion.
2-10	Once the compost is free of ammonia, full fresh air is introduced, dropping the compost temperature rapidly to spawning temperatures in the 76-80°F. range.

Phase II in Bulk

For many people, equipping a standard Phase II room for trays or shelves may be inappropriate, especially if steam is used. The recent development of the bulk system now gives the home grower the ability to perform the Phase II without steam. This system utilizes compost heat more efficiently by loading the compost in mass, five feet deep, into a small well insulated room with a slatted floor. Instead of air diffusing through the compost by convection, air is blown under the floor and forced up through the compost. The wide compost to air temperature differential so essential to conventional Phase II processes is eliminated; compost and air temperatures are now no more than 5°F. apart. This narrow differential is in part related to a reduced compost-to-air volume ratio, which in a bulk room is 1:1 or 1:¾. This reduction of air space, coupled with the airtight, well insulated room, results in full utilization of compost heat generation. A large measure of control over compost temperatures becomes possible and optimum temperatures within the mass can be tightly regulated.

Bulk Room Design Features

The size of the bulk room varies according to individual needs, but should be large enough that there is sufficient compost mass to supply heat.

1. At a fill depth of 4-5 feet, one ton of compost requires approximately 8-10 sq. ft. of floor space.
2. Bulk rooms are well insulated. The walls and door are R-19; the ceiling is R-30 minimum. A vapor barrier should protect all insulation.
3. The room has a double floor. The bottom floor is concrete, insulated to R-19 with styrofoam or other water impervious material, and covered with tar or temperature resistant plastic as a vapor barrier. The compost floor is 12-18 inches above the bottom floor, and is made of 4 x 4's with spacers in between to leave 20% air space. This floor is removable to permit periodic cleaning.
4. The interior walls and ceiling are made of exterior grade plywood, treated with a wood preservative or marine epoxy. Allow 1/4 inch for expansion. Caulk or seal with fiberglass tape.
5. The room must be airtight. Caulk all cracks and corners.
6. The access door runs the width of the room for easy loading and unloading. An airtight seal is essential.
7. A wood plank wall is inserted before the access door to prevent the compost from pressing against it. The plank wall is held in place by runners on either wall.
8. The ventilation system is powered by a centrifugal, high pressure belt driven blower, with a capacity of 90-120 CFM per ton of compost at a static pressure of up to 4 inches of water gauge. The recirculation duct comes out on the top of the back wall and down to the fan. The supply duct goes from the fan to the air chamber under the compost floor. All ductwork should be insulated.
9. The fresh air inlet and damper are located before the fan. This damper also regulates the recirculated air. The fresh air should be filtered.
10. The exhaust outlet is located on the access door. This is a free swinging damper that operates on room pressure. This outlet is covered by a coarse filter.
11. Standard inside dimensions are 6-12 feet wide by 8-10 feet high.
12. For better temperature control the bulk room should be built inside a larger building, like a garage, where temperature differences are less extreme. The introduction of cold fresh air hampers the process by neutralizing the compost heat.

A simple variation of this bulk room is a well insulated bin. The bin is constructed using the principles just outlined. Rather than a mechanical air system, fresh air is admitted through adjustable vents at floor level and exits through similar vents in the ceiling. Because air passage is by convection, the compost should be filled loosely and to a depth of no greater than four feet.

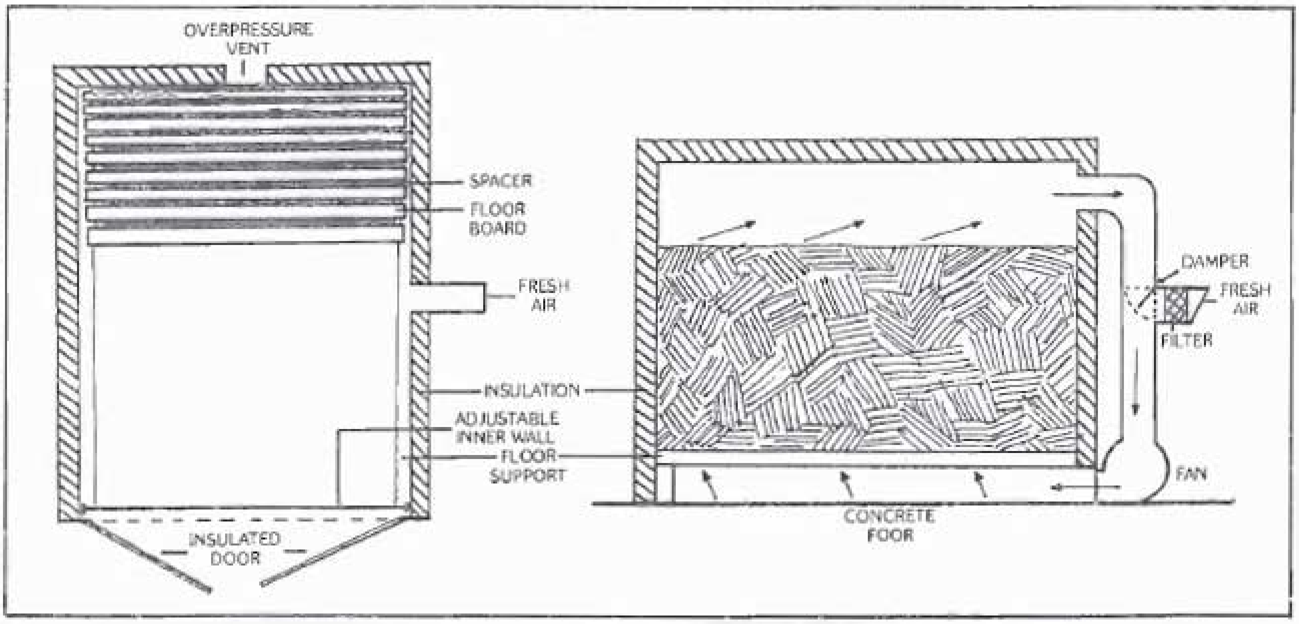

Figure 99 - Bulk pasteurization room. Ventilation system on side wall. (Design - Claron)

Bulk Room Filling Procedures

1. Fill as quickly as possible to minimize heat loss.
2. Compost should have good structure and optimum moisture content. Do not fill a dense, overwet compost.
3. Fill evenly. Compost density is important. Avoid localized compaction as well as gaps. Gaps or holes in the compost become air channels to the detriment of the surrounding material. Be sure the compost presses firmly and evenly against all sides of the room.
4. Before filling the last three feet, put the inside board wall in place. Now fill the remaining area. The compost should press firmly against the board wall.

Bulk Room Phase II Procedures

Day	Bulk Room Phase II Procedures
0	**Filling**. Compost is brought into the room. If remote reading temperature sensors are used, place 2-4 sensors in different locations within the compost, and one in the air above. If remote sensors are not used, place one thermometer in the return air duct and one downstream from the fan in the supply duct. The compost temperature should be within the readings of these two air thermometers. Turn the fan on, close the fresh air damper and re-circulate until 120°F. is reached. This should take 8-24 hours. Then open the fresh air damper to the minimum setting, 8-10%.
1-2	**Pasteurization**: Allow the temperature to rise to 132-135°F. Adjust the fresh air damper to hold this temperature for at least six hours and a maximum of ten hours. Once completed, introduce sufficient fresh air to bring the temperature down to 122°F. This should take approximately 12 hours. Be sure to anticipate temperature trends and adjust the fresh air accordingly.
2-10	**Conditioning**: By adjusting the amount of fresh air, the compost is held in the 118-122°F. range until all ammonia is gone. Fresh air should gradually be reduced as thermogenesis subsides. The temperature in the return air duct should always be higher than in the supply duct.
4-10	**Cool-down**: Once the ammonia content of the air is below 10 parts per million (ppm) full fresh air is given to reduce the compost temperature to 80°F. The cool-down should proceed as rapidly as possible.

Testing for Ammonia

The basic ammonia detection test has always been the sense of smell. The odor of ammonia must be completely gone from the compost before it can be spawned. Odors are always good indicators of compost suitability. However, to be absolutely certain, other methods are also used.

1. Cresyl Orange and filter paper: Pre-cut strips of white filter paper are saturated with a few drops of cresyl orange liquid which turns the white paper yellow. Expose the paper to the inside of the Phase II room or to the exhaust air of the bulk room. The paper can also be placed into small holes dug into the compost. The presence of ammonia turns the paper varying shades of red. Purple indicates the highest concentration, while pink indicates a lower one. When the yellow paper remains unchanged in color, free ammonia is absent.
2. Air samplers using gas detection tubes: These tubes are filled with chemicals that change color as air samples are drawn into them. The tubes are calibrated in parts per million (ppm) and give accurate readings down to 1 ppm. The air samplers are manufactured by Mine Safety Co. and the Draeger Corp. Individual tubes cost from $2.00-$4.00 in lots of ten. (See sources in Appendix).

Aspect of the Finished Compost

The following guidelines can be used to determine whether a compost is ready for spawning. (See Color Photographs 5-8).

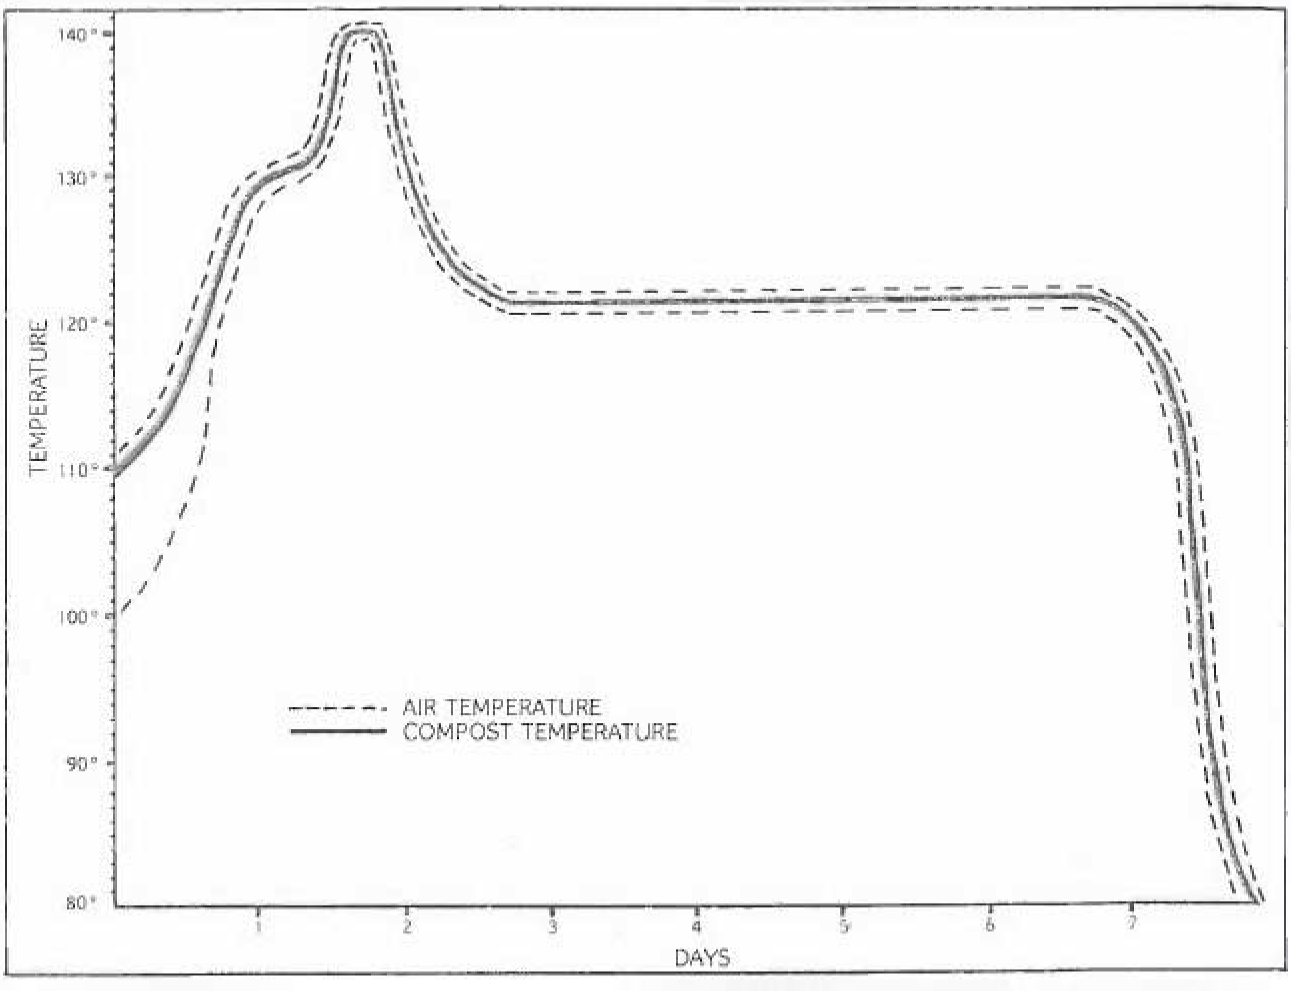

Figure 100 - Bulk room Phase II temperature profile. (Dutch procedure)

1. The raw pungent odor is gone; the odor is now light and pleasant, even slightly sweet.
2. The ammonia odor is completely gone. The cresyl orange test shows no reaction. Detector tubes read 10 ppm or less.
3. The pH is below 7.8, preferably 7.5.
4. Straws appear dull and uniformly chocolate brown, speckled with whitish actinomycetes.
5. The compost is soft and pliable and can be sheared easily.
6. When squeezed the compost holds its form. No water appears and the hand remains relatively clean.
7. Moisture content is 64-66% for horse manure and 67-68% for synthetics.
8. Nitrogen content is 2.0-2.3%; the C:N ratio is 17:1.

Alternative Composts and Composting Procedures

Sugar Cane Bagasse Compost

Sugar cane bagasse is the cellulosic by-product of sugar cane after most of the sugars have been removed. It is generally a short fibrous material with a high moisture holding capacity. Total nitrogen amounts to 0.18%. In 1960, Dr. Kneebone of Pennsylvania State University reported growing *Psilocybe aztecorum* on a bagasse based compost. He later reported in more detail on experiments using bagasse compost for growing *Agaricus brunnescens*. Bagasse used as stable bedding produced yields comparable to the horse manure based control. Bagasse supplemented with a commercial activator ("Acto 88") yielded poorly.

Dr. Kneebone's composts were prepared using the standard techniques elucidated in this chapter with a turn schedule on days 0-2-5-7-9. The supplemented bagasse was composted 3 days longer and all bagasse based composts had moisture contents ranging from 75-83%. Significantly, the bagasse compost with the lowest moisture content had the highest yield. All bagasse composts had larger mushrooms than the control.

This work by Kneebone demonstrates the value of bagasse as a mushroom growing substrate. Using the compost formula format, composts can be devised to meet the needs of the two species named and many others. A good supplement would be horse droppings on wood shavings. If the bagasse compost becomes too short or wet, the gypsum can be increased from 5% to 8% of the dry weight.

The Five Day Express Composting Method

During the past 20 years compost research has been directed towards shortening the overall preparation period. The goal is to reduce handling and further conserve the nutrient base (dry matter). But so far, no one has been able to consistently produce a high yielding compost by rapid preparation methods. However, a recent article by Kaj Bech (1978) of the Mushroom Research Lab in Denmark reports the most promising method to date. According to Bech, total dry matter loss is held to 20-25% with a composting time of 8-10 days (5 day Phase I and 3-5 day Phase II). His method and materials follow:

Day	Procedure
-2	Take one ton wheat straw based horse manure (moisture content 50%, nitrogen content of 1.0-1.1). Homogenize well and make up the pile using standard dimensions.
0	**1st turn**: Add ammonia sulfate, $(NH_4)_2SO_4$, 11.25 kg. Wet thoroughly with approximately 450 liters of water.
2	**2nd turn**: add calcium carbonate ($CaCO_3$) 33.75 kg. Add approximately 180 liters of water.
3	Mix well and fill trays, shelves or tunnel for standard Phase II.

VI. NON-COMPOSTED SUBSTRATES

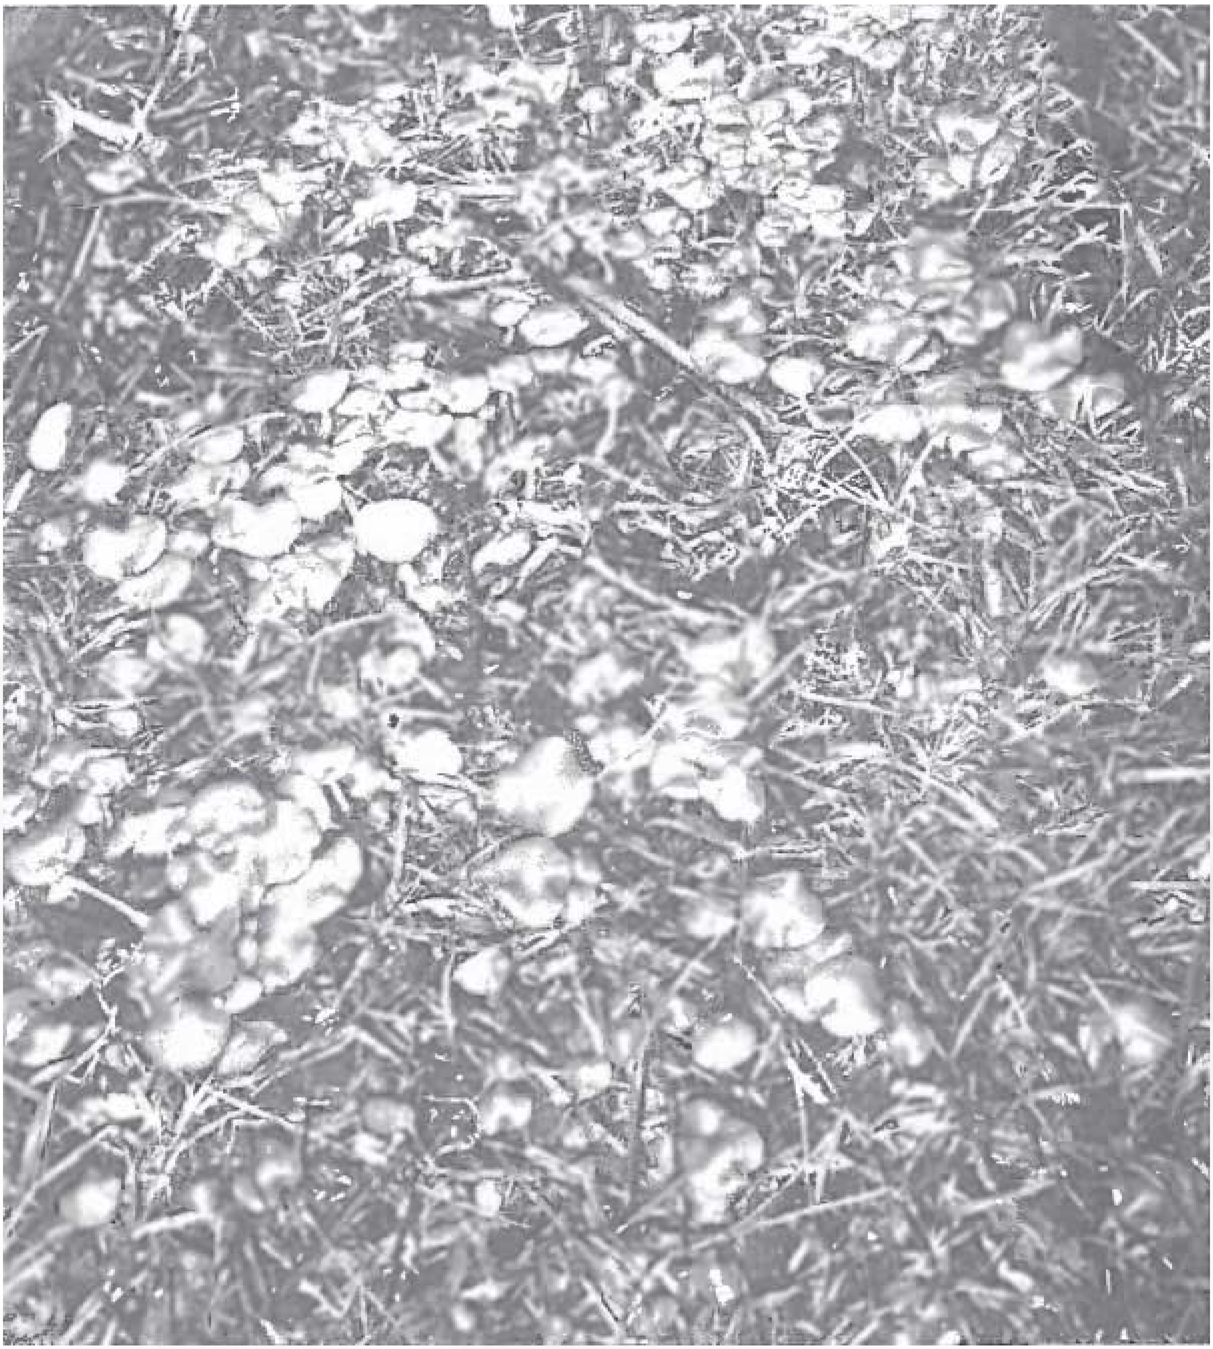

Figure 101 - *Psilocybe cyanescens* fruiting outdoors in a bed of fresh alder chips.

The use of non-composted and semi-composted materials as mushroom growing substrates is common among commercial growers of *Pleurotus, Voivarielia, Flammulina* and *Stropharia*. Because of the simplicity and ease by which they are produced, these substrates are ideal for the home cultivator. The advantages of these substrates are the rapid preparation times and the easily standardized mixtures formulated from readily available raw materials. These substrates can be treated by sterilization, pasteurization or used untreated in their natural state.

Natural Culture

For most people mushroom cultivation implies an indoor process employing sterile culture techniques and a controlled growing environment. Although this has been the natural progression of events for commercial cultivators and is the only way to consistently grow year round crops, it need not be the sole method available to the home cultivator. For hundreds of years home growers have made up outdoor beds and have enjoyed harvesting seasonal crops of mushrooms. In fact, most mushrooms now being grown commercially were originally grown using natural culture techniques.

By observing wild mushrooms fruiting in their natural habitats, one can begin to understand their growth requirements. To fully illustrate how this methodology works, the development of natural culture for *Psilocybe cyanescens* will be used as an example. *Psilocybe cyanescens* grows along fence lines and hedge rows, in tall rank grass, in berry thickets, in well mulched rhododendron beds, in piles of wood chips and shavings and in ecologically disturbed areas. In many instances, the mushrooms are found growing in soil, but upon close examination of the underlying mycelial network, it is apparent that they are feeding on wood or other similar cellulosic material. Due to the thick strandy mycelium of *Psilocybe cyanescens*, it is relatively easy to locate and gather colonized pieces of substrate. These pieces are considered virgin spawn and are used to inoculate similar materials. Freshly cut chips of alder, maple and fir all support healthy mycelial growth. Because alder is high in sugar content, without resins and abundant in northwestern North America, it has been selected as the primary substrate material.

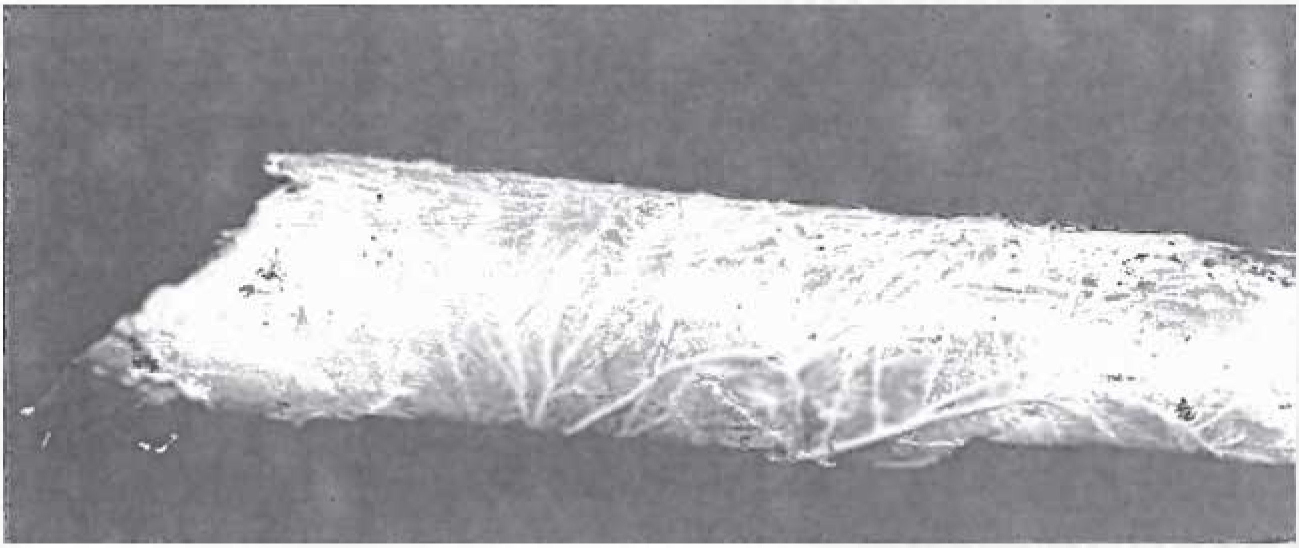

Figure 102 - Virgin spawn: *Psilocybe cyanescens* mycelium on a wood chip.

Even though such a virgin spawn is not absolutely clean, *Psilocybe cyanescens* mycelium colonizes fresh substrate pieces so rapidly that there is little risk of contamination. In order to prepare inoculum for the following year, the newly inoculated chips are kept indoors in gallon jars or other protective containers. With sufficient moisture, minimal air exchange and normal indoor temperatures, the mycelium soon spreads throughout the fresh chips. For the best results a 1:5 ratio of virgin spawn to fresh chips is recommended. As one jar becomes fully permeated, it can be used to produce more spawn.

In the spring freshly cut wood branches are chipped, then mixed with the fully colonized inoculum and made into a ridge bed directly on the ground. Experience has shown that irregular chips approximately 1-3 inches long give better results than finely ground material such as sawdust. Fresh chips not only provide a greater nutrient and water reservoir, but also have substantial surface area for primordia formation. Strong mycelial growth can be sustained on wood chips for a prolonged period of time. (Mycelial growth on fresh sawdust is at first rapid and rhizomorphic but soon slows and loses its vitality).

The ridge beds should be made 4-6 inches deep and 2 feet wide. To insure a humid microclimate for mushroom development the bed should be made under rhododendrons or other leafy ornamentals, along a fence or hedge row, or on grass which is allowed to grow up through the bed. The bed must never be placed where it is exposed to direct sunlight but it should not be so well protected that rainfall can not reach it.

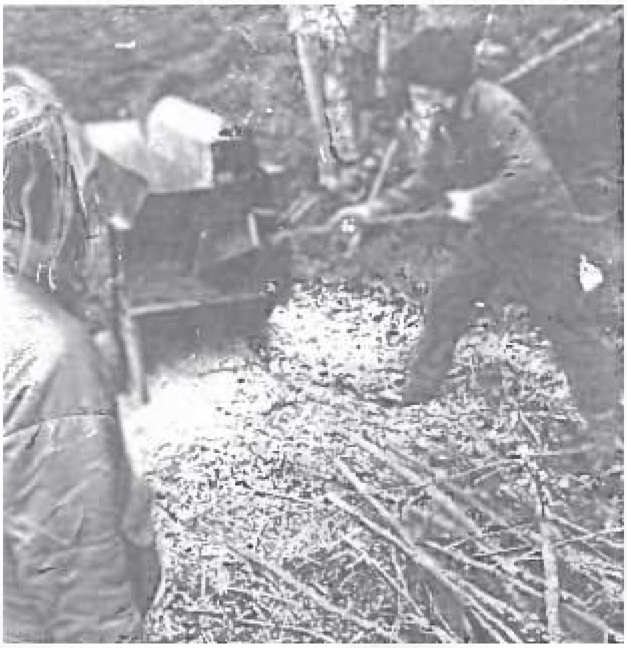

Figure 103 - Chipping freshly cut alder branches.

During the spring and summer the mycelium colonizes the fresh substrate which should be covered with plastic or cardboard to prevent drying. A weekly watering helps to keep the moisture content high. In the fall the bed is uncovered and given a heavy watering twice a week, but with care not to flood it. When the mushrooms begin to fruit, watering should be gauged according to environmental conditions and natural precipitation. As long as the temperature stays above freezing the mushrooms will grow continuously. If a freeze is expected, the beds can be protected with a plastic covering. Extended freezing weather ends outdoor cropping until the following year.

Throughout the winter the beds can be protected by a layer of straw, cardboard or new chips topped with plastic. This is particularly important for harsh climates. Other possibilities include making the bed inside a cold frame or plastic greenhouse. Certain regions of the country like the North-west are better suited to natural culture than others. In this respect it is desirable to use a local strain adapted to local conditions. In climates unsuited to outdoor cultivation, the wood chips can be filled into trays and brought inside.

Once the primary bed has been established outdoors, it can be likened to a perennial plant, which is the nature of mushroom mycelium. Indoor spawn preparation and incubation become unnecessary. With each successive year chips can be drawn from the original bed and used as inoculum. This means that the total bed area can be multiplied by five on an annual basis. (See Figure 164 of *Psilocybe cyanescens* fruiting indoors in tray of alder chips).

Semi-sterile and Sterile Wood Based Substrates

Mushrooms that grow on wood or wood wastes are termed lignicolous due to their ability to utilize lignin, a microbial resistant substance that constitutes the heart wood of trees. The main components of wood, however, are cellulose and hemicellulose, which are also nutrients available to lignin degrading mushroom mycelium. The chart appearing below shows a typical analysis of different wood and straw types. This table not only illustrates the similarities between wood and straw, but also the important differences between coniferous and broad leaf trees. The high concentrations of resins, turpentine and tanins make conifers less suitable for mushroom growing. Conifers are used on occasion, but they are mixed one to one with hardwood sawdust. In general, the wood of broad leaf or hardwood species have proven to be the best mushroom growing substrates. Specifically these tree types are: oak; elm; chestnut; beech; maple; and alder.

Type	Resin	N	P-2 0-5	K_2O	Hemicell.	Cell.	Lignin
Spruce (*Picea excelsa*)	2.30	0.08	0.02	0.10	11.30	57.84	28.29
Pine (*Pinus silvestris*)	3.45	0.06	0.02	0.09	11.02	54.25	26.25
Beech (*Fagus silvatica*)	1.78	0.13	0.02	0.21	24.86	53.46	22.46
Birch (*Betula verrucosa*)	1.80	-	-	-	27.07	45.30	19.56
Wheat Straw (*Triticum sativum*)	0.00	0.60	0.30	1.10	-	36.15	16.15

Table of the analyses of various types of wood and straw. Figures are percent of dry weight. (Adapted from H. Rempe (1953)).

The most notable commercial species grown on wood is *Lentinus edodes*, the shiitake mushroom. Traditional methods use oak logs, 3-6 inches in diameter and three feet long, cut between fall and spring when the sap content is the highest. Special care should be taken not to injure the bark layer when cutting and handling the logs. The bark is of critical importance for fruiting and is one of the key factors considered by commercial growers when selecting tree species. The logs should be scraped clean of lichens and fungi and then drilled with four longitudinal rows of one inch deep holes spaced eight inches apart. Next, these holes are plugged with spawn and covered with wax. After 9 to 15 months of incubation the logs begin to fruit. (See the species parameter section in Chapter XI.) The use of freshly cut logs provides a semi-sterile substrate with no special treatment and is a very effective method for the home cultivator.

Commercial growers of lignicolous mushrooms are turning increasingly to sawdust based substrates. Such substrates have been developed in Japan for growing *Pleurotus, Flammulina* and *Auricularia*. They are also being utilized with some modifications by commercial shiitake growers in the United States. The development of these mushroom specific substrates follows certain well defined guidelines.

The basic raw material is cellulose, a major constituent of sawdust, straw, cardboard or paper wastes, wood chips, or other natural plant fibers. Any of these materials should be chopped or shredded, but never so finely as to eliminate their inherent structural qualities. This cellulosic base comprises approximately 80% of the total substrate mixture.

To these basic substrate materials are added various nutrient supplements and growth stimulators in meal or flour form. By supplying proteins, carbohydrates, vitamins and minerals, the supplements serve to enhance the yield capabilities of the substrate base. Protein sources include concentrates like soya meal or soya flour, wheat germ and brewer's yeast. The most suitable carbohydrate sources are starchy materials such as rice, potatoes, corn and wheat. Some supplements are well balanced and provide both carbohydrates and proteins. Examples of these are bran, oatmeal and grains of all types. The number of possible supplements is extensive and need not be limited to those listed. The supplements comprise approximately 8-25% of the total dry weight. The addition of gypsum at a rate of 5% of the dry weight can improve the structure and porosity. It should be considered an optional ingredient.

Japanese growers of *Flammulina velutipes, Auricularia auricula* and allies, and *Pleurotus ostreatus* have a standard substrate formula consisting of 4 parts sawdust and 1 part bran. The sawdust can be aged up to one year, which is said to improve its moisture holding capacity. Presoaking the sawdust prior to mixing in the bran is an effective way to achieve the required 60% moisture optimum. A firm squeeze of the mixture should produce only a few drops of water between the fingers. If the mixture has too much moisture, loose water collects in the bottom of the substrate container, a condition predisposing the culture to contamination.

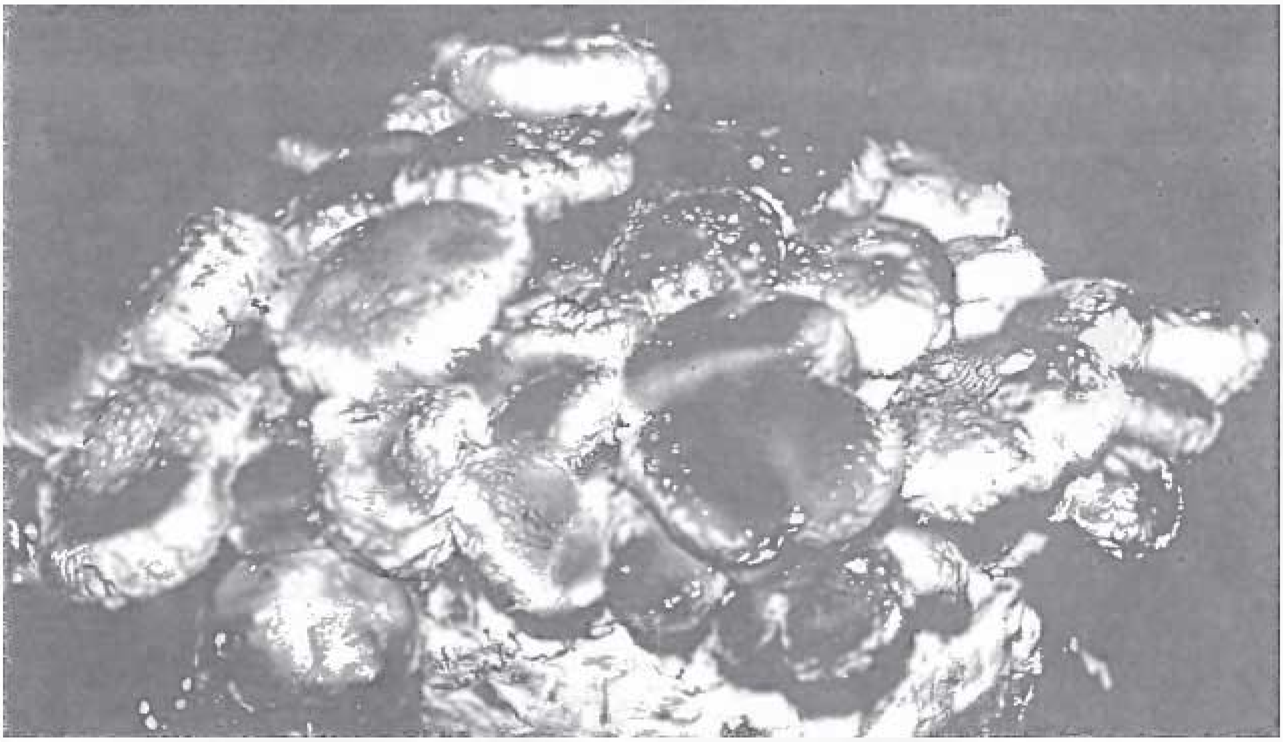

Figure 108 - Photograph of shiitake mushrooms growing on a sawdust block.

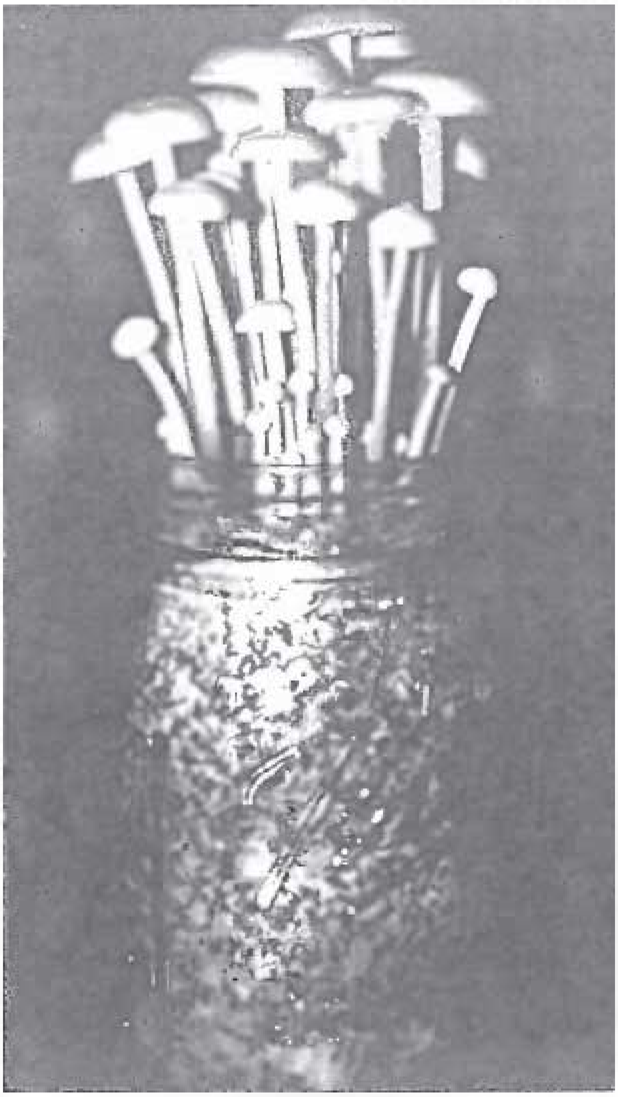
The substrate can be filled into a number of different containers. Mason jars, polypropylene jars or high density, heat-resistant polyethylene bags are commonly employed. The containers are closed and sealed with a microporous filter. They are sterilized at 15 psi for 60-90 minutes. After sterilization the containers are cooled to ambient temperature and inoculated. The inoculum can be either grain spawn or sawdust-bran spawn.

During incubation substrate filled plastic bags can be molded to the desired cropping form. Common shapes are round mini-logs or rectangular blocks. Some *Pleurotus* growers mold the sawdust substrate into a cylindrical shape, 6-8 inches long and 4-5 inches in diameter. The fully colonized "logs" are stacked together on their sides with the ends exposed as the cropping surfaces. An alternative is to slit the bag lengthwise in four places, exposing the substrate to air while retaining the plastic as a humidity hood. If growing in jars, *Flammulina* and *Pleurotus* fruit from the exposed surface at the mouth of the jars.



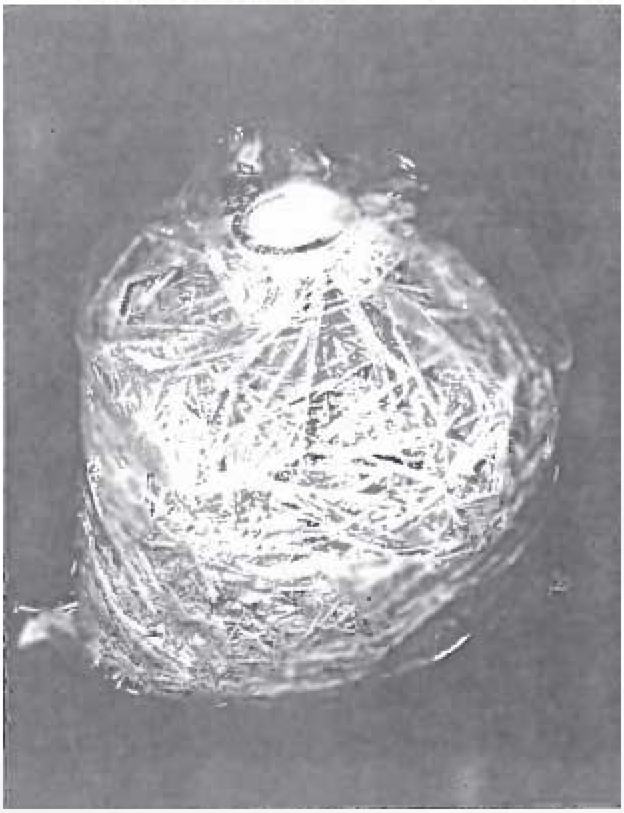


Figure 109 - *Flammulina velutipes*, the Enoke Mushroom, fruiting in mason jar containing sawdust mixture.

Figure 110 - Autoclavable plastic bag and microporous filter disc, known in the Orient as the Space Bag.

Growing on Pasteurized Straw

In commercial mushroom production one of the most frequently used substrate materials is cereal straw. Not only does straw form the basis for mushroom composts, but it is also used uncomposted as the sole ingredient for the growth of various mushroom species. Although all types of straw are more or less suitable, most growers use wheat because of its coarse fiber and its availability. The straw should be clean, free from molds and unspoiled by any preliminary decomposition. Preparation simply involves chopping or shredding the dry straw into 1-3 inch pieces. This can be done with a wood chipper, a garden compost shredder or a power mower. The shredding increases moisture absorption by expanding the available surface area. Shredding also increases the density of the substrate mass.

The chopped straw is treated by pasteurization which can be carried out with live steam or hot water. Presoaked to approximately 75% water, the straw is filled into a tunnel or steam room as described in the corn posting chapter. It is steamed for 2-4 hours at 140-150°F., then cooled to 80°F. and spawned. An alternative program calls for 12-24 hours at 122°F. after the high temperature pasteurization. This program is designed to promote beneficial microbial growth giving the straw a higher degree of selectivity for mushroom mycelium.

The method best suited to the home cultivator is the hot water bath. Figure 111 illustrates a simple system utilizing a 55 gallon drum and a propane burner. The drum is half filled with water that is then heated to 160-170°F. Chopped dry straw is placed into the wire mesh basket and submerged in the hot water. (A weight is needed to keep the straw underwater.) After 30-45 minutes the straw is removed from the water and allowed to drain. It is very important to let all loose water run off.

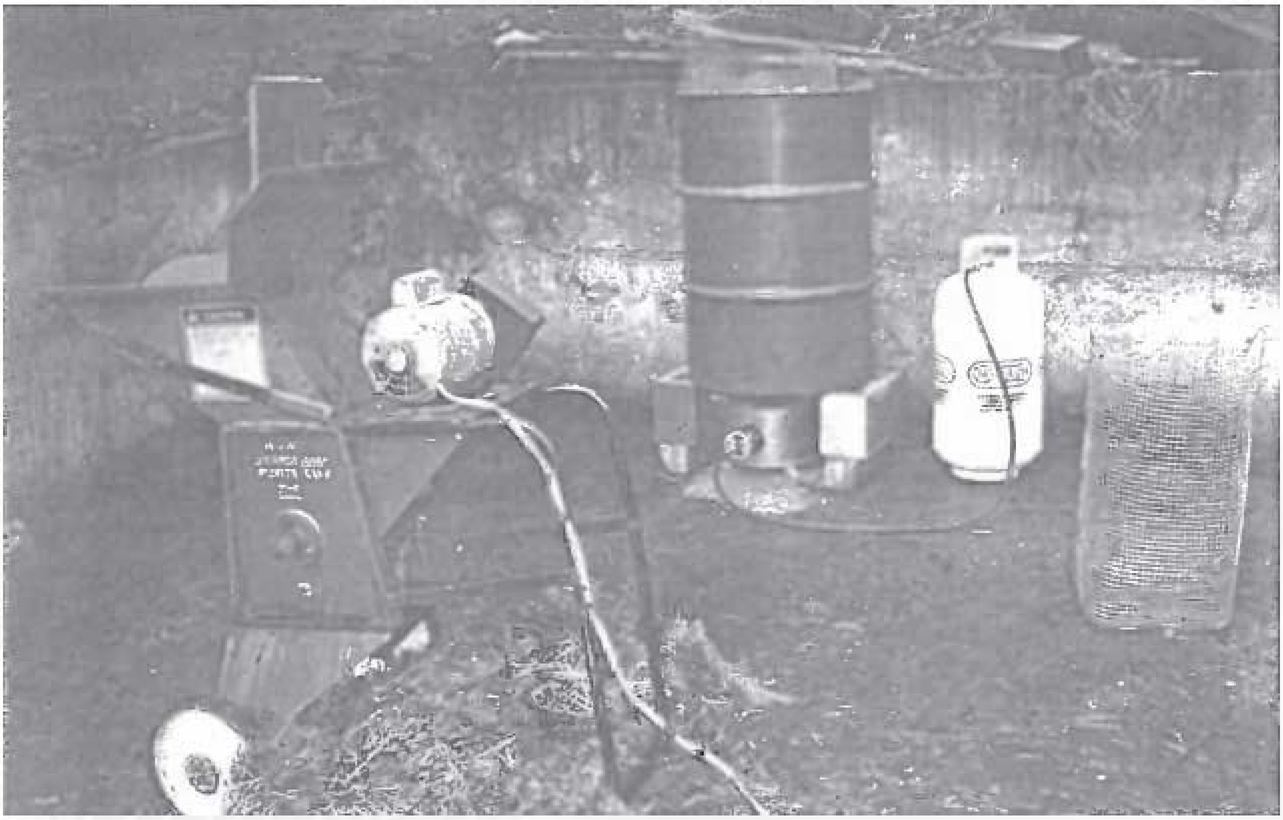

Figure 111 - Equipment needed for pasteurization of straw: 55 gallon drum; gas burner; shredder; hardware cloth basket and straw.

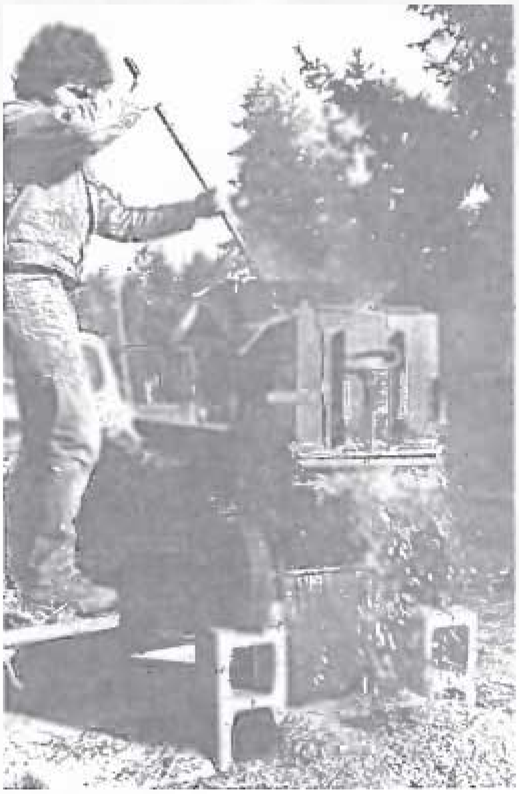

Figure 112 - Shredding the straw.

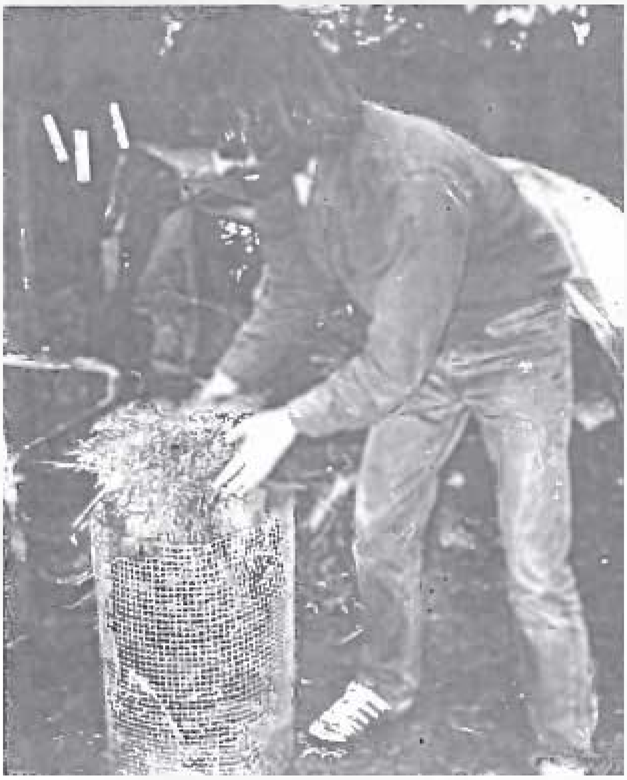

Figure 113 - Filling the shredded straw into the wire basket.

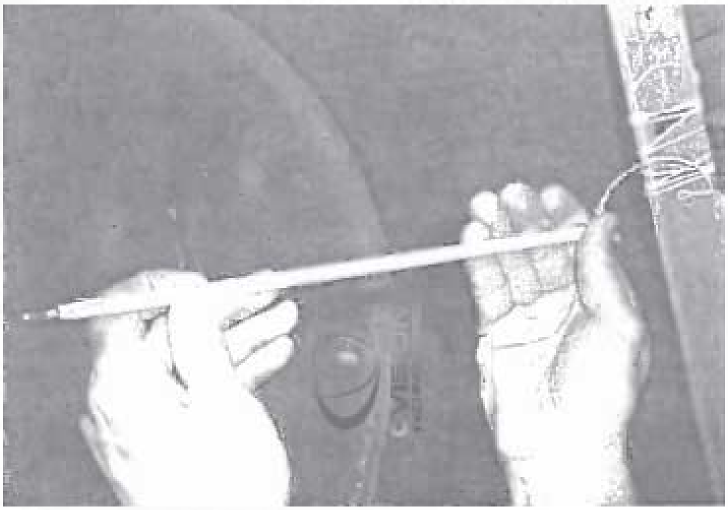

Figure 114 - Checking the water temperature.

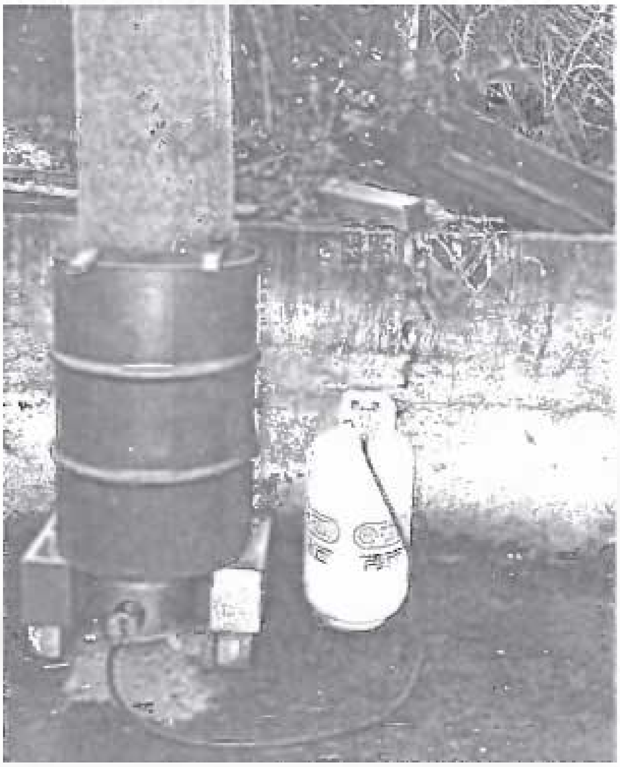

Figure 115 - Draining the pasteurized straw.

Once drained, the straw is spread out on a clean surface and allowed to cool to 80°F. (or less), at which point it can be spawned. The straw is evenly mixed with spawn and filled into trays, shelves or plastic bags. Some compression of the straw into the container is desirable because the cropping efficiency will be increased.

The use of plastic bags is a simple and efficient way to handle straw substrates. A five gallon bag (1-2 mils thick) is well suited to most situations. Two dozen nail sized holes equally spaced around the bags provide aeration. Upon full colonization, the mycelia of species like *Pleurotus ostreatus* and *Psilocybe cubensis* actually hold the straw together, at which time the bag can be completely removed. Another alternative is to perforate or strip the bag from the top or side to allow easy cropping.

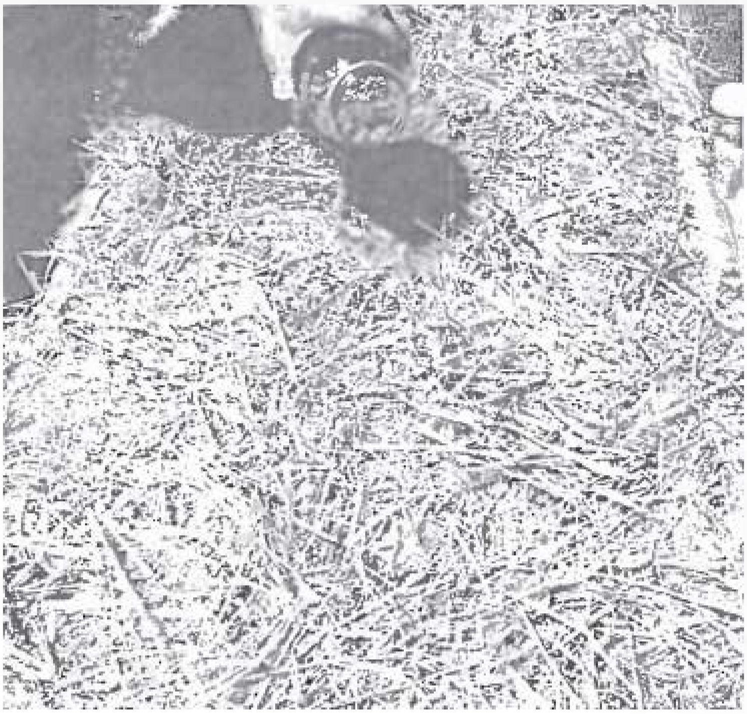

Figure 116 - Inoculating grain spawn onto the cooled pasteurized straw.

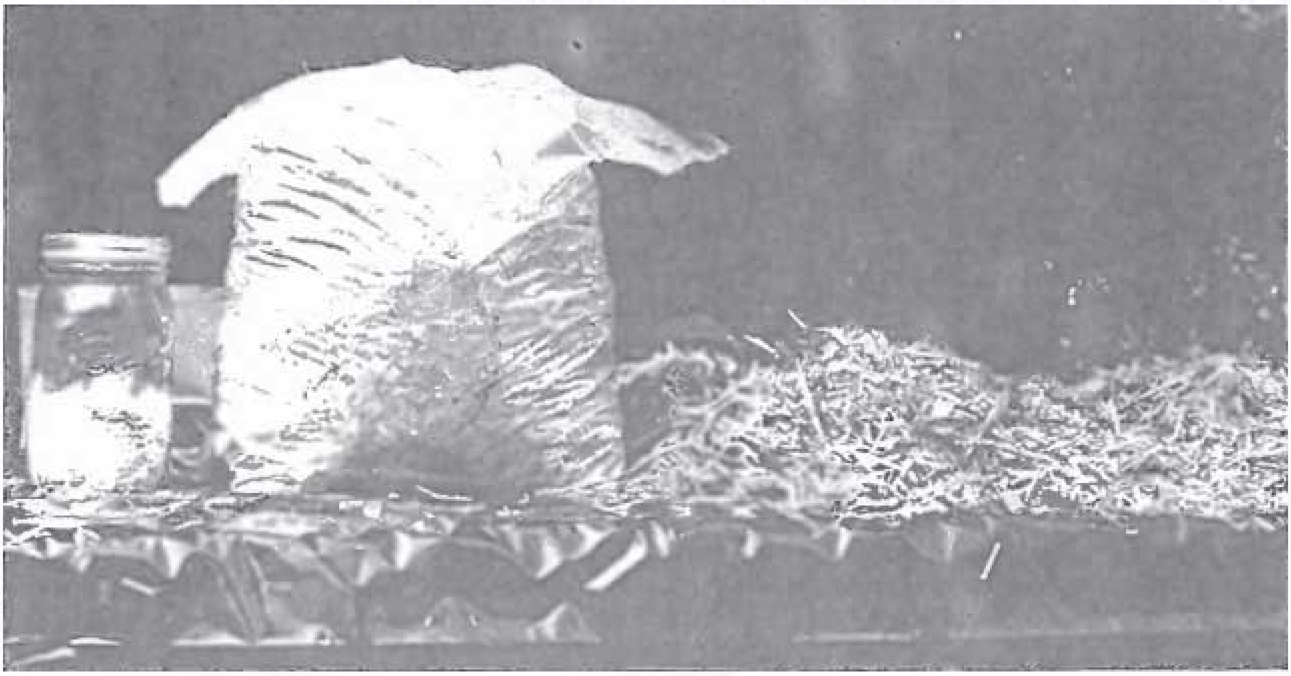

Figure 117 - Pasteurized straw stuffed into plastic bags which are then perforated with nail size holes.

Wheat straw prepared and pasteurized in this manner can be used to grow *Pleurotus ostreatus, Stropharia rugoso-annulata, Panaeolus cyanescens* and *Psilocybe cubensis*. It is quite possible that other species can utilize this substrate or a modification of it. Studies with *Pleurotus ostreatus* have demonstrated yield increases with the addition of 20% grass meal prior to substrate pasteurization. Supplementation of the straw after a full spawn run is another method of boosting yields (See Chapter VII). Bono (1978) obtained a yield increase of 85% with *Pleurotus flabellatus* by adding cottonseed meal to the fully colonized straw. The optimum rate of addition was 132 grams per kilogram of dry straw (approximately 22 grams crude protein per kilogram straw). Bono also found that supplementation increased the protein content and intensified the flavor of the mushrooms.

VII. SPAWNING AND SPAWN RUNNING IN BULK SUBSTRATES

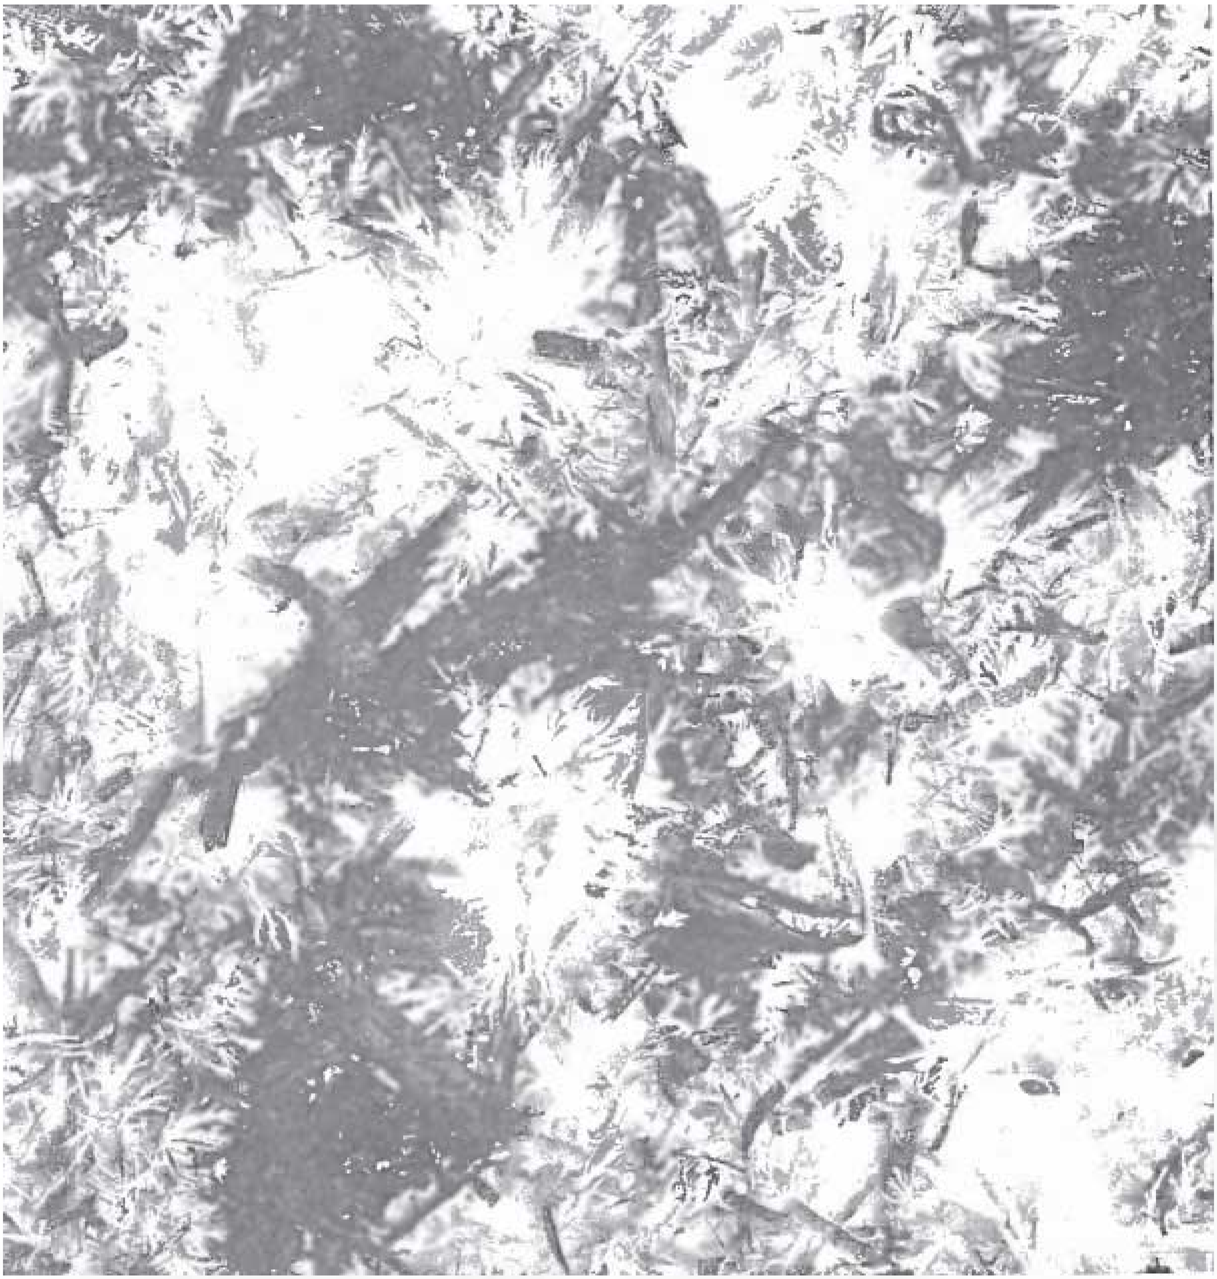

Figure 118 - Mycelium running through compost.

The inoculation of compost or bulk substrates is called spawning. The colonization of these substrates by the mushroom mycelium is known as spawn running. At spawning and during spawn running there are several factors that must be considered if yields are to be maximized. These factors are:

1. Moisture content of the substrate.
2. Temperature of the substrate.
3. Dry weight of the substrate per square foot of cropping surface.
4. Duration of spawn running.

Moisture Content

Mushroom mycelium does not grow in a substrate that is either too dry or too wet. A dry substrate produces a fine wispy mycelial growth and poor mushroom formation because the water essential for the transport and assimilation of nutrients is lacking. On the other hand, an over-wet substrate inhibits mycelial growth and produces overly stringy mycelia. Controlled experiments with *Agaricus brunnescens* grown on horse manure composts have shown yield depressions when the moisture content deviates more than 2% from the optimum. Deviations greater than 5% generally result in a spawn run that does not support fruitbody production. A dry compost at spawning should be lightly watered and mixed well to guard against the formation of wet spots. For an over-wet compost the common procedure is to add gypsum until the loose water is bound.

Substrate Temperature

Since mushroom mycelium grows within the substrate, the substrate temperature must be monitored closely. Thermometers are placed both in the center of the substrate - the hottest region - and in the room's atmosphere. These two thermometers establish a temperature differential. If the hottest point in the substrate is 80°F. and the air is 70°F. then the temperature of the total mass must lie within this range.

The optimum temperature for mycelial growth varies depending on the mushroom species. *Agaricus brunnescens* grows fastest at 77°F. whereas *Psilocybe cubensis* prefers 86°F. Temperatures higher or lower simply slow mycelial growth. The growth curve shown in Figure 119 illustrates the effect of temperature on the growth of *Agaricus brunnescens* mycelium. Note that growth slows at a faster rate as the temperature rises above the optimum. Therefore the object during spawn running is to keep the substrate within the temperature range that is optimal for the fastest growth of mycelium.

Dry Weight of Substrate

Other factors aside, the dry weight of substrate per square foot of cropping surface largely determines total yield. Commercial *Agaricus* growers aim for at least five pounds of dry weight of compost per square foot and sometimes compress up to eight pounds per sq. ft. into their containers. Cropping efficiencies are calculated by dividing total yield per square foot into the dry weight of one square foot of the substrate. Thus a yield of four pounds per sq. ft. of freshly picked mushrooms divided by five pounds dry weight of substrate equals an 80% cropping efficiency. Efficiencies of 80-100% are considered to be close to the maximum yield potential of *Agaricus brunnescens*.

The actual amount of substrate that can be compacted into one square foot of growing area and managed depends upon the cooling capabilities of the control system as well as the outside temperature. Experiments using tracer elements in mushroom beds three feet deep have shown that nutrients from the farthest point are transported to the growing mushrooms. Yields per sq. ft. increased although at a lower substrate efficiency.

During spawn running the metabolism of the growing mycelium generates tremendous quantities of heat. Substrate temperatures normally reach a peak on the 7th-9th days after spawning and can easily reach 90°F. At this temperature thermophilic microorganisms become active, thereby increasing the possibilities of further heat generation. The substrate can easily soar above 100°F. and a compost can actually rise again to conditioning temperatures. Temperatures between 95-110°F. can kill the mycelium of many mushrooms. Even if the mycelium is not completely killed, these temperatures do irreversible harm to mycelial vitality and fruiting potential. These elevated temperatures also stimulate the activity of competitor molds and may render the substrate unsuitable for further mushroom growth. Because of the enhanced heat generating capabilities of deeply filled beds, *Agaricus* growers rarely fill more than 12 inches of compost into the beds.

The decision on how deep to fill the spawned substrate is an important one. Here again, the ratio of substrate to free air space in the growing room is significant. (See Chapter IV). An efficient method of spawn running is to the fill trays 6-8 inches deep with compost and stack them closely together in the room. In this manner the heat generated within each tray remains controllable, while at the same time the total compost heat will be sufficient to heat the room. Outside air temperature as well as the capacity of the heating and cooling equipment should determine how many substrate filled containers can be placed within a given space. Fresh air is generally used to provide cooling except when it is warmer than the room temperature.

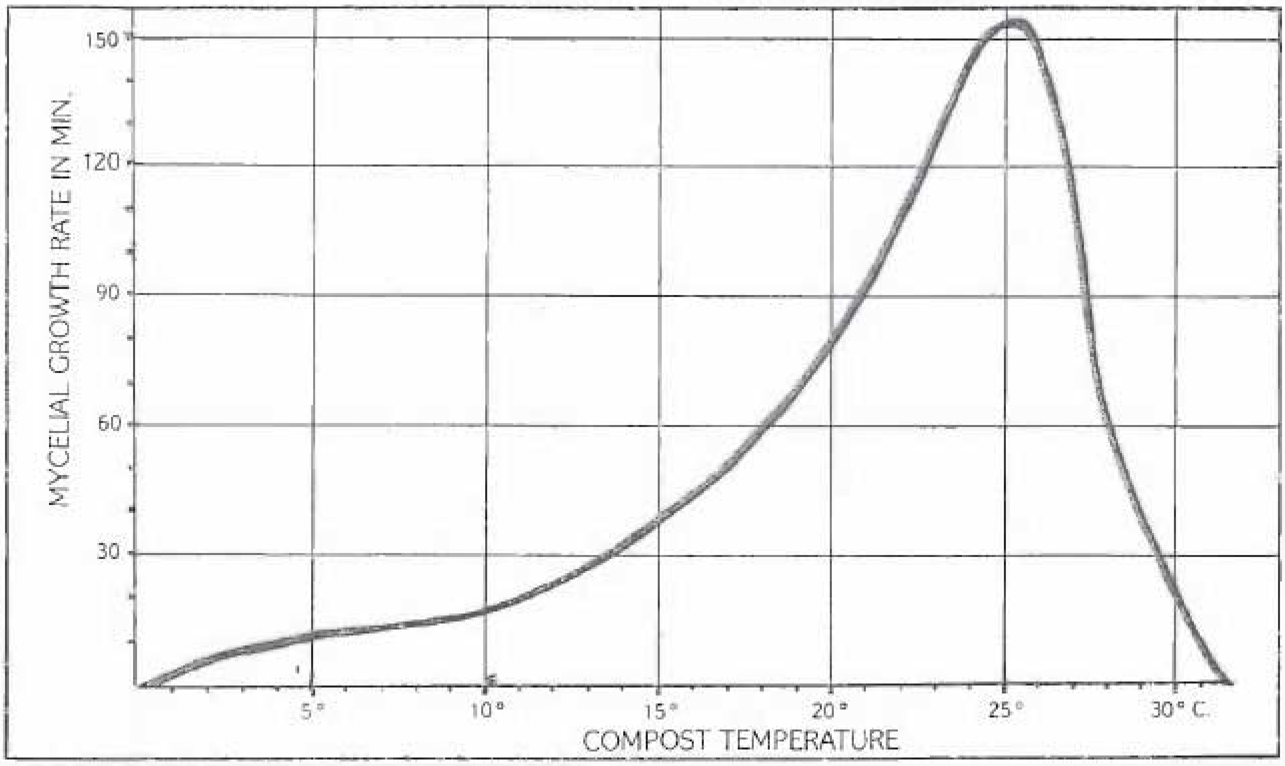

Figure 119 - Growth curve of *Agaricus brunnescens* on compost.

Duration of Spawn Run

Once colonization is complete, the substrate should be cased, or if casing is not used, it should be switched to a fruiting mode. If spawn running is continued beyond this point, valuable nutrients that could be utilized for production of fruitbodies will be consumed by further vegetative growth. If for some reason the cropping cycle must be delayed, the substrate should be cooled until a more opportune time.

Spawning Methods

Spawning methods, like spawn itself, have evolved over the years. As late as 1950 *Agaricus brunnescens* growers customarily planted walnut sized pieces of manure spawn or kernels of grain spawn in holes poked into the compost at regular intervals. Using this method spawn running was slow, and areas far from the inoculum were more susceptible to invasion by competitors. The full potential of grain spawn was not realized until the development of "mixed spawning". The principle of mixed spawning is the complete and thorough mixing of the grain kernels throughout the substrate. In this manner all parts of the substrate are equally inoculated, resulting in the most rapid and complete colonization possible.

The standard spawning rate used by *Agaricus* growers is seven liters/ton of compost or one quart/8 sq. ft. If spawn is readily available and cheap, it is advantageous to use high spawning rates which lead to more rapid colonization. It is also advantageous to break up the grain spawn into individual kernels the day before spawning. If the spawn is fresh, the grain should break apart easily. If the spawn can not be used when fresh, it should be refrigerated at 38°F.

The basic principle of spawn running is the same regardless of the type of mushroom or substrate. COLONIZATION MUST PROCEED AS RAPIDLY AS POSSIBLE TO PREVENT OTHER ORGANISMS FROM BECOMING ESTABLISHED. Once the mushroom mycelium becomes dominant, natural antibiotics secreted into the substrate inhibit competitors. To prevent invasion by competitors it is important that spawning take place under carefully controlled hygienic conditions. Fungus gnats in particular must be excluded, and for this purpose a tight, well sealed working area is best. This area and all tools should be disinfected one day prior to spawning with a 10% bleach solution. When using disinfectants be sure your skin is protected and avoid breathing any fumes.

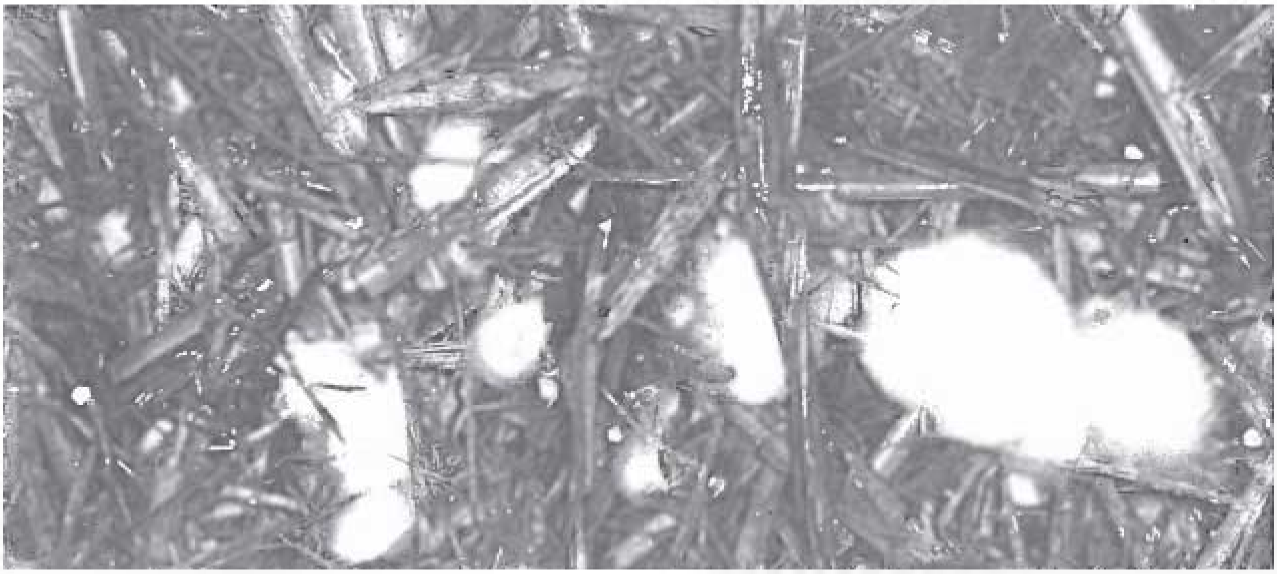

Figure 120 - *Psilocybe semilanceata* mycelium running through pasteurized wheat straw.

If the substrate has been filled into shelves, the spawn is broadcast over the surface and mixed in with a pitchfork or by hand. With trays, a similar method can be used, or alternatively, the substrate can be dumped out on a clean surface, mixed with spawn and then replaced in the trays. Substrates from a bulk room are removed, mixed with spawn and then placed into the chosen container.

It is common procedure to level and compress the substrate to avoid dehydration caused by excessive air penetration. The degree of compression depends upon substrate structure. Long, airy materials can be compacted more than short, dense ones. Commercial tray growers compact the compost into the trays with a hydraulic press so that the compost surface resembles a table top. This enables the application of an even casing layer.

Environmental Conditions

The required environmental conditions for spawn running are very specific and must be closely monitored. Substrate temperatures are controlled by careful manipulation of the surrounding air temperature. Heating and cooling equipment are helpful but not absolutely essential unless the outside climate is extreme. A well insulated room with provisions for fresh air entrance and exhaust air exit should be adequate for most situations. The steady or periodic recirculation of room air by means of a small fan helps to keep an even temperature throughout the room and guards against localized over-heating, especially in the uppermost containers. Humidity is extremely important at this time and must be held at 90-100%. If the humidity falls below this level, water evaporates from the substrate surface to the detriment of the growing mycelium. Humidification can be accomplished by steam humidifiers or by cold water misters. If steam is used, care must be taken that the increase in air temperature does not drive the substrate temperature above the optimal range. One common method of counteracting drying is to cover the substrate with plastic. Be ready to remove the covering during the period of peak activity if temperatures rise too quickly.

During spawn run the mushroom mycelium generates large quantities of carbon dioxide. In fact, it has been demonstrated that mushroom mycelium is capable of CO_2 fixation. Because of this ability to absorb CO_2, room concentrations of 10,000-15,000 ppm are considered beneficial and desirable. A CO_2 level high enough to stop growth is uncommon under normal circumstances. Being heavier than air, CO_2 settles at the bottom of the room, which is yet another reason for even air circulation within the growing environment.

Super Spawning

Super spawning is also called "active mycelium spawning" vis á vis the Hunke-Till process. Essentially, a set amount of substrate is inoculated and colonized in the normal manner. The fully run substrate is then used as inoculum to spawn increased amounts of a similar substrate. One could theoretically pyramid a small quantity of inoculum into a considerable amount of fully colonized substrate. This technique requires the primary substrate to be contaminant free; otherwise contamination, not mycelium, will be propagated. The possibilities inherent in this method may be of greater application when transferring naturally occurring mycelial colonies to non-sterile yet mushroom specific substrates. An excellent example of this is the propagation of *Psilocybe cyanescens* on wood chips. (See Chapter VI.)

Supplementation at Spawning

One of the newest advances in *Agaricus* culture is the development of delayed release nutrients added to the compost at spawning. These supplements are specially formulated nutrients encapsulated in a denatured protein coat. They are designed to become available to the growing mushrooms during the first three flushes. The application rate is 5-7% of the dry weight of the substrate. Yield increases of ½ to 1 lb/sq. ft. are normal. Here again, complete and thorough mixing is essential to success. Caution: these materials enrich the substrate, making it more suitable to contaminants if factors predisposing to their growth are present. (For suppliers of delayed release nutrients, refer to the resource section in the Appendix).

Supplementation at Casing (S.A.C.)

SACing is another method used to boost the nutritional content of the substrate. The materials used are soy bean meal, cottonseed meal, and/or ground rye, wheat or kafir corn grains. The fully colonized substrate is thoroughly mixed with any one of these materials at a rate of 10% of the dry weight of the substrate. The substrate and the supplements must both be clean and free from contaminants; otherwise contamination will spread and threaten the entire culture. High substrate temperatures should be anticipated on the second to third day after supplementation. With this type of nutrient enhancement yield increases of ½-2 lbs/sq. ft. are possible.

VIII. THE CASING LAYER

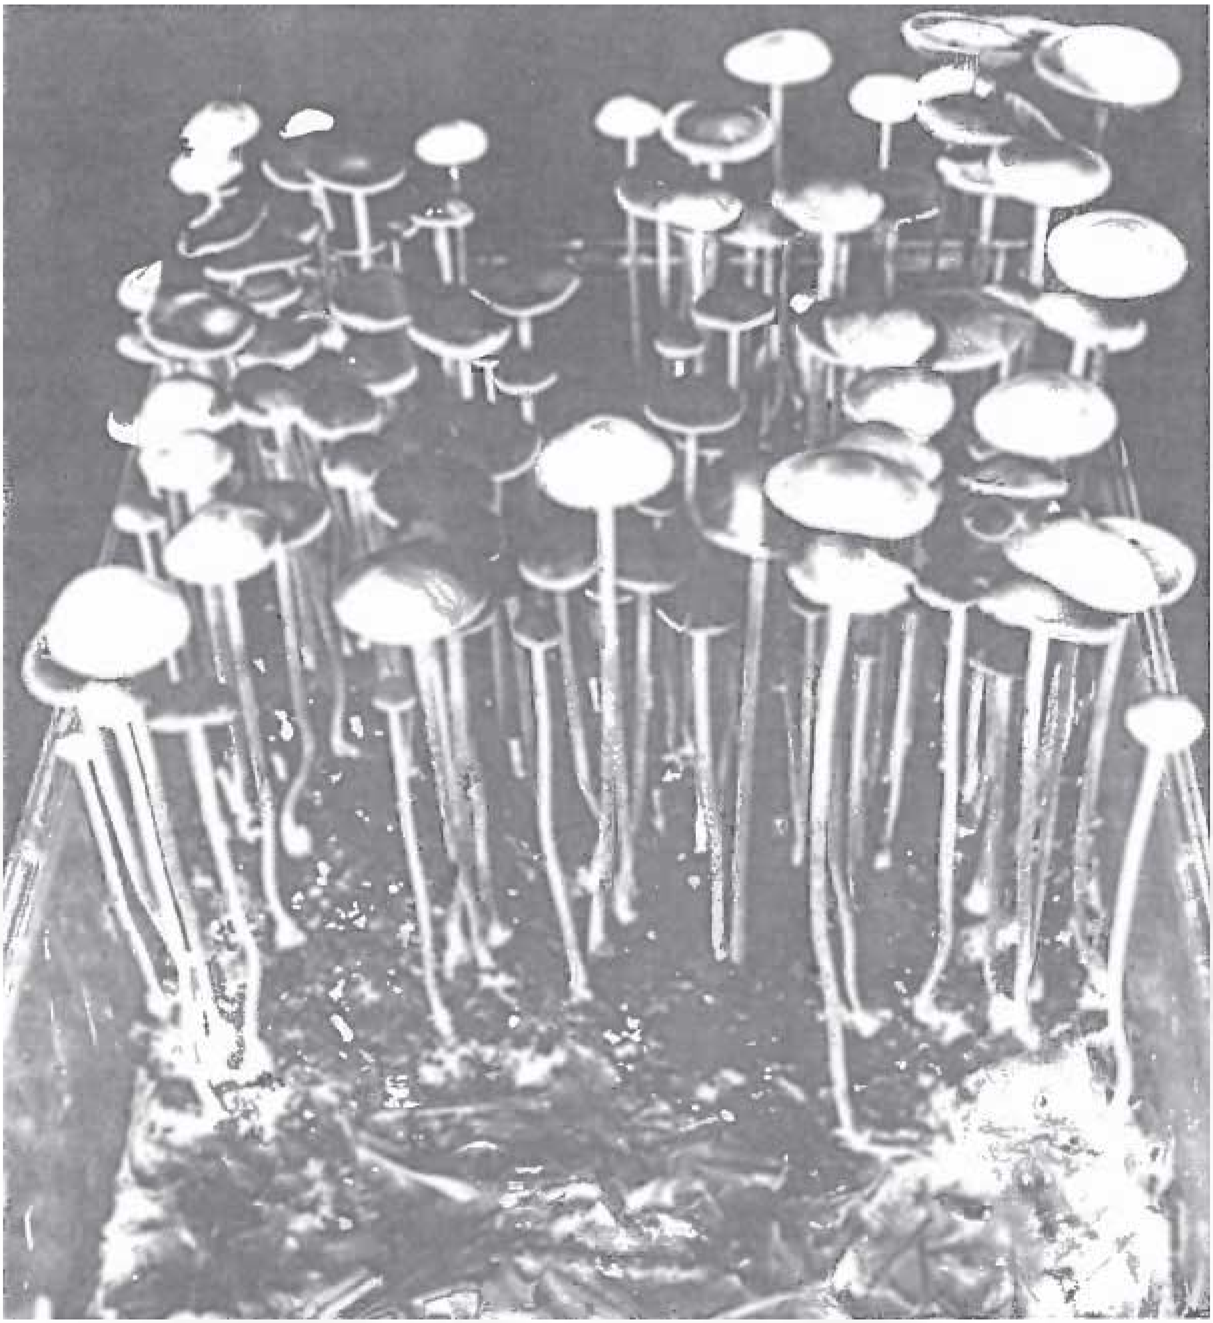

Figure 121 - *Panaeolus cyanescens* fruiting in tray of pasteurized straw. Note mushrooms formed only on cased half.

Covering the substrate surface with a layer of moist material having specific structural characteristics is called **casing**. This practice was developed by *Agaricus* growers who found that mushroom formation was stimulated by covering their compost with such a layer. A casing layer encourages fruiting and enhances yield potential in many, but not all, cultivated mushrooms.

In all species where the use of a casing has been indicated as optional, yields are clearly enhanced with the application of one. The chart above [below] refers to the practical cultivation of mushrooms in quantity. It excludes fruitings on nutrified agar media or on other substrates that produce but a few mushrooms. Consequently, casing has become an integral part of the mushroom growing methodology.

SPECIES	CASING OPTIONAL	CASING REQUIRED	CASING NOT REQUIRED

Psilocybe tampanensis		■	
Stropharia rugoso-annulata		■	
Volvariella volvacea			■

Functions

The basic functions of the casing layer are:

1. **To protect the colonized substrate from drying out**.
   Mushroom mycelium is extremely sensitive to dry air. Although a fully colonized substrate is primarily protected from dehydration by its container (the tray, jar or plastic bag), the cropping surface remains exposed. Should the exposed surface dry out, the mycelium dies and forms a hardened mat of cells. By covering the surface with a moist casing layer, the mycelium is protected from the damaging effects of drying. Moisture toss from the substrate is also reduced.

2. **To provide a humid microclimate for primordia formation and development**.
   The casing is a layer of material in which the mushroom mycelium can develop an extensive, healthy network. The mycelium within the casing zone becomes a platform that supports formation of primordia and their consequent growth into mushrooms. It is the moist humid microclimate in the casing that sustains and nurtures mycelial growth and primordia formation.

3. **To provide a water reservoir for the maturing mushrooms**.
   The enlargement of a pinhead into a fully mature mushroom is strongly influenced by available water, without which a mushroom remains small and stunted. With the casing layer functioning as a water reservoir, mushrooms can reach full size. This is particularly important for heavy flushes when mushrooms are competing for water reserves.

4. **To support the growth of fructification enhancing microorganisms**.
   Many ecological factors influence the formation of mushroom primordia. One of these factors is the action of select groups of microorganisms present in the casing. A casing prepared with the correct materials and managed according to the guidelines outlined in this chapter supports the growth of beneficial microflora.

Properties

The casing layer must maintain mycelial growth, stimulate fruiting and support continual flushes of mushrooms. In preparing the casing, the materials must be carefully chosen according to their chemical and physical properties. These properties are:

1. **Water Retention**: The casing must have the capacity to both absorb and release substantial quantities of water. Not only does the casing sustain vegetative growth, but it also must supply sufficient moisture for successive generations of fruitbodies.

2. **Structure**: The structure of the casing surface must be porous and open, and remain so despite repeated waterings. Within this porous surface are small moist cavities that protect developing primordia and allow metabolic gases to diffuse from the substrate into the air. If this surface microclimate becomes closed, gases build up and inhibit primordia formation. A closed surface also reduces the structural cavities in which primordia form. For these reasons, the retention of surface structure directly affects a casing's capability to form primordia and sustain fruitbody production.

3. **Microflora**: Recent studies have demonstrated the importance of beneficial bacteria in the casing layer. High levels of bacteria such as *Pseudomonas putida* result in increased primordia formation, earlier cropping and higher yields. During the casing colonization period these beneficial bacteria are stimulated by metabolic gases that build up in the substrate and diffuse through the casing. In fact, dense casing layers and deep casing layers generally yield more mushrooms because they slow diffusion. It is desirable therefore to build-up CO_2 and other gases prior to primordia formation. (For a further discussion on the influence of bacteria on primordia formation, see Appendix II.)
   The selection of specific microbial groups by mycelial metabolites is an excellent example of symbiosis. These same bacteria give the casing a natural resistance to competitors. In this respect, a sterilized casing lacks beneficial microorganisms and has little resistance to contaminants.

4. **Nutritive Value**: The casing is not designed to provide nutrients to developing mushrooms and should have low nutritional value compared to the substrate. A nutritive casing supports a broader range of competitor molds. Wood fragments and other undecomposed plant matter are prime sites for mold growth and should be carefully screened out of a well formulated casing.

5. **pH**: The pH of the casing must be within certain limits for strong mycelial growth. An overly acidic or alkaline casing mixture depresses mycelial growth and supports competitors. *Agaricus brunnescens* prefers a casing with pH values between 7.0-7.5. Even though the casing has a pH of 7.5 when first applied, it gradually falls to a pH of nearly 6.0 by the end of cropping due to acids secreted by the mushroom mycelium. Buffering the casing with limestone flour is an effective means to counter this gradual acidification. The optimum pH range varies according to the species. (See the growing parameters for each species in Chapter XI.)

6. **Hygienic Quality**: The casing must be free of pests, pathogens and extraneous debris. Of particular importance, the casing must not harbor nematodes or insect larvae.

Materials

To better understand how a casing layer functions requires a basic understanding of soil components and their specific structural and textural characteristics. When combined properly, the soil components create a casing layer that is both water retentive and porous.

1. **Sand**: Characterized by large individual particles with large air spaces in between, sandy soils are well aerated. Their structure is considered "open". Sandy soils are heavy, hold little water and release it quickly.

2. **Clay**: Having minute individual particles bound together in aggregations, clay soils have few air pockets and are structurally "closed". Water is more easily bound by clay soils.

3. **Loam**: Loam is a loose soil composed of varying proportions of sand and clay, and is characterized by a high humus content.

Agaricus growers found that the best type of soil for mushroom growing was a clay/loam. The humus and sand in a clay/loam soil open up the clay which is typically dense and closed. The casing's structure is improved while the property of particle aggregation is retained. The humus/clay combination holds moisture well and forms a crumbly, well aerated casing.

There are two basic problems with using soils for casing-the increased contamination risk from fungi and nematodes, and the loss of structure after repeated waterings. Cultivators can reduce the risk of contamination by pasteurization, a process whereby the moistened casing soil is thoroughly and evenly steamed for two hours at 160°F. An alternative method is to bake the moist soil in an oven for two hours at 160°F.

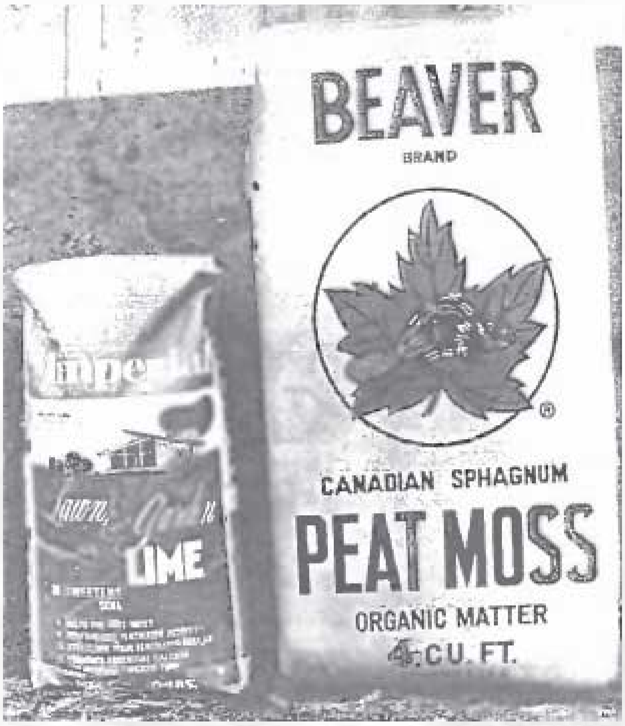

Figure 122 - Sphagnum peat and limestone flour needed for casing.

The development of casings based on peat moss has practically eliminated the use of soil in mushroom culture. Peat is highly decomposed plant matter and has a pH in the 3.5-4.5 range. Since this acidic condition precludes many contaminants from colonizing it as a substrate, peat is considered to be a fairly "clean" starting material. Peat based casings rarely require pasteurization. But because peat is too acidic for most mushrooms, the addition of some form of calcium buffering agent like limestone is essential. "Liming" also causes the aggregation of the peat particles, giving peat a structure similar to a clay/loam soil. A coarse fibrous peat is preferred because it holds its structure better than a fine peat. In essence, the properties of sphagnum peat conform to all the guidelines of a good casing layer.

Buffering agents are used to counter the acidic effects of peat and other casing materials. Calcium carbonate ($CaCO_3$) is most commonly used and comes in different forms, some more desirable than others.

1. **Chalk**: Used extensively in Europe, chalk is soft in texture and holds water well. Chunks of chalk, ranging from one inch thick to dust, improve casing structure and continuously leach into the casing, giving long lasting buffering action.

2. **Limestone Flour**: Limestone flour is calcitic limestone mined from rock quarries and ground to a fine powder. It is the buffering agent most widely used by *Agaricus* growers in the United States. Limestone flour is 97% $CaCO_3$ with less than 2% magnesium.

3. **Limestone Grit**: Produced in a fashion similar to limestone flour, limestone grit is rated according to particle size after being screened through varying meshes. Limestone grit is an excellent structural additive but has low buffering abilities. A number 9 grit is recommended.

4. **Dolomitic Limestone**: This limestone is rarely used by *Agaricus* growers due to its high magnesium content. Some researchers have reported depressed mycelial growth in casings high in magnesium.

5. **Marl**: Dredged from dry lake bottoms, marl is a soft lime similar to chalk but has the consistency of clay. It is a composite of clay and calcium carbonate with good water holding capacity.

6. **Oyster Shell**: Comprised of calcium carbonate, ground up oyster shell is similar to limestone grit in its buffering action and its structural contribution to the casing layer. But oyster shell should not be used as the sole buffering agent because of its low solubility in water.

Material	Absorption Potential milliliters water/gram	% Water at Saturation
Vermiculite	5.0	84%
Peat	2.5	79%
Potting Soil	0.7	76%
Loam	0.3	25%
Chalk	0.6	37%
Limestone Grit	0.2	15%
Sand	0.2	18%
Values vary according to source and quality of material used. (Tests run by the authors.)		

Casing Formulas and Preparation

The following casing formulas are widely used in *Agaricus* culture. With pH adjustments they can be used with most mushroom species that require a casing. Measurement of materials is by volume.

FORMULA 1	FORMULA 2
Coarse peat: 4 parts	Coarse peat: 2 parts
Limestone flour: 1 part	Chalk or Marl: 1 part
Limestone grit: ½ part	Water: Approximately 1-1¼ parts
Water: Approximately 2-2¼ parts	

One half to one part coarse vermiculite can be added to improve the water retaining capacity of these casing mixtures and can be an aid if fruiting on thinly laid substrates. When used, it must be presoaked to saturation before being mixed with the other listed ingredients.

An important reference point for cultivators is the moisture saturation level of the casing. To determine this level, completely saturate a sample of the casing and allow it to drain. Cover and wait for one half hour. Now weigh out 100 grams of it and dry in an oven at 200°F. for two to three hours or until dry. Reweigh the sample and the difference in weight is the percent moisture at saturation. This percentage can be used to compare moisture levels at any point in the cropping cycle. Optimum moisture content is normally 2-4% below saturation. Typically, peat based casings are balanced to a 70-75% moisture content.

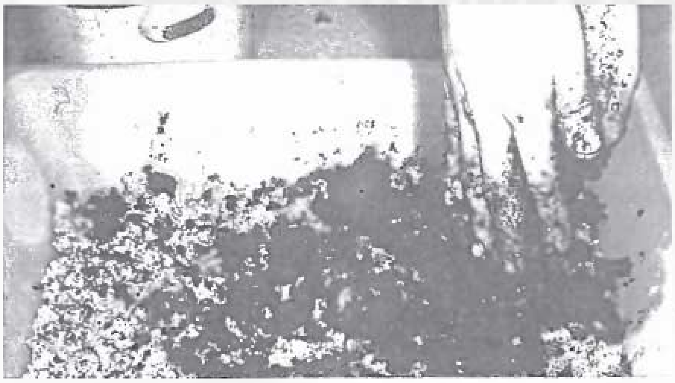
Application

To prepare a casing, assemble and mix the components while in a dry or semi-dry state. Even distribution of the limestone buffer is important with a thoroughly homogeneous mixture being the goal. When these materials have been sufficiently mixed, add water slowly and evenly, bringing the moisture content up to 90% of its saturation level. There is an easy method for preparing a casing of proper moisture content. Remove 10-20% of the volume of the dry mix and then saturate the remaining 80-90%. Then add the remaining dry material. This method brings the moisture content to the near optimum. (Some growers prefer to let the casing sit for 24 hours and fully absorb water. Prior to its application, the casing is then thoroughly mixed again for even moisture distribution.)

At this point apply the casing to the fully run substrate. Use a pre-measured container to consistently add the same volume to each cropping unit.

1. **Depth**: The correct depth to apply the casing layer is directly related to the depth of the substrate. Greater amounts of substrate increase yield potential which in turn puts more stress on the casing layer. Prolific first and second flushes can remove a thin casing or damage its surface structure, thereby limiting future mushroom production. A thin casing layer also lacks the body and moisture holding capacity to support large flushes. AS A GENERAL RULE, THE MORE MUSHROOMS EXPECTED PER SQUARE FOOT OF SURFACE AREA, THE DEEPER THE CASING LAYER.
   Agaricus growers use a minimum of one inch and a maximum of two inches of casing on their beds. Substrate depths of six to eight inches are cased 1¼ to 1½ inches deep. Substrates deeper than 8 inches are cased 1½ to 2 inches deep. Nevertheless, experiments in Holland using casing depths of 1 inch and 2 inches demonstrated that the deep casing layer supported higher levels of microorganisms and produced more mushrooms. (See Visscher, 1975). To gain the full benefits of a casing layer, an absolute minimum depth on bulk substrates is 1 inch. For fruiting on sterilized grain, the casing need not be as deep as for fruitings on bulk substrates. Shallow layers of grain are commonly cased ¾ to 1 inch deep.

2. **Evenness**: The casing layer should be applied as evenly as possible on a level substrate surface. An uneven casing depth is undesirable for two reasons: shallower regions can easily be overwatered, thereby stifling mycelial growth; and secondly, the mycelium breaks through the surface at different times, resulting in irregular pinhead formation. When applying the casing to large areas, "depth rings" can be an effective means to insure evenness. These rings are fabricated out of flat metal or six inch PVC pipe, cut to any depth. They are placed on the substrate and covered with the casing, which is then leveled using the rings as a guide. Once the casing is level and even, the rings are removed.
   Although the casing layer must be even, the surface of the casing should remain rough and porous, with small "mountains and valleys". The surface structure is a key to optimum pinhead formation and will be discussed in more detail in the next chapter.



Figures 123, 124 & 125 - Casing a tray of grain spawn. First the fully colonized grain is carefully broken up and evenly distributed into the tray. As an option, a layer of partially moistened vermiculite can be placed along the bottom of the tray to absorb excess water. If the grain appears to have uncolonized kernels, cover the container with plastic and let the spawn recover for 24 hours before casing. Otherwise, casing can proceed immediately after the spawn has been laid out.

Casing Colonization

Environmental conditions after casing should be the same as during spawn running. Substrate temperatures are maintained within the optimum range for mycelial growth; relative humidity is 90-100%; and fresh air is kept to a minimum. (Fresh air should only be introduced to offset over-heating). The build-up of CO_2 in the room is beneficial to mycelial growth and is controlled by an airtight room and tightly sealed fresh air damper. If the entrance of fresh air cannot be controlled, a sheet of plastic should be placed over the casing. This plastic sheet also prevents moisture loss from the casing.

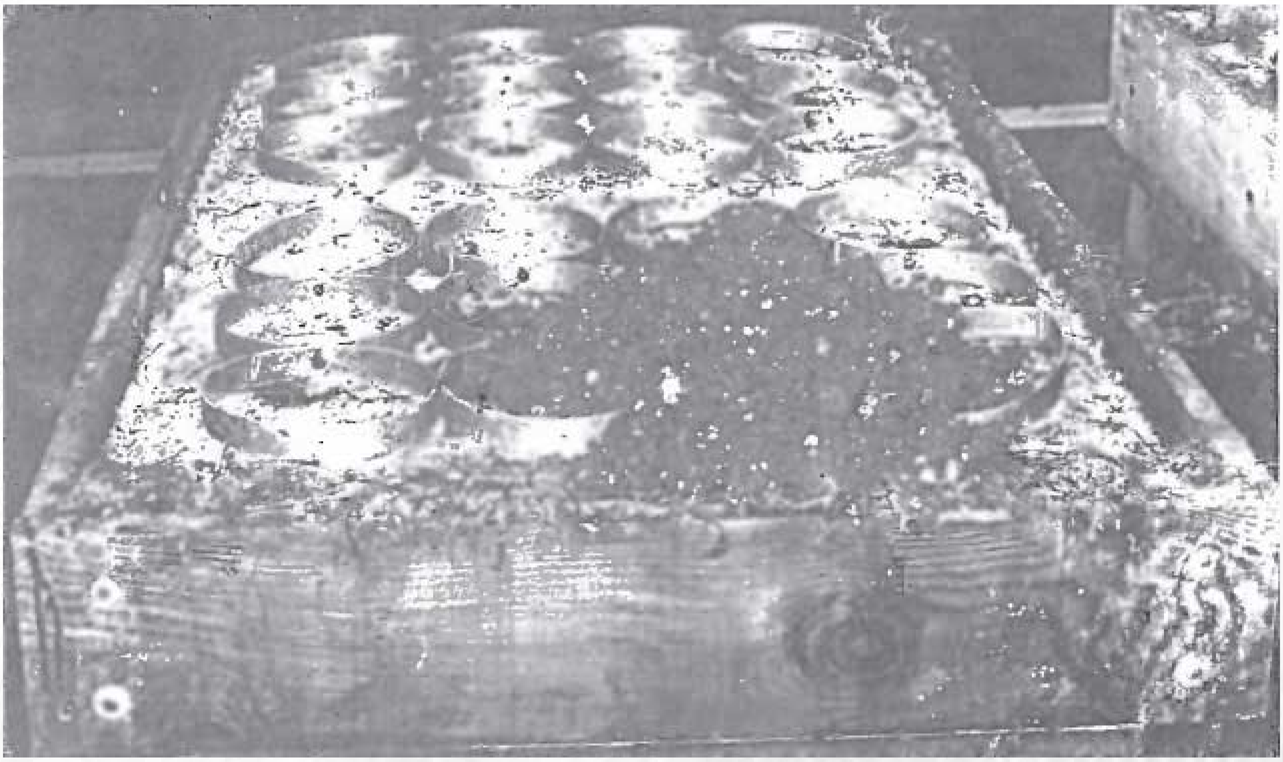


Figure 126 - Depth rings used for even casing application on bulk substrates.

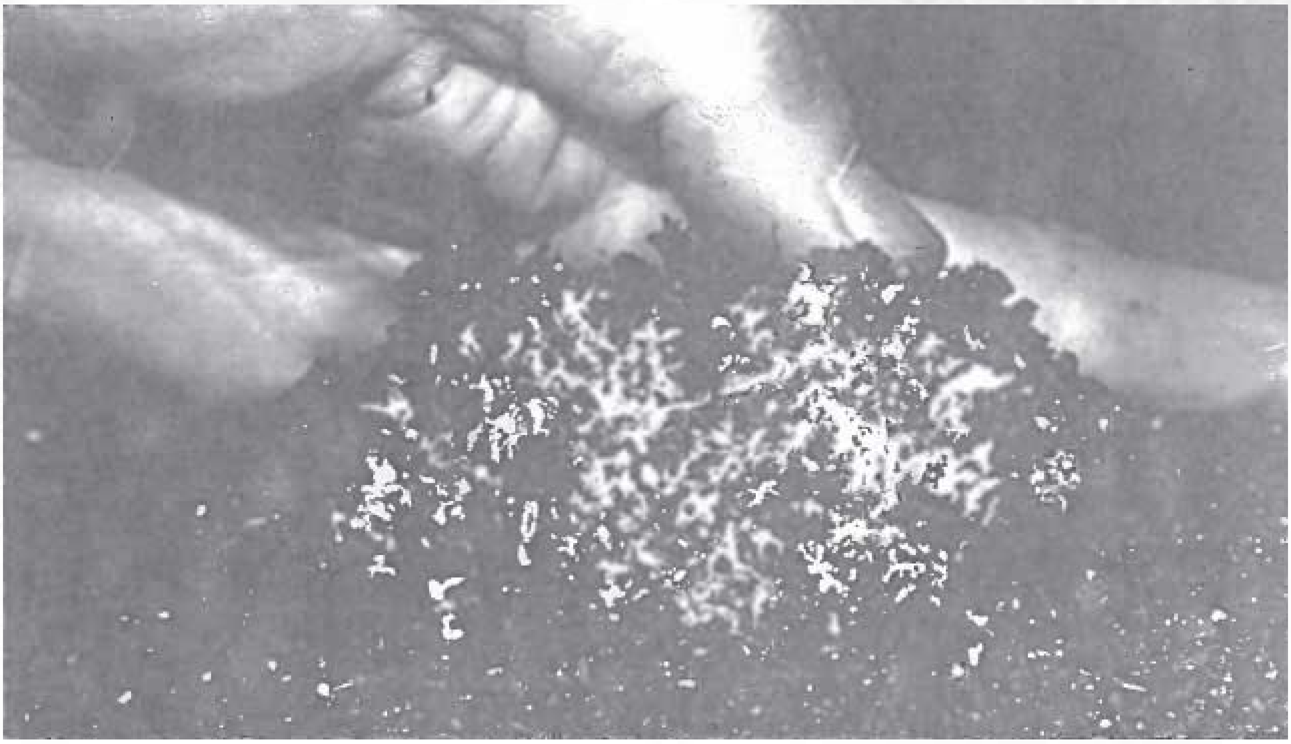

Figure 127 - Mycelial growth (*Agaricus brunnescens*) into casing with optimum moisture.

Soon after casing, substrate temperatures surge upward due to the hampered diffusion of metabolic gases which would normally conduct heat away. This surge is an indication of mycelial vitality and is a positive sign if the room temperature can be controlled. This temperature rise can be anticipated by lowering either the temperature of the substrate prior to casing or lowering the air temperature of the room after casing.

Within three days of application, the mycelium should be growing into the casing layer. Once mycelial growth is firmly established, the casing is gradually watered up to its optimum moisture holding capacity. This is accomplished by a series of light waterings with a misting nozzle over a two to four day period (depending upon the depth of the casing). Deeper casings require more waterings. Optimum moisture capacity should be achieved at least two days before the mycelium reaches the surface. IT IS EXTREMELY IMPORTANT THAT THE WATERINGS DO NOT DAMAGE THE SURFACE STRUCTURE OF THE CASING. Heavy direct watering can "pan" the casing surface, closing all the pore spaces and effectively sealing it. The growing mycelium is then trapped within the casing layer and may not break through it at all. The ultimate example of panning is a soil turned to mud.

To repair a casing surface damaged by watering, the top ¼ inch can be reopened by a technique called "scratching". The tool used is simply a 1 x 2 x 24 inch board with parallel rows of nails (6 penny) slightly offset relative to one another. With this "scratching stick", the casing is lightly ruffled prior to the mycelium breaking through to the surface. After the surface has been scratched, the casing should be given its final waterings prior to pinning.

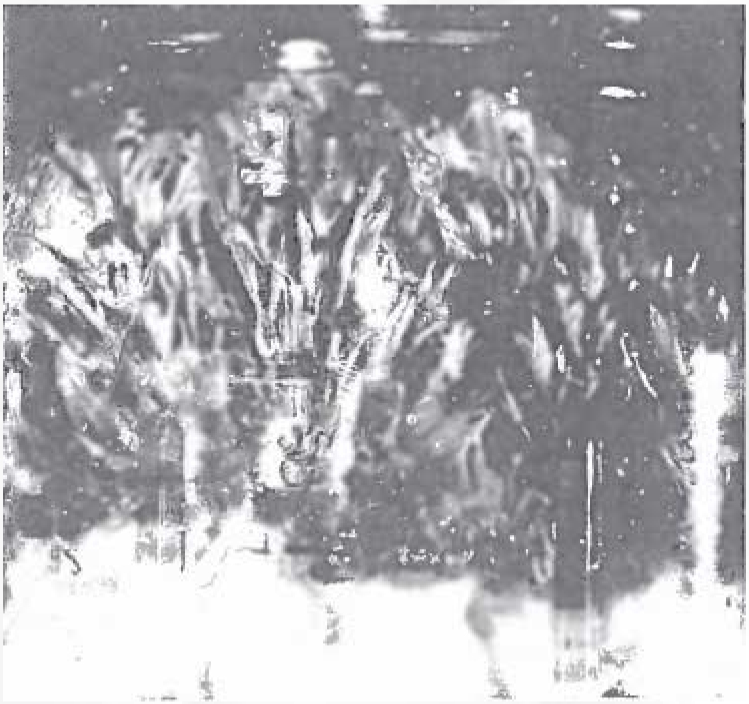

Figure 128 - Mycelial growth (*Psilocybe cubensis*) into casing with optimum moisture.

A modified application of this technique is "deep scratching". When the mycelium is midway through the casing, the entire layer is thoroughly ruffled down to the bulk substrate. The agitated and broken mycelium rapidly reestablishes itself and within three to four days it completely colonizes the casing. The result is an early, even and prolific pinhead formation. Before using this technique, the grower must be certain that the substrate and casing are free of competitor molds and nematodes.

Casing Moisture and Mycelial Appearance

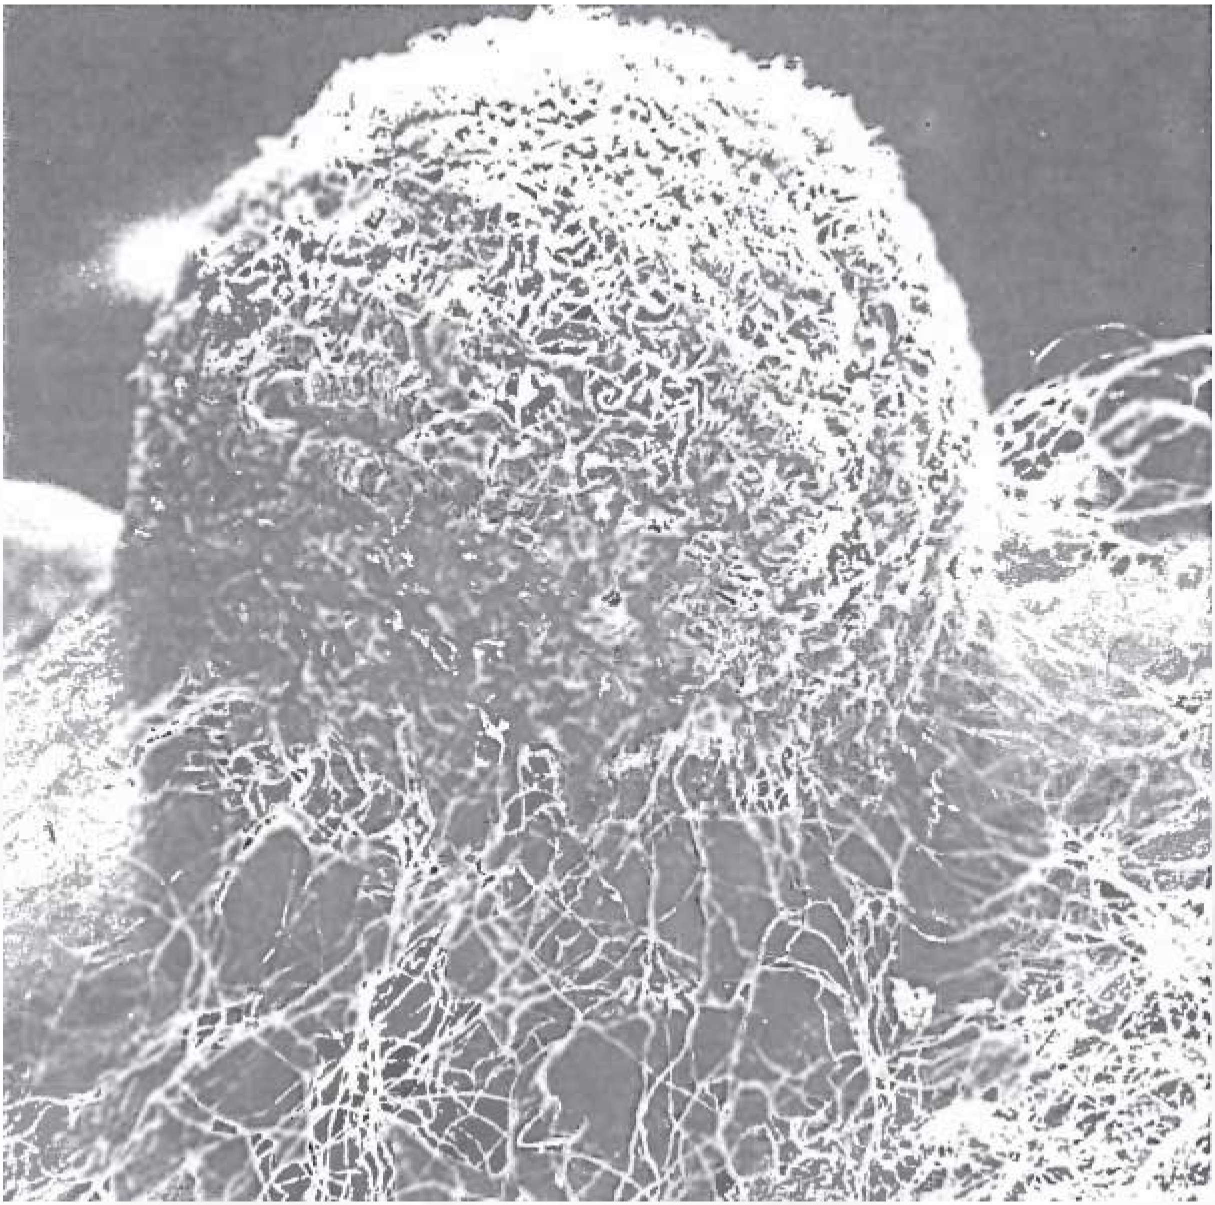
Moisture within the casing layer has a direct effect on the diameter and degree of branching in growing mycelium. These characteristics are indicators of moisture content and can be used as a guide to proper watering.

1. **Optimum Casing Moisture**: Mushroom mycelium thrives in a moist humid casing, sending out minute branching networks. These networks expand and grow, absorbing water, CO_2 and oxygen from the near saturated casing. This mycelial growth is characterized by many thick, white rhizomorphic strands that

branch into mycelia of smaller diameters and correspondingly smaller, finer capillaries. The overall aspect is lush and dense. When a section of casing is examined, it is held firmly together by the mycelial network but will separate with little effort. The casing itself remains soft and pliable.

2. **Overly dry casing**: In a dry casing, the mycelium is characterized by a lack of rhizomorphs and an abundance of fine capillary type mycelia. This fine growth can totally permeate the casing layer, which then becomes hard, compact and unreceptive to water. It is common for puddles to form on a dry casing that has just been watered. Also, a dry casing rarely permits primordia formation because of its arid microclimate and is susceptible to "overlay". Mushrooms, if they occur, frequently form along the edges of the tray.
   Overlay is a dense mycelial growth that covers the casing surface and shows little or no inclination to form pinheads. Overlay directly results from a dry casing, high levels of CO_2 and/or low humidity. (See Chapter IX on pinhead initiation)
3. **Overly Wet Casing**: In a saturated casing, the mycelium grows coarse and stringy, with very little branching and few capillaries. Mycelial growth is slow and sparse which leaves the casing largely uncolonized. Often the saturated casing leaches onto the substrate surface which then becomes waterlogged, inhibiting further growth and promoting contamination. Subsequent drying may eventually reactivate the mycelium, but a reduction in yield is to be expected.

IX. STRATEGIES FOR MUSHROOM FORMATION (PINHEAD INITIATION)



Fiqure 129 - Scanning electron micrograph of *Psilocybe cubensis* primordia.

The change from the vegetative state of mycelial growth to the generative one of primordia formation is called pinning, pin setting, pinhead initiation or fructification. Primordia or pinheads are knots of mycelium that precede development into small mushrooms. All species require a set of environmental conditions for pinning that are quite different from the conditions for mycelial growth. By understanding the factors that regulate this change in the mushroom life cycle, the cultivator can control the pinning process.

In nature primordia formation is primarily influenced by seasonal changes in environmental conditions. In temperate climates most mushrooms fruit during the cool, wet fall whereas in tropical and subtropical climates mushrooms fruit during the rainy season. The fruiting period ends when the season changes and environmental conditions become too hot, too cold or too dry. The mycelium then lies dormant or grows slowly, reactivated only by the warming of spring and summer. These seasons are times for the mycelium to expand its network, absorb nutrients and rebuild its energy reserves. Once the cool wet conditions of fall return, these reserves are used to support another crop of mushrooms.

Basic Pinning Strategy

Mushrooms fruit indoors in response to much the same conditions that trigger fruiting in the wild. Several environmental factors, working in combination, provide an ideal environment in which mushrooms flourish. Most, if not all cultivated mushrooms fruit at lower temperatures than the optimum for the growth of mycelium. Usually, a drop in temperature is accompanied by rain or an increase in humidity. Water is essential for the absorption of nutrients by the mycelium. And vaporous water creates the humid microclimate that is so critical for the developing primordia. Primordia have a low tolerance to CO_2 and need ample fresh air. And while the mycelium has no requirement for light, many species need light to initiate pinheads and to mature into healthy mushrooms. Mushrooms form only when there is a coincidence of all these factors. Cultivators create an artificial environment that prolongs these optimum conditions so that mushrooms are given the best possible environment in which to grow.

Primordia formation strategies are well defined for species now under cultivation. These procedures are similar in their approach and differ only in certain environmental requirements. Given that the substrate has sufficient nutrients, the interaction of water, humidity, temperature, fresh air, CO_2 and light all play determining roles in the fructification process. (In some cases, specific microorganisms must be present before fruiting can occur). The modification of any one of these factors beyond the fruiting requirements can inhibit or stop the process. Hence, the cultivator must have precise control over conditions within the growing room if this critical phase is to be carried out successfully.

Primordia Formation Procedures

Agaricus brunnescens culture illustrates the interplay of environmental factors in pinhead initiation. It serves as a useful model for setting primordia in many species, especially those using a casing layer. In each of the following stages, the main considerations are highlighted and then discussed in detail. Although *Agaricus* does not require light, and since most cultivated mushrooms do, this requirement has been listed as the last parameter.

Stage I: Preparation

Following its application, the casing is conditioned to allow even mycelial growth into it. Once mycelial growth is well established, the casing layer microclimate and the growing room are carefully managed to meet the following requirements.

1. The casing layer is at optimum moisture capacity.
2. The casing layer surface is rough and porous.
3. The relative humidity of the growing room's air is 95%.
4. The substrate is incubated in total darkness.

During the casing colonization period, the casing layer is being conditioned for pinhead initiation. Gradually, the moisture content is brought up to the optimum and a microclimate with high relative humidity is carefully maintained. Water in the casing moves by capillary action to the surface where it is drawn into the air by evaporation. This constant movement slowly depletes the casing of the moisture needed to protect pinhead development. Therefore, in conjunction with an optimum casing moisture level, the relative humidity of the room must be held at 95%. Lower humidities must be accompanied by light but regular waterings. The higher the humidity (rH), the less water will be lost to evaporation.

Given optimum moisture conditions in and directly above the casing layer, the next step is to prepare the casing surface. Whether by initial application or by ruffling at a later time, the casing surface should be rough and open - with minute mountains and valleys. A rough open casing has more surface area where pinheads can form, provides a humid environment conducive to that formation and allows the diffusion of metabolic gases.

Stage II: Environmental Transition - The Prelude to Setting Primordia

Pinhead initiation techniques should begin when the mycelium reaches the valleys of the casing surface. Once the mycelium is clearly established in the valleys, the cultivator can begin the first steps leading to the setting of pinheads. Within this one to two day period, the

1. Substrate and air temperatures are lowered to the fruiting range.
2. The humidity is maintained at the 95% level.
3. The carbon dioxide content of the room is reduced by the introduction of fresh air.
4. The room is lighted on a 12 hour on/off cycle.

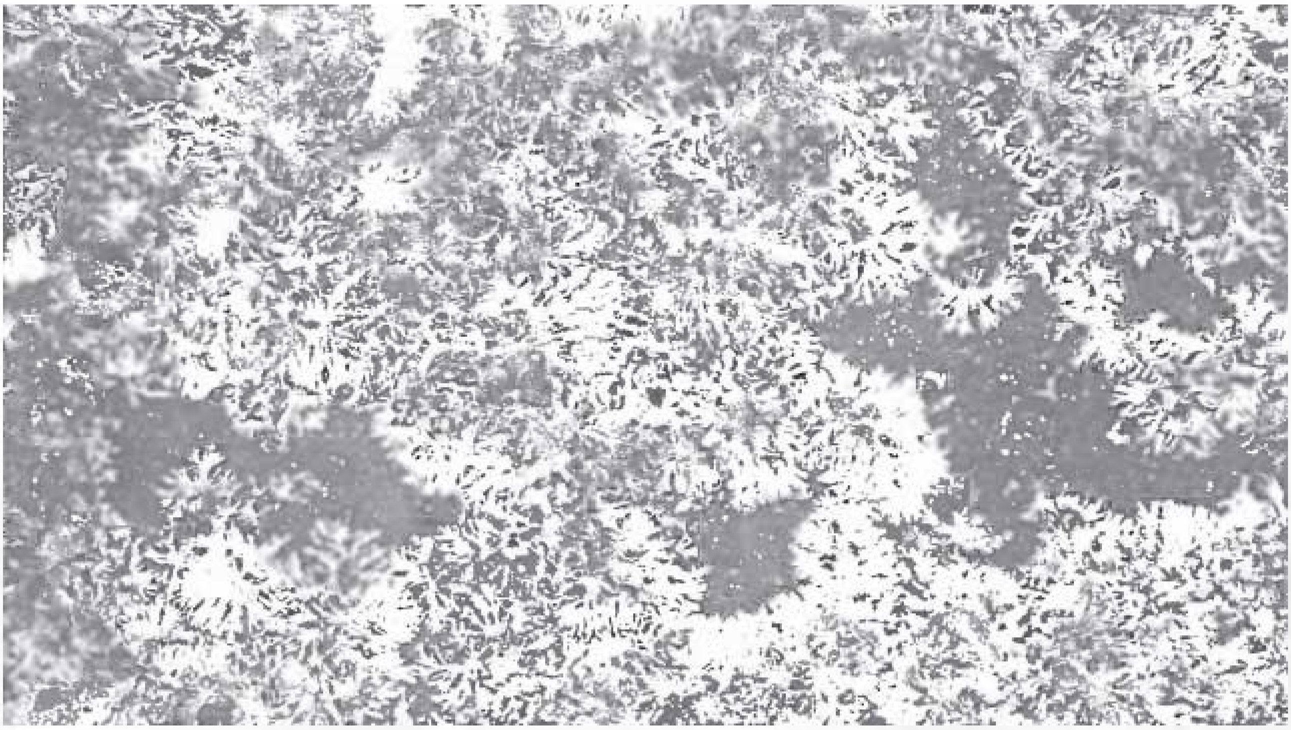


Figure 130 - Overlay.

Mycelium breaking through the casing surface early should be lightly sprinkled with moist casing. Uneven growth through the casing layer is usually an indication of a casing with irregular depths. By "patching" shallow areas, an even mycelial spread is assured. Note that **the more even the distribution of the mycelium in the valleys of the casing's surface, the more even the pin-set and the greater the first and second flushes**.

The exact time for initiation varies with the strain and according to the experience of the individual grower. Some strains continue to grow vegetatively for a period after the initial temperature shock whereas others stop immediately. For this reason, some cultivators initiate when 20% of the valleys show mycelial growth while others wait until 90% are run through with mycelium. Normally within 12-48 hours from the time the mycelium is first visible in the valleys, the initiation sequence is started.

The first step in the pinhead initiation process is to lower the substrate and air temperature from the mycelial growth optimum to the fruiting range. This temperature "shock" is accomplished by ventilation with a large volume of cool fresh air, thereby lowering the room's temperature to a point 5-20° below the optimum for spawn running. (For *Agaricus brunnescens*, this would mean dropping air temperature from 70°F. to 64°F.). Whatever the air temperature may be, the bed temperature is normally several degrees warmer. The length of time needed to affect this change is determined by the total volume of substrate and the temperature of the air being introduced. Within 48 hours, the substrate temperature should fall to fruiting temperatures, effectively slowing vegetative growth. This change signals to the mycelium that it is time to fruit.

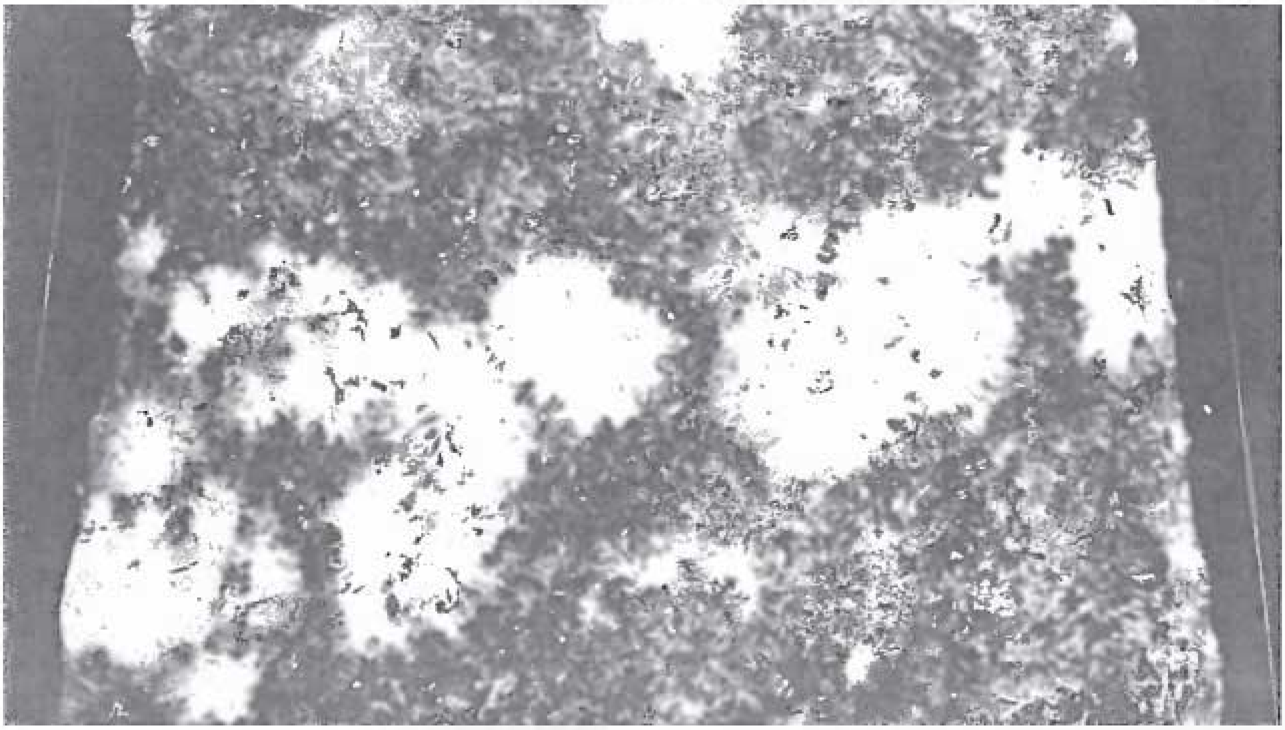

Figure 131 - Cased grain culture of *Agaricus brunnescens* showing overlay and stroma.

Fresh air also removes high concentrations of carbon dioxide and other metabolic gases from the room. Since *Agaricus brunnescens* does not pin properly at CO_2 concentrations above 2000 ppm, lowering the carbon dioxide content of the room's air to under 2000 ppm is critical. The inhibitory effect of carbon dioxide on mushroom formation gives *Agaricus* growers a high degree of control over the pinning process. Not until carbon dioxide is removed will pinheads form. If carbon dioxide levels remain high, the mycelium will totally cover the casing surface, a condition called overlay.

The mycelial mat formed by overlay makes the casing impervious to water and produces few pinheads. Overlay also occurs if the casing surface is too dry, the humidity (rH) is too low or the air temperature remains too high. Overlay can be counteracted by patching, but the cause must be diagnosed and carefully corrected if the culture is to be revived. Few flushes will be as great from a casing with overlay as from a casing properly managed.

Stage III: Primordia Formation (Knotting)

Once substrate temperatures have been lowered and CO_2 levels have been reduced, primordia will begin to form. Maintain:

1. A constant fresh air supply to remove metabolic gases, and CO_2 at levels less than 1000 ppm.
2. A constant temperature in the growing room that is within the fruiting range.
3. A relative humidity of 95%.
4. A 12 hour on/off light cycle.

The combination of temperature drop, high humidity and reduction of metabolic gases by a constant supply of fresh air now provides an environment conducive to pinhead formation. These parameters should be held constant until the pins are set. Any abrupt changes in temperature or humidity will be harmful to primordial growth. Pinhead initials form in the humid valleys of the casing layer and are visible as small knots of mycelium. This is the earliest stage of fruiting. Within five days these knots enlarge into small mounds or buttons that soon differentiate into mushrooms.

Due to slowed mycelial growth in the cooled substrate, carbon dioxide evolution is greatly reduced. Consequently, the fresh air supply can be moderated to the minimum level necessary to maintain 1000 ppm of carbon dioxide. At this time, oversupply of fresh air can lead to high evaporation rates and excessive drying. The humidity should **never** be allowed to fall below 90%. If dry air becomes a problem, a light misting of the casing surface, two to five times daily, should keep the microclimate moist. In fact, some growers knock down the mycelium with a forceful watering on the first day of initiation. Others mist daily as a standard practice. However, once pinning has begun, any forceful watering will kill a number of developing pins, and damage others. Given sufficient casing moisture and a high humidity, these watering practices become unnecessary.

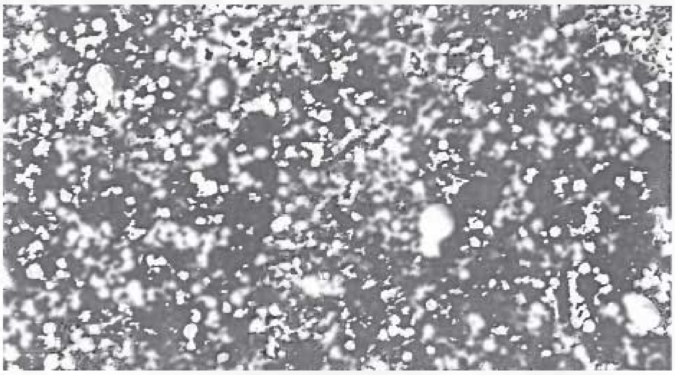
Stage IV: Pinhead Development

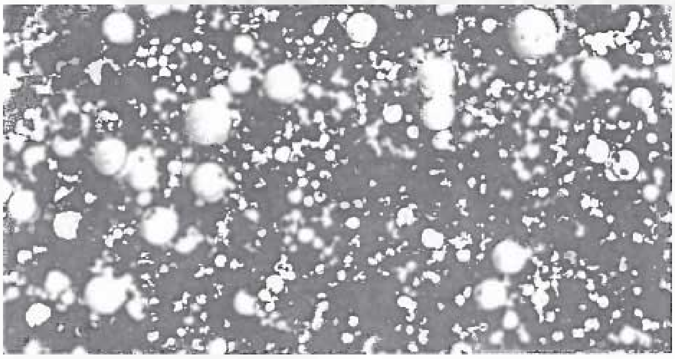
After the pinheads have grown to pea size (3-5 mm.), their further development is primarily dependent on air temperature and relative humidity. To insure that they mature into healthy mushrooms, the

1. Air temperature is held constant within the fruiting range.
2. Relative humidity is lowered to 85-92%.
3. A constant fresh air supply with CO_2 below 2000 ppm.
4. A 12 hour on/off light cycle.

The humidity is lowered to 85-92%, thereby increasing the evaporation rate, an essential requirement for pinhead maturation. If humidity remains too high, pinhead development will be retarded. The easiest way to reduce humidity is to raise the air temperature by 1-2°F. or to increase air movement within the room. Under no circumstances should pockets of stagnant air be allowed to form. Evaporation is negligible in stagnant air pockets which are also excellent breeding grounds for mushroom pathogens.

At this time, a slightly higher level of carbon dioxide is desirable (in the 1500-2000 ppm range) and fresh air can be cut back accordingly. Given proper CO_2 levels, and sufficient evaporation, the pins continue to develop. The exact rate of growth depends on the air temperature in the room. Work done by Lambert (1938) has shown that a pinhead of *Agaricus brunnescens* with a diameter of 2 millimeters fully develops into a mature mushroom in twenty-two days at 50°F., in ten days at 60°F. and in six days at 70°F. Although mushrooms develop more quickly at 70°F., overall yields diminish. Optimum temperature for cropping in *Agaricus brunnescens* is 62-64°F.





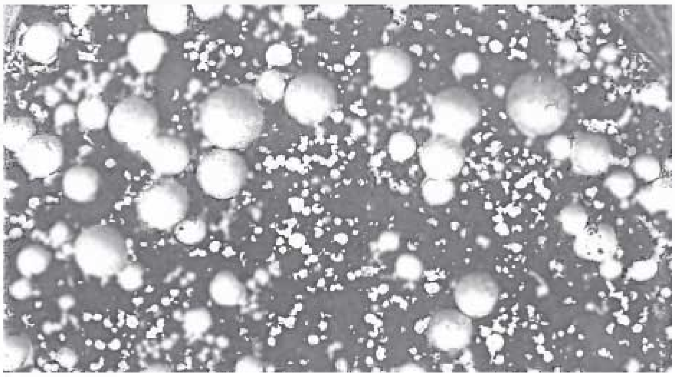


Figure 132, 133 & 134 - Three day pinhead development sequence in *Agaricus brunnescens*. Change-over from Stage III to Stage IV occurs within this time frame.

The Relationship Between Primordia Formation and Yield

The importance of the primordia formation period can not be over-emphasized. For maximum yields an optimum number of pinheads must be set, matured and brought to harvest. Certain relationships exist between the pinning process and yields. These are:

1. **During the primordia formation period, pinheads for the first and second flush are being generated**. The second flush primordia are present as thickened mycelial knots which develop after the first flush is harvested. Once the first flush is off the beds, the second set of primordia begin to enlarge and within days attain button size. Because 60-75% of the total yield is normally harvested from the first two flushes, the few days of pinhead initiation are the most critical in the growing of mushrooms. Hence, all environmental factors must be carefully monitored to insure the best possible pin-set.

2. **The greater the number of pins set for the first flush, the higher the yield**, provided sufficient nutrients are available to support their growth. However, with more pinheads competing for the same nutrient base, the smaller are the mushrooms arising from it. Fewer pinheads result in larger mushrooms, but lower total yields.

3. **The substrate will only support the development of a certain number of primordia per flush**. Under normal circumstances with an even pin-set, pinheads may "abort" because of insufficient nutrients or late formation.

4. **Pins that form early delay the growth of neighboring primordia**. Good examples of this can be found in shallow areas or along the borders of the substrate container. Removing these relatively few "volunteers" before they develop is advantageous to the remaining primordia that constitute the first flush.

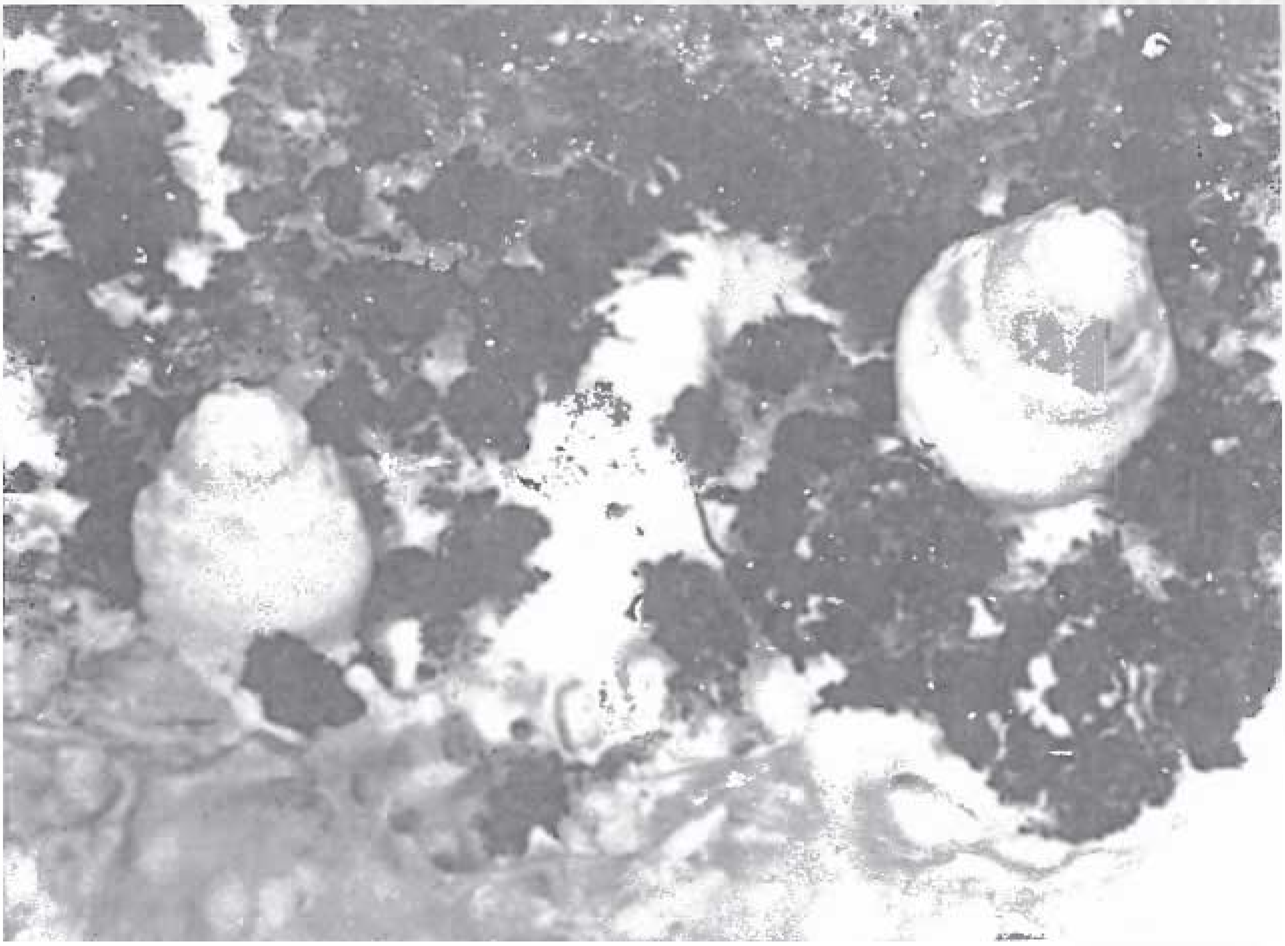

Figure 135 - Three pinheads of *Coprinus comatus* forming on cased section of compost. Note mycelial knot in upper center.

The Influence of Light on Pinhead Initiation

Mushroom species requiring light for primordia formation are said to be **photosensitive**. Although light is not necessary to induce fructification in all mushrooms (i.e. *Agaricus brunnescens*), certain spectra have proven to be stimulatory to pinhead initiation and are critical for the normal development of the fruitbody. *Psilocybe cubensis* and *Pleurotus ostreatus* are two such photosensitive species.

A thorough investigation on the photosensitivity of *Psilocybe cubensis* can be found in a master's thesis by E.R. Badham (1979). His work reinforces the conclusions of other researchers working with the Basidiomycetes: more pinheads are initiated upon exposure to blue and ultra-violet light with distinct peaks at 370, 440 and 460 nanometers. Badham showed that light stimulation at these wavelengths for as little as half a millisecond per day caused primordia to form. In contrast, red, infra-red and green light having wavelengths greater than 510 nanometers were ineffective.

With this knowledge, the cultivator of photosensitive species can develop initiation strategies incorporating the influence of light. Ideally a fully colonized substrate should be incubated in total darkness and exposed to light only after the mycelium first shows through the casing layer. If the cultivator wants to check the culture without the chance of premature pinning, red light is recommended. (The proper location and type of light is discussed in more detail in Chapter IV).

X. ENVIRONMENTAL FACTORS: SUSTAINING THE MUSHROOM CROP

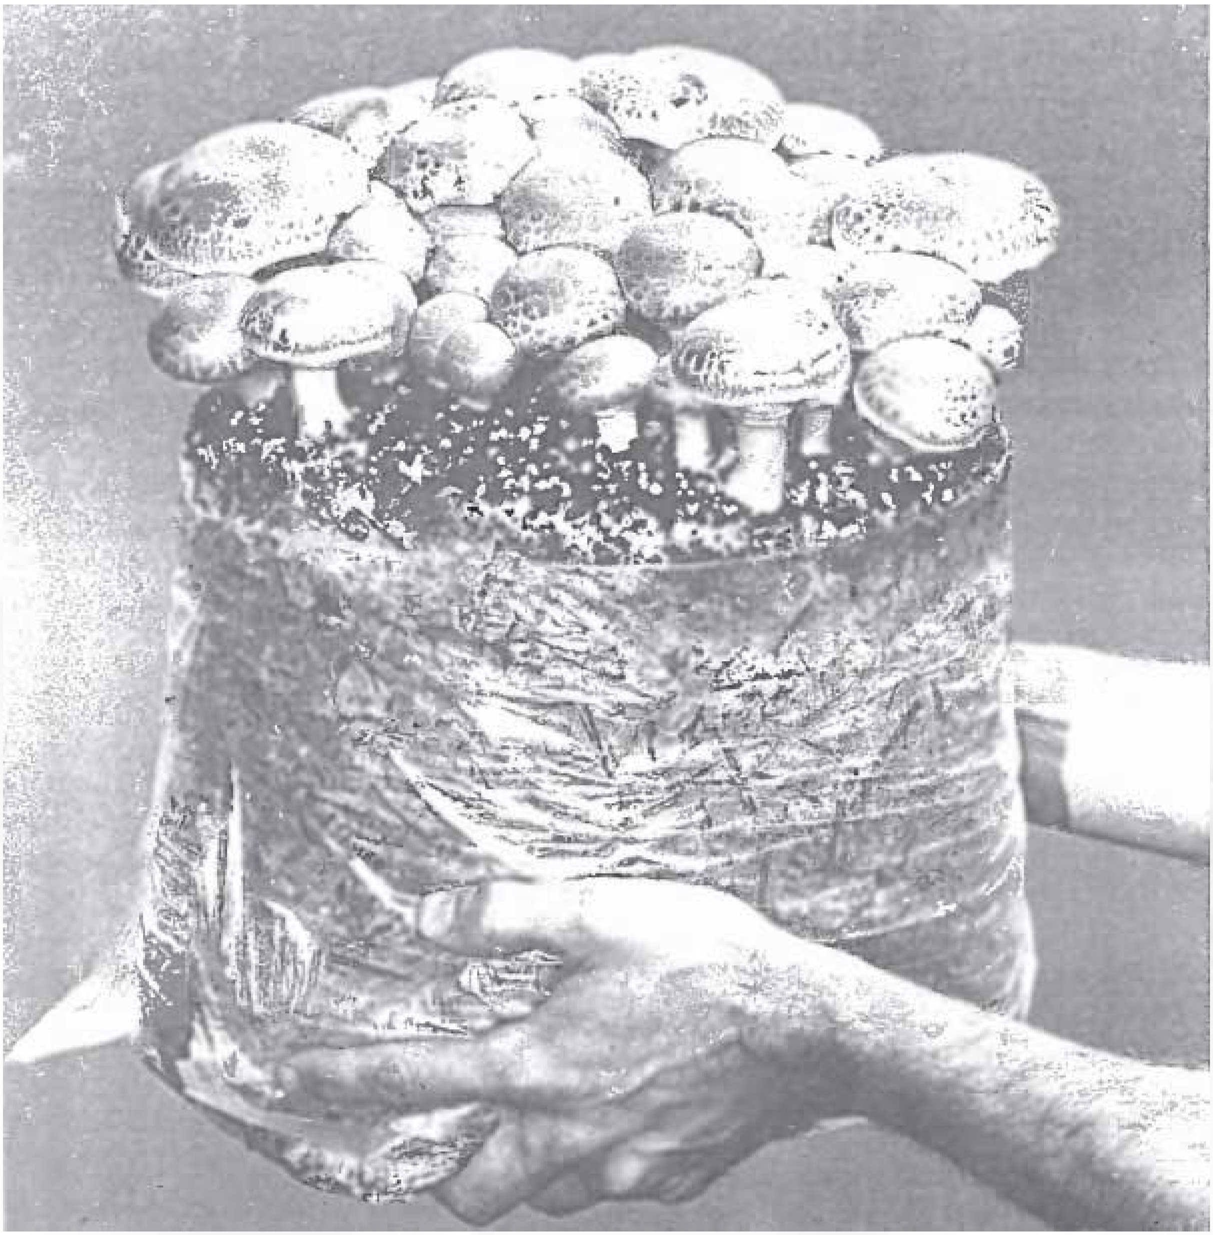

Figure 136 - Wild strain of *Agaricus brunnescens* fruiting in bag of cased compost.

For the home cultivator the onset of cropping is a time of excitement and anticipation. It is also a time for increased attention to the finer details of environmental control. Temperature, humidity, light and airflow in the growing room all play vital roles which together determine the nature of further mushroom development.

Temperature

During the vegetative growth period, the substrate was held in the optimum range by careful manipulation of the air temperature. But once the change to generative growth is initiated, the substrate temperature becomes less important and air temperature becomes the controlling factor.

The time it takes button sized mushrooms to mature is influenced primarily by the air temperature of the growing chamber. Each species has an optimum temperature for fruitbody development that lies within a broader growing range. Knowing the temperature parameters as outlined in Chapter XI, the cultivator can speed or slow development depending on which end of the cropping range is chosen. Lower temperatures can be used to postpone or lengthen the harvesting period and allow for maximum quality control. High temperatures serve to shorten the cropping period by promoting rapid, intense flushes. However, the dangers of high temperatures include the risk of heat building up in the substrate and consequent CO_2 generation, as well as the ability of insects and contaminants to grow and reproduce at faster rates. Commericial *Agaricus* growers commonly lower the air temperature by 2°F. 48 hours prior to the peak of the first and second flushes. Further flushes are then run hotter to speed the crop to completion. It is important that the cultivator evaluate the heat generating capabilities of the crop and insure that the environmental control system is capable of handling them.

Flushing Pattern

The mushroom crop grows in cycles called flushes or "breaks". Depending on the species being grown these flushes normally come in seven to ten day intervals with each successive flush bearing fewer mushrooms. The manner in which these flushes appear is determined during the pin initiation period. Even pinning sets up a uniform pattern of flushing that continues throughout the cropping cycle. Uneven flushing creates difficult situations for proper watering and environmental control. To encourage even flushing, early forming pinheads are picked off as buttons unless it appears that these pins constitute the flush itself. Poor first flushes are indicative of faulty pinning procedures and lead to lower total yields and a longer cropping period as the cultivator tries to maximize yields from the following flushes. But keep in mind that many times it is the progressive build-up of competing contaminant organisms that eventually bring mushroom growth to a halt. For this reason, the goal is to maximize yields in the early flushes.

To further increase the flushing speed the actual harvest period in each flush should be kept short and concise. Late developing mushrooms are removed with or on the day after peak production. The sooner the flush is completely removed the quicker the next one will appear and the shorter the overall cropping cycle. Stunted undeveloped mushrooms are also cleared from the cropping surface between breaks with care not to disturb the casing. Small dead pinheads should be left in place and cause little harm. (As a rule, an aborted mushroom can be removed as long as the casing is not touched in the process.) At no time should the casing be over-handled in an attempt to clean. Such handling can spread disease spores and damage subsequent pin formation.

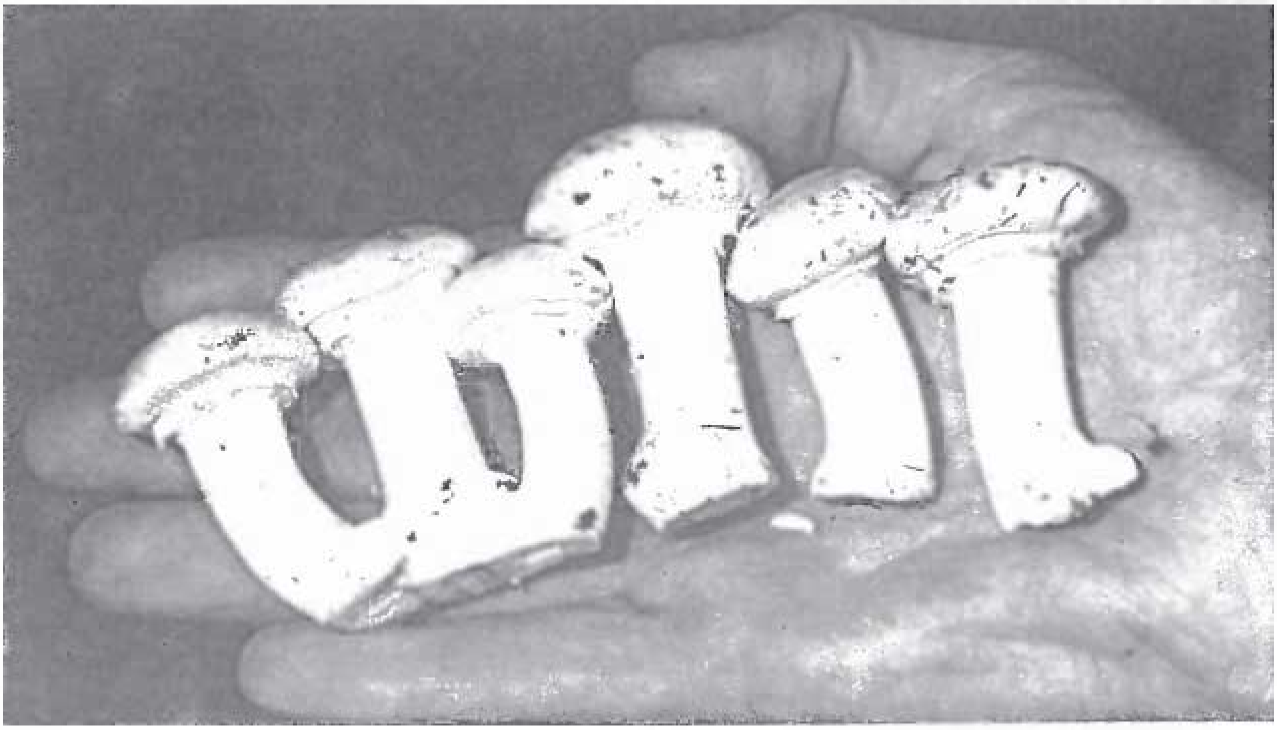

Figure 137 - *Agaricus brunnescens* affected by high CO_2 concentration. Note long stems and underdeveloped caps.

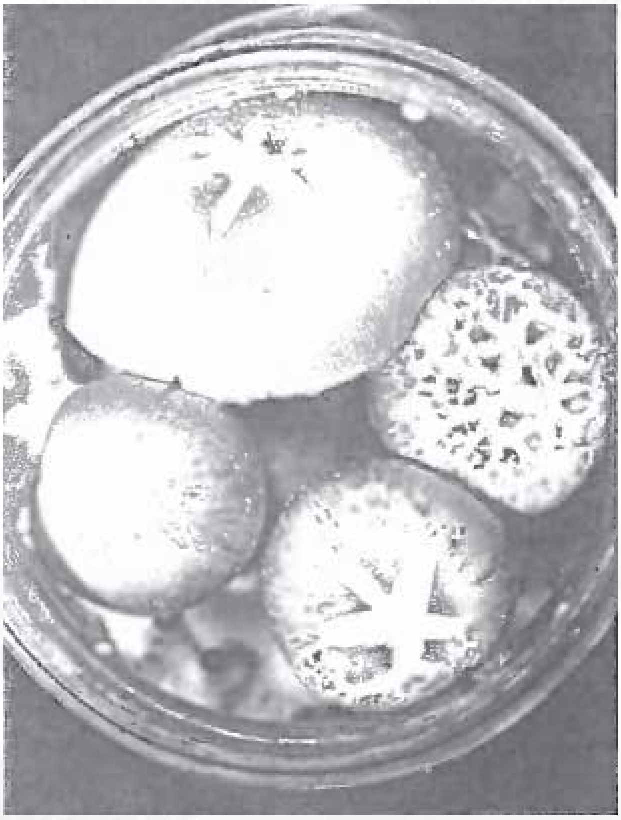

Figure 138 - The effect of dry air on *Psilocybe cubensis* caps, a condition known as "scaling".

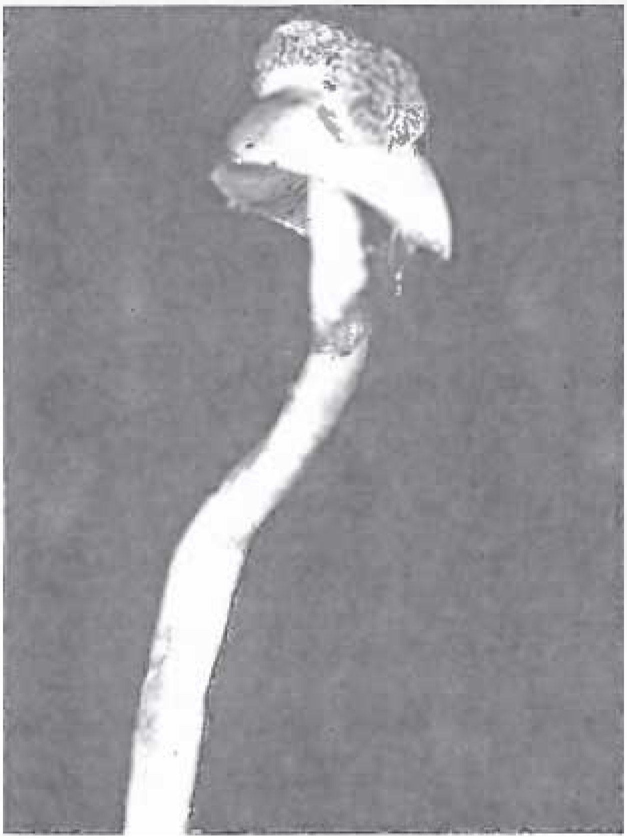

Figure 139 - Rosecomb on *Psilocybe cubensis*, an abnormality caused by contact with chemicals, especially those that are petroleum based.

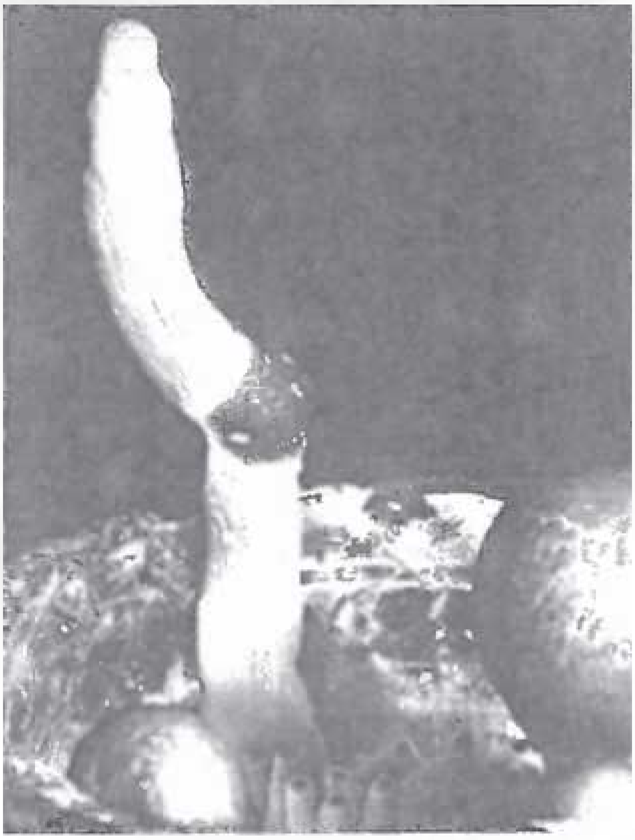

Figure 140 - Fruitbody abnormality occasionally seen in *Psilocybe cubensis*.

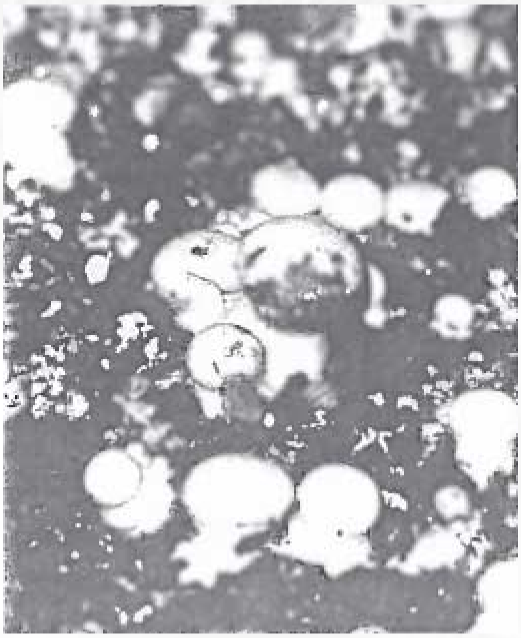
Air Movement

Air movement in the growing room is designed to create an even flow across all levels of cropping surface. This even airflow counteracts temperature stratification and dead air pockets by equalizing the environment of the room. In this manner the crop can be managed as a whole, giving the grower greater control over the cropping cycle.

During the pin initiation period fresh air is introduced into the room to remove metabolic gases produced by the mushroom mycelium. Although gas production is reduced once this vegetative growth has been slowed, the maturing mushrooms create more carbon dioxide, the removal of which requires a continuous supply of fresh air. The number of these air changes varies depending upon the air/bed ratio and the CO_2 requirement of the mushroom species being grown. *Agaricus bitorquis* needs only half the amount of fresh air required by *Agaricus brunnescens*. A common rate for *Agaricus brunnescens* is 4-6 changes per hour. For more CO_2 tolerant species such as *Psilocybe cubensis*, 2-3 changes per hour is sufficient. (The most accurate method for determining fresh air requirements employs the multiple gas detector. This instrument measures CO_2 content of the air in parts per million (ppm), from 300 (natural level) up to 20,000 ppm. See Appendix for sources.)

Because many mushrooms are sensitive to carbon dioxide, the physical development of the mushroom can also be used as a guide. High CO_2 environments produce long stems and small underdeveloped caps in *Agaricus brunnescens* and *Pleurotus ostreatus*. *Pleurotus* exhibits similar symptoms in conditions of low light intensity.



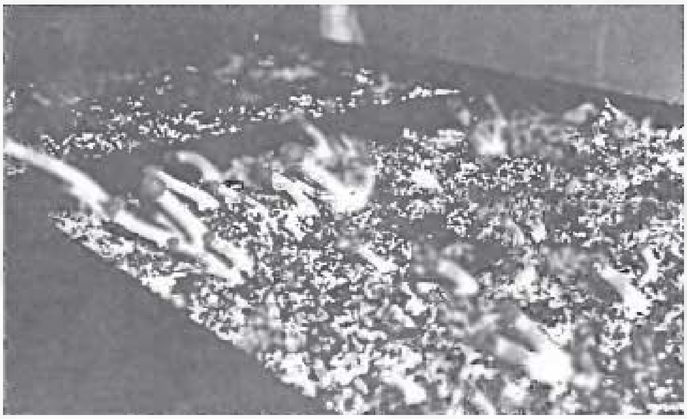


Figure 141 - Bacterial blotch parasitizing *Agaricus brunnescens*.

Figure 142 - Characteristic phototropic response of *Psilocybe cubensis* toward light.

In general, too much fresh air is preferable to insufficient air supply. However, fresh air displaces the existing room air which is then exhausted from the room. Unless this fresh air is preconditioned to meet the requirements of the species, one will be constantly disrupting the growing environment and thereby overworking the heating and humidification systems. For this reason the air circulation system should be designed to recirculate the room air. This is accomplished by a mixing box with an adjustable damper that proportions fresh and recirculated air. In this regard, CO_2 tolerant species give the grower a distinct advantage in maintaining the correct environment because they need less fresh air for growth.

An important effect of air circulation and fresh air supply is the evaporation of moisture from the cropping surface. Excessive humidity without adequate air movement and evaporation retards mushroom development. Saturated stagnant air pockets are also breeding areas for contaminants like the Forest Green Mold (*Trichoderma*) and Bacterial Blotch (*Pseudomonas*). As stated in the previous chapter on pinhead initiation, once the primordia are set, the relative humidity should be lowered to 85-92% and held constant within this range throughout cropping. Besides the creation of a cool surface by "evaporative cooling", evaporation aids in the transport of nutrients (in solution) from the substrate to the growing mushrooms. If the evaporation rate is too high and the humidity falls below 85%, excessive drying occurs, causing small stunted mushrooms and cracked scaly caps. A dry cropping surface further reduces yields and is difficult to recondition. In this respect, it is critical for the grower to reach a balance between air circulation, fresh air and humidification. This is but one aspect of the "Art" of mushroom culture.

Watering

Maturing mushrooms have water requirements that must be met if maximum yields are to be achieved. Mushrooms grown on uncased substrates draw their moisture from the substrate, whereas those grown with a casing draw equally from both. Uncased substrates are more susceptible to dry air and therefore require a relative humidity of 90-95% as well as periodic misting of the cropping surface. If the cropping surface dries and forms a dead mycelial mat, it can be reopened to further flushing by raking or scratching. This technique is often used by *Pleurotus* growers to stimulate later flushes.

The advantages of using a casing layer are many. Protected from atmospheric drying, the substrate moisture is channeled solely to the mushroom crop. And, the water reservoir provided by the casing not only supplies the mushroom flushes but also serves to keep a high humidity in the cropping surface microclimate. In order to sustain these benefits, the grower must learn to gauge casing moisture and know when to water.

Other than light mistings, any substantial waterings before the button stage can result in damaged pins. But once the mushrooms have reached button size, it is time to begin building the casing moisture back up to the peak reached at pre-pinning. The aim is to reach capacity just prior to the main harvest. This is accomplished by a series of daily, light to moderate waterings with a fine misting nozzle. Commercial *Agaricus* growers have traditionally used a rose-nozzle but many have now switched to nozzles with finer sprays and variable volume outputs. This enables the grower to add moisture without damaging the casing surface. In this regard, high water pressures and close nozzle proximity to the casing should be avoided.

The goal is to keep the surface of the casing open and porous throughout the cropping cycle. Putting on too much water at once is the most common cause of panning. By watering 2-4 times/day rather than just once, the casing can slowly absorb the water without damage to the surface.

After the first flush is harvested the casing should be kept moist with light mistings until the next flush reaches the button stage. The casing moisture is then built up again. Each new flush is treated in this manner, although later flushes will have fewer mushrooms and therefore require less water. At no time should the casing be allowed to dry out. Mushrooms pulled from a dried casing carry large chunks of casing with them, creating gaps in the cropping surface and at times exposing the substrate to possible colonization by contaminants. If the substrate is exposed during picking, the holes should be filled with moist casing. To recondition a dry casing, moisture should be added slowly over a period of a few days.

One of the common contaminants in mushroom growing is Bacterial Blotch (see Chapter XIII). Blotch results from mushroom caps that remain wet for extended periods of time. *Agaricus* growers attempt to dry recently watered mushroom caps as quickly as possible by lowering the humidity of the room. This is accomplished by increasing air circulation and introducing more fresh air or by raising the air temperature 1-2°F. *Agaricus* growers also stop watering once the mushroom cap has reached adolescence because wet mushroom caps become prime sites for disease. Small scale growers may be able to water around maturing mushrooms without directly hitting the caps. If Bacterial Blotch or other diseases appear on the mushrooms or the casing soil, these areas should not be watered. Watering contaminated regions will spread the infection further. A common strategy for serious disease outbreaks is to lower the relative humidity and run the casing drier than normal. *Agaricus* cultivators also use slightly chlorinated water (150 ppm).

Harvesting

The way an individual picks mushrooms can dramatically affect future flushes. Damage to resting pinheads and disturbance of the casing soil must be minimized during picking. Often times pinheads are in close proximity to developing mushrooms and enlarge directly after the mature ones are picked. Should any pinhead be harmed, the grower will have lost a potential fruitbody. Moreover, these damaged pin heads are easily parasitized by fly larvae and other contaminants. The best pickers are meticulous, unhurried, and above all treat the mushrooms with care. Carelessness in picking, when multiplied by hundreds of cultures, can be costly indeed.

The most important factor in harvesting mushrooms is timing. *Agaricus brunnescens* should be picked before the veil breaks and the stem elongates. *Psilocybe cubensis* is morphologically distinct from *Agaricus* species, having a longer stem, a less fleshy cap and a more delicate veil. It is both natural and desirable to have tall stands of *Psilocybe* mushrooms while this is not the case with *Agaricus*. Cultivators of these two species, however, share many things in common. One particular problem is the massive release of spores from the mature mushrooms. These spores often times cover the casing layer and can inhibit further pinhead development. High spore loads can also cause allergic reactions amongst workers. For these reasons, one should pick the mushrooms at the stage when the veil begins to tear or soon thereafter.

The nature of the crop determines how the mushrooms should be picked. Flushes with mushrooms in varying stages of development are more difficult to harvest. This is especially true if the primordia formation period was interrupted by fluctuations in the environment. One example is a phenomenon common to *Psilocybe cubensis* culture in mason jars. Mushrooms sometimes form between the casing and the glass. These "border breaks" are due to high humidity pockets and premature light stimulation. In tray culture where mycelium is not exposed to side light and proper moisture is easily managed, border breaks are uncommon. Mushrooms then grow uniformly from the surface of the casing layer where they can be easily picked.

Harvesting techniques

1. Equipped with a basket and short bladed paring knife, grasp the base of the stem, and with a twisting motion, pull the mushroom from the casing layer being careful not to disturb neighboring pinheads.
2. Trim the stem base, removing only flesh to which the casing or substrate is attached. Mushrooms having thin stems are best cleaned using a knife in a downward scraping motion. All trimmings should be placed in a sealed plastic bag and removed from the cropping area.
3. Mushrooms growing in clumps or clusters should be broken apart and harvested individually when possible. Special care must be taken with those clumps containing both mature and immature mushrooms. Leave immature mushrooms attached to the casing layer or substrate to insure continued growth.

Preserving Mushrooms

If not served within four days, mushrooms can be preserved by drying freezing or canning. Air drying of mushrooms is the method most widely used by home cultivators and field hunters. Since most mushrooms are 90% water, they must be dried within a few hours or fly larvae and bacteria will consume them. Provided mushrooms are placed in a flow of warm, dry air, this large fraction of water soon evaporates into the air. Dried mushrooms are smaller, lighter and less fragrant than fresh ones. Once dried, they are sealed in airtight moisture proof plastic containers and refrigerated. Mushrooms will be preserved for years in this manner. When needed, simply rehydrate them in water before cooking. They will regain much of their original size and flavour.

Commercially available food dehydrators are well suited for drying mushrooms. Their only disadvantage is that the trays are often too close together, necessitating the cutting of large mushrooms into thin slices. Or, one can build a dehydrator solely designed for this function and customized to an individual's particular needs. A good dryer should be able to dry the mushrooms in 24-48 hours by passing warm air no hotter than 110°F. Open air drying at room temperature is also feasible using dehumidifiers in combination with air circulation fans. "Flash" drying at high temperatures should be avoided since the mushrooms lose much of their nutritive value and, as the case may be, much of their psilocybin content.

Freezing is another method of preserving mushrooms. But unless the mushrooms are first dried, frozen mushrooms are soggy and unappealing upon thawing. In freezing, the water constituting 90% of a mushroom's mass becomes crystallized. Frozen mushrooms are held together more by ice crystals rather than their own cellular structure. Since ice expands upon crystallization, cells break under the stress. Because frozen mushrooms disintegrate into a formless mass when thawed, they are mostly used in soups or stews.

The best of both drying and freezing is freeze drying. This is the ideal method for preserving the flavor, nutrition, form and/or psilocybian content of mushrooms. Because of the expense, only a few commercial mushrooms, such as shiitake (*Lentinus edodes*) are freeze dried.

Freeze dryers operate on the principle of first flash freezing fresh mushrooms which are then placed onto heated trays in a cooled, high vacuum chamber. The frozen water within the mushrooms begins to melt from the heat generated from the trays. But instead of becoming a liquid, the water is immediately transformed into a vapor that is pumped out of the freeze drier. Freeze drying preserves much of the original cell structure and hence mushrooms dried in this manner are often life-like in appearance. Since commercial freeze driers are prohibitively expensive, few home cultivators can afford them. Many people have discovered, however, that mushrooms placed in a frost-free refrigerator are almost as well preserved.

Canning is another method for storing mushrooms. Mushrooms preserved by canning must be carefully cleaned beforehand, precooked for 3 or 4 minutes in boiling water, then inserted into glass jars with a small amount of vinegar and sterilized in a pressure cooker. (Sterilization for mushrooms is usually 30-40 minutes at 10 psi. Consult a book on mushroom cookery for further information on canning mushrooms). Canned mushrooms, especially those that have been pickled, are preferred by many epicureans to those preserved by other means.

No matter what the technique, fresh mushrooms are undoubtedly better tasting than preserved mushrooms. If one chooses to dry, freeze or can, young mushrooms should be selected over old ones. Label each container with the species, the name of who grew or identified the mushrooms, the date and the place of origin. (One general rule recommended by all mycologists is: when eating wild mushrooms for the first time, always leave one or two small specimens aside in case illness ensues and a mycologist or a doctor needs to be consulted.)

XI. GROWING PARAMETERS FOR VARIOUS MUSHROOM SPECIES

Figure 143 - *Stropharia rugoso-annulata* fruiting in a bed of wood chips.

Growing parameters for mushrooms vary with every species. Through time spent in countless trials and from observations by both home and commercial cultivators, specific cultural requirements have been ascertained.

Mushrooms fruit in response to unique sets of conditions involving nutrition (substrate), temperature, pH, relative humidity, light and carbon dioxide. What follows are outlines pin-pointing the optimal environmental ranges for each stage in the mushroom's life cycle. By adhering to these optima, a cultivator can maximize fruitbody production in a precise and deliberate fashion.

SPECIES: *Agaricus bitorquis* (Quel.) Saccardo

= *Agaricus rodmanll* Peck
= *Agaricus campestris* var. *edulis* Vitt.
= *Agaricus edulis* (Vitt.) Moller and Schaeff.

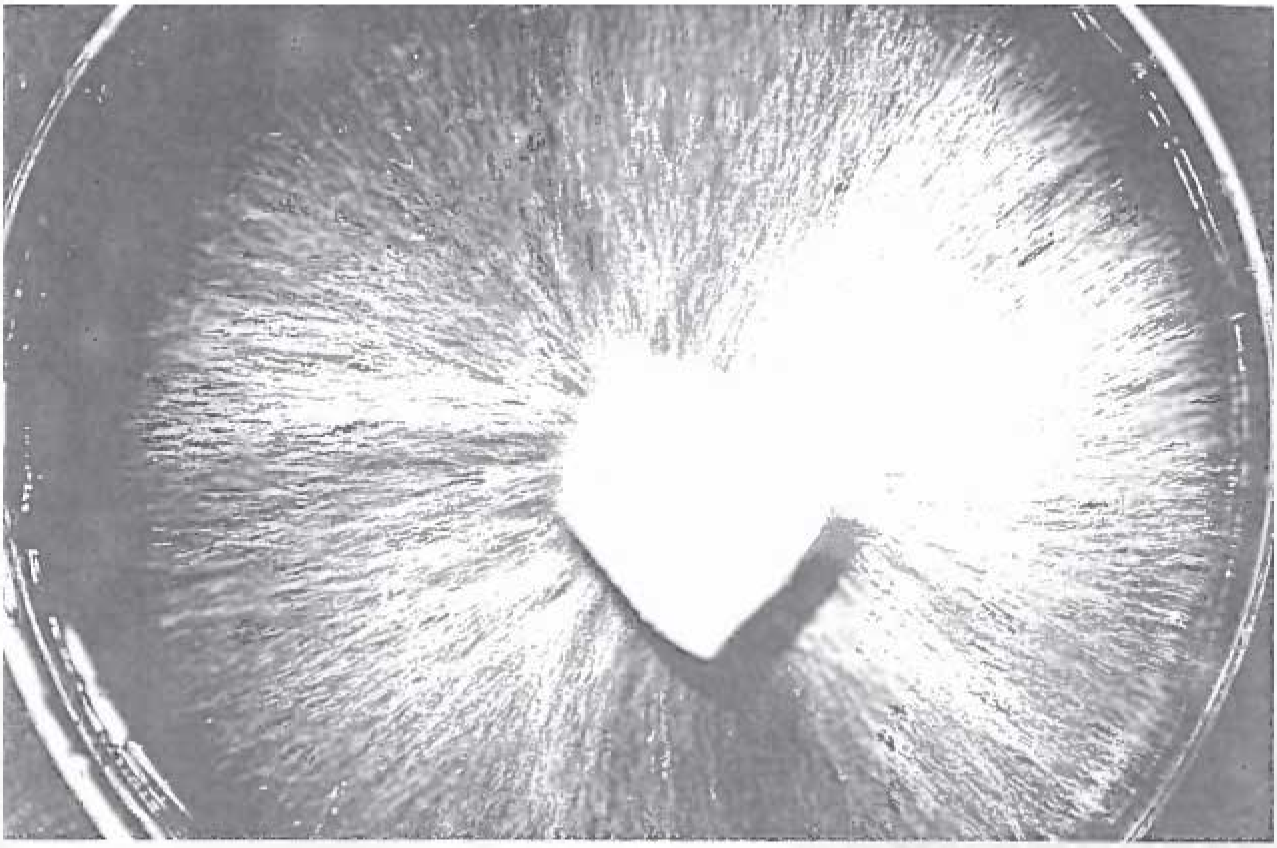

Figure 144 - Linear (longitudinally radial) mycelium of *Agaricus bitorquis*.

STRAINS: Horst B30 (The first commercial strain to be developed by Gerda Fritsche at the Dutch Mushroom Research Center in Horst, Holland).
Horst K26, K32 (These are two second generation strains from Horst B30 and are distinctive from it in that they fruit earlier, give higher yields and have slightly longer stems. Spawn of this species is now available from Amycel.)

COMMON NAME: Rodman's Agaricus

GREEK ROOT: *Agaricus* comes from the greek word "agarikon" which scholars believed originated with a Scythian people called Agari who were well versed in the use of medicinal plants and employed a fungus called "agaricum", probably a polypore in the genus *Fomes*. The species epithet *bitorquis* means having two rings, for the double annulus that so distinguishes this species from close relatives like *Agaricus campestris*, the Meadow Mushroom.

GENERAL DESCRIPTION: Cap smooth, white, thick fleshed, convex to broadly convex to plane with age. The cap margin is incurved at first but soon decurves. The gills are pinkish at first, soon darkening to chocolate brown with spore maturity. The stem is thick, relatively short and adorned with a double membranous annulus. (The lower ring is often a thin annular zone). Its spores are dark chocolate brown in mass.

NATURAL HABITAT: Naturally found in lawns, gardens, roadside areas, pastures, in enriched grounds and on hard packed soil. A temperate species, widely distributed, *A. bitorquis* fruits primarily in the spring and to a lesser degree in the fall.

A. bitorquis - Growth Parameters

Mycelial Types: Rhizomorphic to linear; whitish to pale whitish in color.

Spawn Medium: Rye grain buffered with calcium carbonate and/or calcium sulfate. See Chapter III.

Fruiting Substrate: Nitrogen enriched wheat straw and/or horse manure based compost balanced to 71-74% moisture content.

Method of Preparation: See Chapter V on compost preparation. Pasteurization achieved through exposure to live steam for 2 hours at 140°F. throughout the substrate. Compost should be filled to a depth of 6-12 inches.

Spawn Run:

Relative Humidity: 90-100%.
Substrate Temperature: 84-86°F. Thermal death limits have been established at 93°F. over prolonged period of time.
Duration: 2 weeks.
CO_2: 5,000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Type of Casing: After fully run, cover with the standard casing whose preparation is described in Chapter VIII. Layer to a depth of 1-2 inches. The casing should be balanced to a pH of 7.2-7.5.

Post Casing/Prepinning:

Relative Humidity: 90-100%.
Bed Temperature: 84-86°F.
Duration of Case Run: 10-12 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Primordia Formation:

Relative Humidity: 95-100%.
Bed Temperature: 77-80°F
Air Temperature: 75-77°F.
Lighting: None required.
CO_2: less than 2000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Watering: Regular misting (once to twice daily) of the beds stimulates primordia formation.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 75-77°F.
CO_2: less than 3000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Flushing Interval: Every 8-9 days.
Harvest Stage: Directly before the partial veil stretches.

Yield Potential: Average commercial yields are reported at 3 lbs/sq.ft. over a 5 week cropping period. Maximum yields are 4 lbs per square foot.

Moisture Content of Mushrooms: 92% water; 8% dry matter.

Nutritional Content: Thought to be similar to *Agaricus brunnescens*.

Comments: The development of *Agaricus bitorquis* has given commercial growers greater flexibility, especially those in warmer climates where elevated temperatures have been a limiting factor. An advantage of this mushroom is its resistance to virus (a devastating disease that attacks *A. brunnescens*) and its tolerance of high CO_2 levels. A disadvantage of growing this warmth-loving *Agaricus* is the higher incidence of disease endemic to the temperature range in which this species flourishes. *Agaricus bitorquis* is coarser, firmer, more strongly flavored and has a longer shelf life than its close relative, *A. brunnescens*.

Genetic Characteristics: Basidia tetrapolar (4-spored), forming haploid spores, heterothallic. The mating of compatible monokaryons can result in fruiting strains. Clamp connections absent. See Chapter XV.

SPECIES: *Agaricus brunnescens* Peck

= *Agaricus bisporus* (Lge.) Sing.

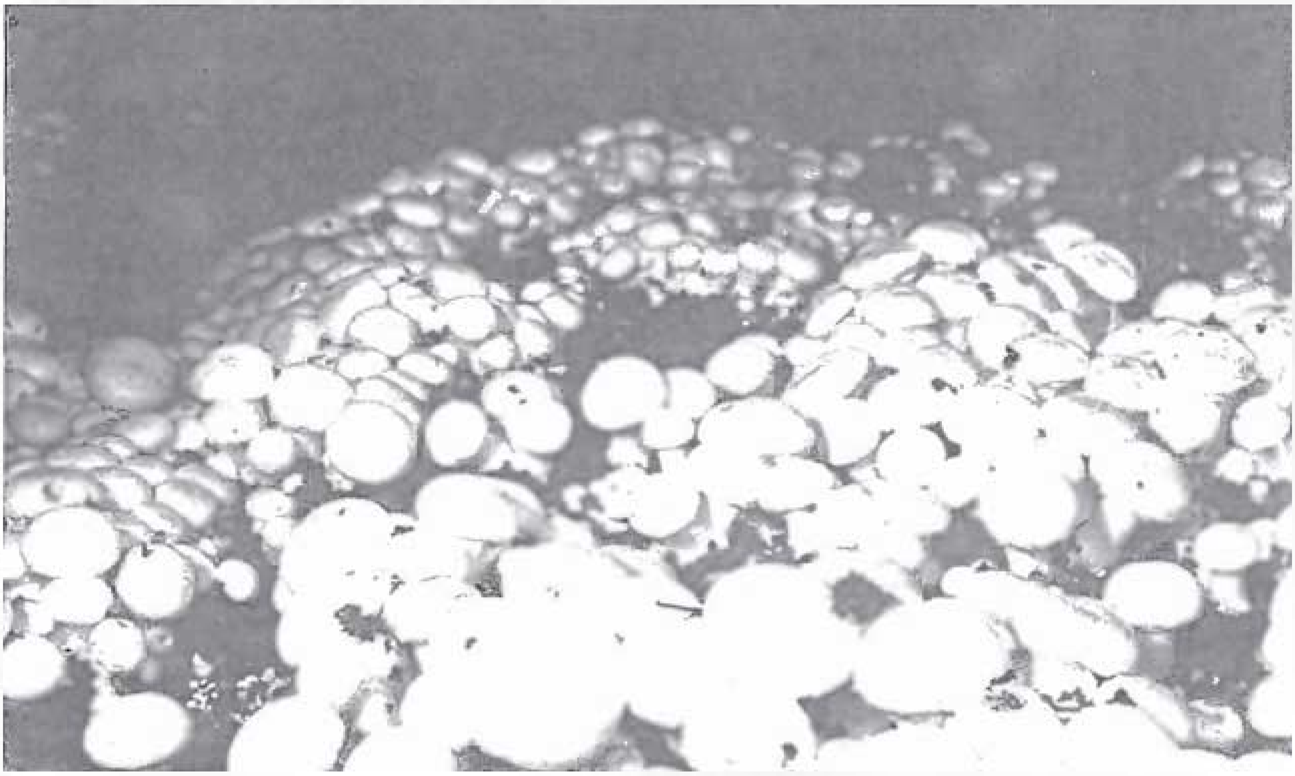

Figure 145 - *Agaricus brunnescens* fruiting in trays of compost.

STRAINS: Type or Brown Variety (var. bisporus)
White Variety (var. albidus)
Cream Variety (var. avellaneous)

COMMON NAME: The Button Mushroom.

GREEK ROOT: *Agaricus* comes from the greek word "agarikon" which scholars believed originated with a Scythian people called Agari who were well versed in the use of medicinal plants and employed a fungus called "agaricum", probably a polypore in the genus *Fomes*. The species epithet *brunnescens* comes from the latin "brunneus" or brown. Literally, the name means the fungus that becomes brown, probably referring to the color change of the flesh upon bruising. Also called *Agaricus bisporus* for the two spored basidia populating the gill faces.

GENERAL DESCRIPTION: A robust, thick fleshed *Agaricus* species, with thin gills that are pinkish when young, and darkening to sepia and then chocolate brown in age. The cap is characteristically brownish, whitish or cream colored. The cap surface is smooth to appressed squamulose and dry. This species has a short, thick stem which is adorned with a persistent membranous annulus from a well developed partial veil. Its spores are chocolate brown in mass.

NATURAL HABITAT: Naturally found in soils enriched with dung, on compost piles and in horse stables. A temperate species, widely distributed, *A. brunnescens* fruits from May until November over much of the northern hemisphere outside the tropical zone.

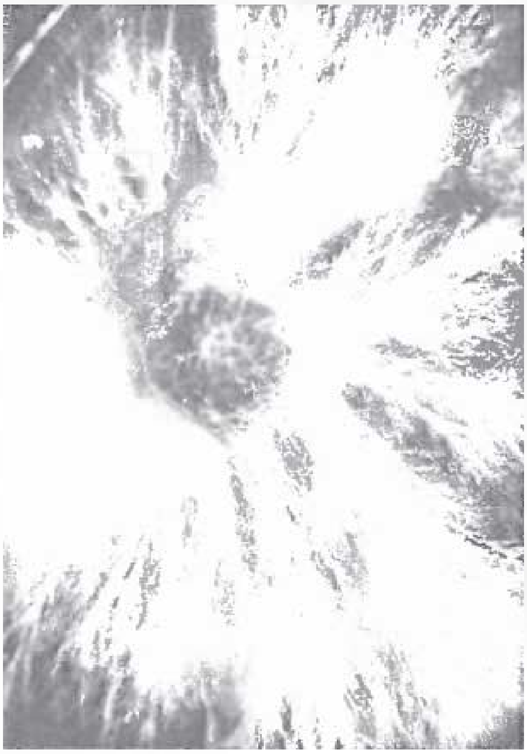
A. brunnescens - Growth Parameters

Mycelial Types: Moderately rhizomorphic; dingy white, sometimes with brownish hues.

Spawn Medium: Rye grain buffered with calcium carbonate and/or calcium sulfate. See Chapter III.

Fruiting Substrate: Nitrogen enriched wheat straw and/or horse manure based compost balanced to 71-74% moisture content. This species also fruits well on rye grain covered with an unsterilized peat based casing layer.

Method of Preparation: See Chapter V on compost preparation. Pasteurization achieved through exposure to live steam for 2 hours at 140°F. throughout the substrate. Compost should be filled to a depth of 6-12 inches.



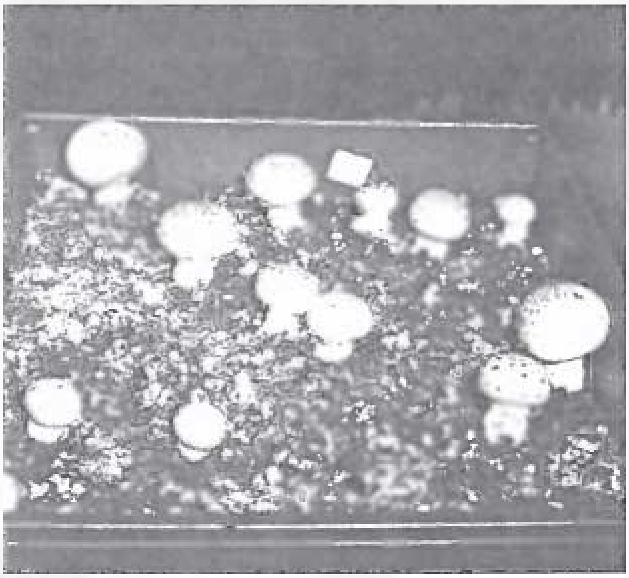


Figure 145a - *Agaricus brunnescens* fruiting on cased rye grain spawn.

Figure 145b - Characteristic *Agaricus brunnescens* mycelium.

Spawn Run:

Relative Humidity: 90-100%.
Substrate Temperature: 76-78°F. Thermal death limits have been established at 96°F. but damage can occur as low as 90°F.
Duration: 2 weeks.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Type of Casing: After fully run, cover with the standard casing whose preparation is described in Chapter VIII. Layer to a depth of 1-2 inches. The casing should be balanced to a pH of 7.0-7.5.

Post Casing/Prepinning:

Relative Humidity: 90-100%.
Bed Temperature: 76-80°F.
Duration of Case Run: 8-12 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Primordia Formation:

Relative Humidity: 95-100%.
Compost Temperature: 65-70°F.
Air Temperature: 62-65°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 4 per hour.
Light: None required.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 62-65°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 4 per hour.
Flushing Interval: 7-10 days.
Harvest Stage: Directly before the partial veil stretches.
Light: None required.

Yield Potential: Average commercial yields are 3 lbs/sq.ft. over a 5 week cropping period. Maximum yield is 6 lbs. per square foot.

Moisture Content of Mushrooms: 92% water; 8% dry matter.

Nutritional Content: 24-44% protein (dry weight); 56 milligrams of niacin per 100 grams dry weight.

Comments: Historically, this species and/or its close relatives were the first mushrooms to be cultivated in Europe during the late 1700's. It remains the most widely cultivated mushroom in the world today. A broad range of commercially available strains exist, many of which have been genetically selected for certain advantageous characteristics, especially yield, color and stature.

This species does not form pinheads on agar media unless activated charcoal or select bacteria are present. A species sensitive to high levels of carbon dioxide, *Agaricus brunnescens* fruits only within narrow environmental parameters. As a secondary decomposer, this species fruits best on substrates that have been transformed by a succession of specific microorganisms.
The common button mushroom is the mainstay of the mushroom growing industry in this country.

Genetic Characteristics: Basidia bipolar (2-spored), forming diploid spores; secondarily homothallic. The mating of compatible dikaryons typically results in strains both more vigorous and higher yielding. Clamp connections absent. See Chapter XV.

SPECIES: *Coprinus comatus* (Mull. ex Fr.) Gray

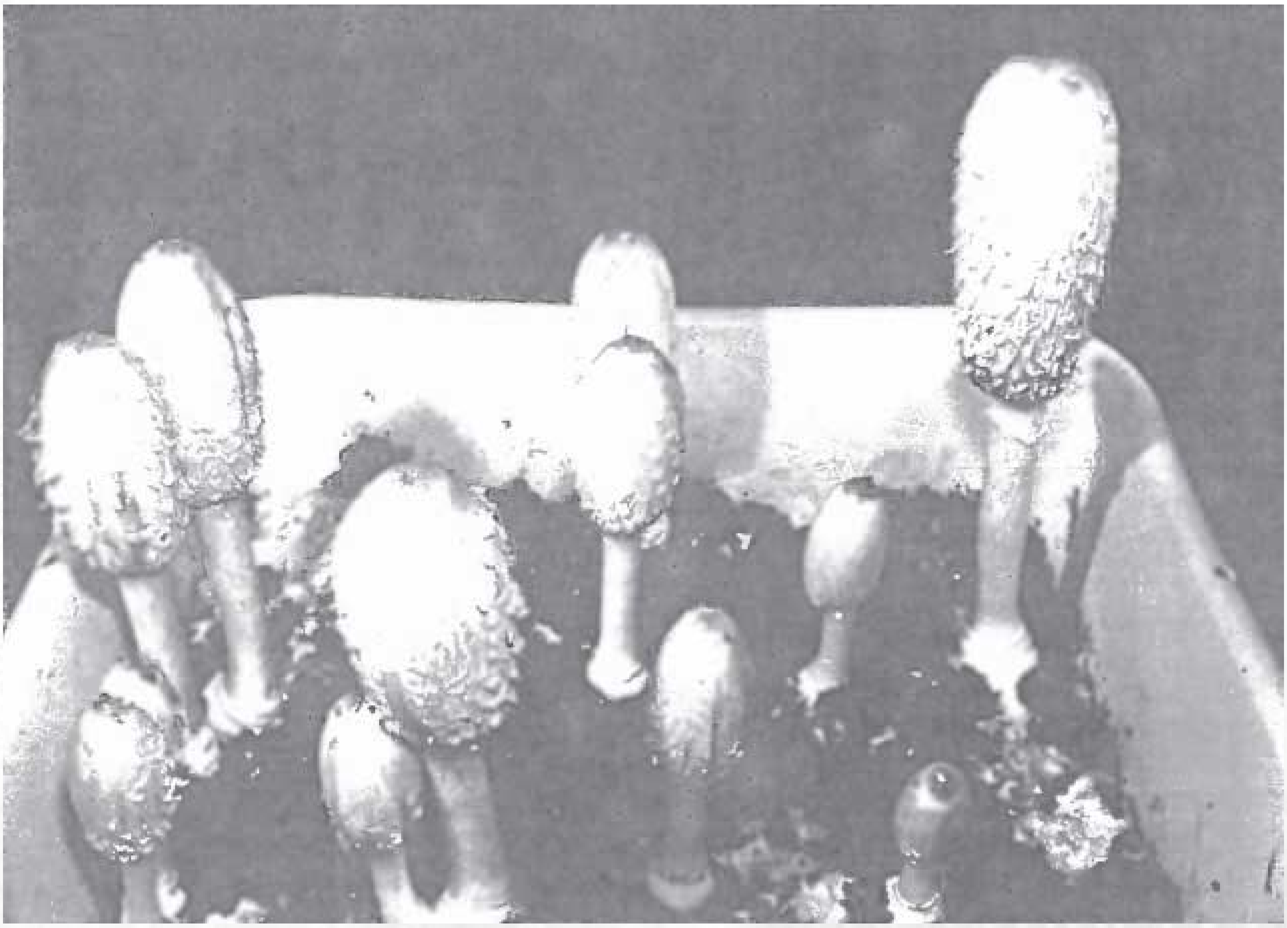

Figure 146 - Fully mature *Coprinus comatus* fruiting in a tray of compost.

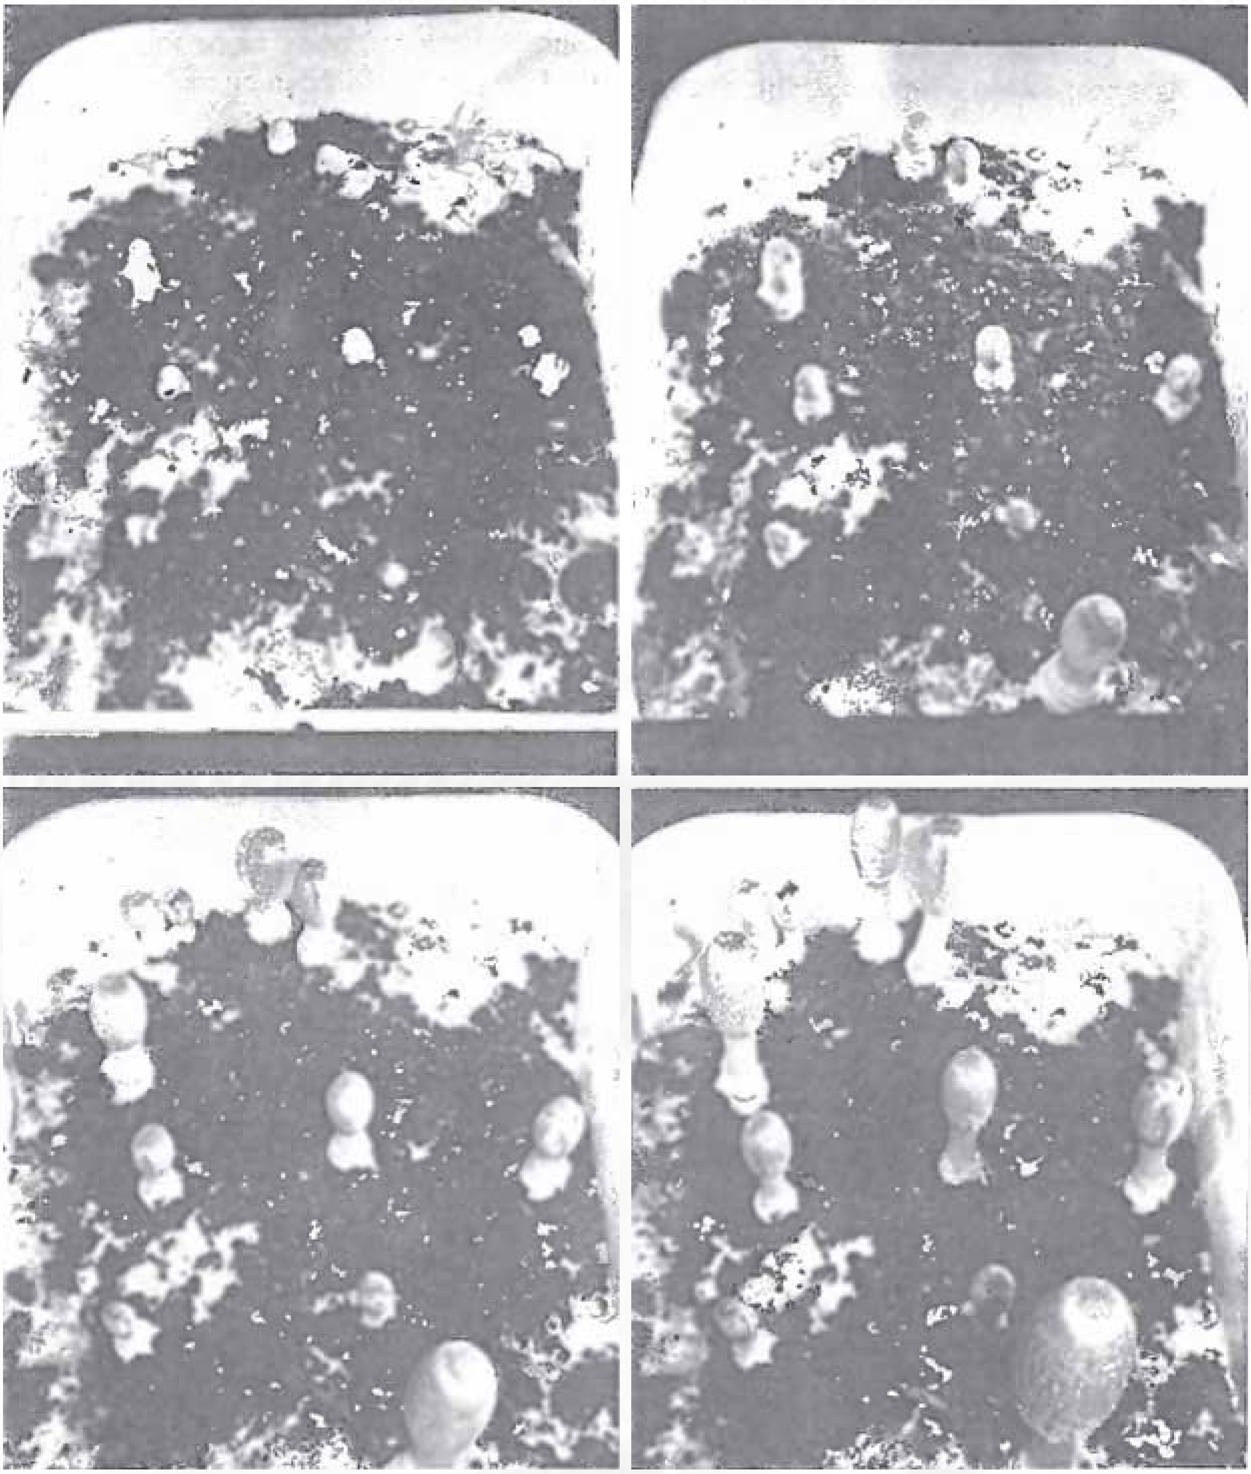
STRAINS: On deposit at the American Type Culture Collection and available through various culture banks, both commercial and private.

COMMON NAME: The Shaggy Mane.

GREEK AND LATIN ROOTS: *Coprinus* comes from the Greek word "kopros" meaning dung and *comatus* from the Latin "coma" meaning shaggy or adorned with hair tufts. The genus *Coprinus* is noted for the several species that grow on dung and for deliquescing gills. The species epithet describes the shaggy texture of the cap's surface.

GENERAL DESCRIPTION: Cap medium to large in size, whitish, ovoid when young, soon elongating upwards and becoming parabolic. As the mushroom matures and spores are produced, the cap begins to disintegrate from the margin's edge by an autodigestive process known as deliquescence. The disintegrating portions progressively darken and eventually liquify. The cap surface is smooth at the disc, scaly below, soon gray, darkening with maturity until black and thin fleshed. The gills are very crowded, whitish at first, soon gray, darkening with age to black. The partial veil membranous, often leaving a fugacious, membranous (collar-like) annulus that can be moved over the stem. The spore deposit is black.

NATURAL HABITAT: Common along roadsides, near debris piles, in lawns and in barnyards during the late summer and fall.



Figures 147-150 - Four day developmental sequence of *Coprinus comatus* fruiting in a tray of compost.

C. comatus - Growth Parameters

Mycelial Types: Linear to cottony, zonate-cottony mycelia; whitish in color.

Spawn Medium: Rye grain. See Chapter III.

Fruiting Substrate: Composted wheat straw enriched with horse and/or chicken manure, adjusted to 70% moisture content. Also, pasteurized chopped wheat straw supports fruitings of this species. Garcha *et al*. (1979) reported that composts having the distinct scent of ammonia after Phase II supported the greatest fruitings of *Coprinus comatus*.

Method of Preparation: See Chapters V & VI on the preparation of compost and straw. Pasteurization achieved through exposure to live steam for 2 hours at 140°F. Compost or straw should be filled to a depth of 6-12 inches.

Spawn Run:

Relative Humidity: 90-100%.
Substrate Temperature: 76-80°F.
Duration: 8-12 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0-1 per hour.

Type of Casing: After fully run, cover with the standard casing whose preparation is described in Chapter VIII. Layer to a depth of 1-2 inches. The casing should be balanced to a pH of 7.0-7.5.

Post Casing/Prepinning:

Relative Humidity: 90-100%.
Bed Temperature: 76-80°F.
Duration of Case Run: 10-12 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0-1 per hour.

Primordia Formation:

Relative Humidity: 95-100%.
Bed Temperature: 65-67°F.
Air Temperature: 62-65°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 4 per hour.
Light: Natural daylight or grow-light recommended on a 12 hour on/off cycle.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 62-65°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 4 per hour.
Flushing Interval: 7-10 days.
Harvest Stage: Directly before the gills begin to deliquesce.
Light: Natural daylight or grow-light on a 12 hour cycle on/off cycle

Yield Potential: Average commercial yields are 2-3 lbs/sq.ft. over a 4 week cropping period. Maximum yield potential has not yet been established.

Moisture Content of Mushrooms: 92-94% water; 6-8% dry matter.

Nutritional Content: 25.4 % protein (dry weight).

Comments: Like many other species in this genus, *Coprinus comatus* is a thermotolerant mesophile that often appears in compost piles. This mushroom was first grown in quantity at the Dutch Mushroom Research Station using the same compost, casing and environmental parameters as for the cultivation of *Agaricus brunnescens*. The authors have grown this species on compost prepared for *Agaricus* and on straw alone, although fruitings appear more substantial on the former.

Coprinus comatus is edible and choice. However, the crops are difficult to keep because of the early onset of deliquescence. By submerging mushrooms in water, deliquescence is slowed and mushrooms remain in good condition for several days after picking.

Extracts from fresh specimens of this species has been shown to have antibiotic properties, similar to those from *Lentinus edodes*.

Genetic Characteristics: Basidia tetrapolar (4-spored), forming haploid spores; heterothallic. Clamp connections present. See Chapter XV.

For further information consult: P.J.C. Vedder 1978, "*Modern Mushroom Growing*", Educaboek, Culemborg, Netherlands. (English edition available from Swiss American Spawn Company, Inc., Madisonville, Texas).

SPECIES: *Flammulina velutipes* (Curt. ex Fr.) Sing.

= *Collybia velutipes* (Curt. ex Fr.) Kumm.

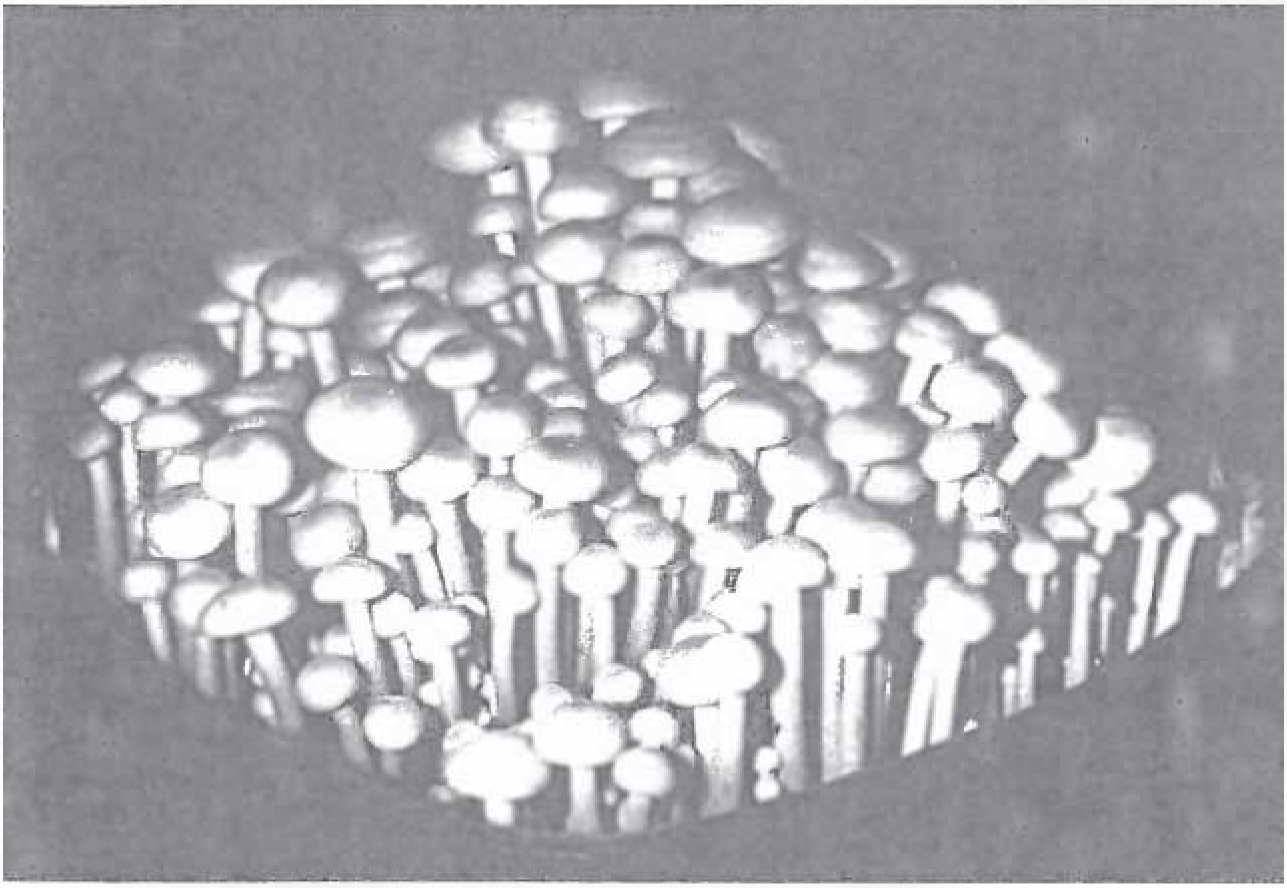


Figure 151 - *Flammulina velutipes* fruiting in tray.

STRAINS: Many wild and domesticated strains of *F. velutipes* are available from commercial and private stocks. (See Appendix). The Japanese have remained at the forefront of Enoke cultivation with two popular commercial strains, "Maruei" and "Ebios".

COMMON NAME: Enoke; Winter Mushroom; or Velvet Stem.

LATIN ROOT: *Flammulina* comes from the latin word "flammeus" or flame colored for the yellowish orange to reddish orange color of the cap. The species epithet *velutipes* is the conjunction of two latin words, the adjective "velutinus" meaning covered with fine hairs and the noun "pes" or foot.

GENERAL DESCRIPTION: Caps typically small, reddish orange to reddish brown, at first hemispherical, soon plane. The cap margin is often irregularly shaped. The gills are yellowish tinged. In wild collections, the stem is densely fibrillose, velvety, short and tough. In culture, however, the stems are long and smooth. A partial veil is absent. Its spores are whitish in mass.

NATURAL HABITAT: Common across the North American continent and in other temperate to boreal regions of the world. Thriving on woody tissue, especially living trees and considered a cold weather mushroom.

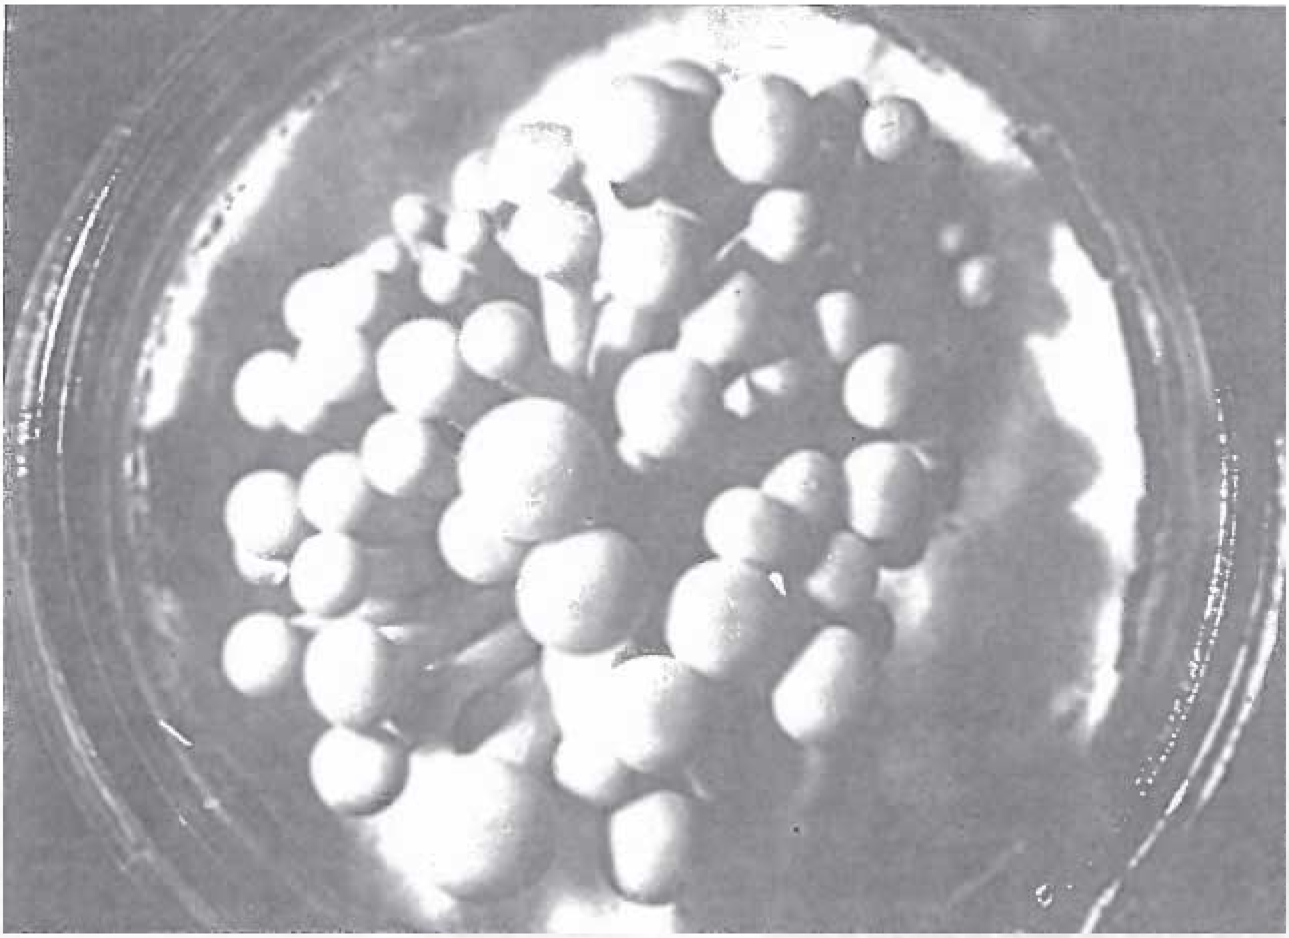

Figure 152 - Developing pinheads of *Flammulina velutipes*.

F. velutipes - Growth Parameters

Mycelial Types: Linear to cottony mycelia, sometimes aerial.

Spawn Medium: Sawdust/bran. One liter (1000 ml.) bottle of spawn inoculates 50-160 (800 ml.) containers. See Chapter III.

Fruiting Substrate: A 80-90% hardwood sawdust and 10-20% rice bran medium. Newly chipped sawdust holds moisture poorly and some Japanese growers age the sawdust for several years before using. Standard fruiting containers are quart mason jars or 800 ml. small mouthed plastic bottles. Some growers are currently experimenting with the cultivation of this species on bulk substrates in trays. Adjust moisture content of substrate to 58-60%.

Method of Preparation: See Chapter III for the preparation of sawdust/bran media. A 4:1 volumetric ratio of sawdust to bran (equivalent to a mass ratio of 10:1 sawdust to bran) is recommended. Sterilize for 1-2 hours at 250°F. (15 psi).

Spawn Run:

Relative Humidity: 90-100%.
Substrate Temperature: 72-77°F.
Duration: 20-30 days using standard methods; 12-13 days using in vitro inoculation methods.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Type of Casing: None required.

Primordia Formation:

Relative Humidity: 85%.
Air Temperature: 50-55°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 4 per hour.
Light: None needed.

Cropping:

Relative Humidity: 85%.
Air Temperature: 50-55°F.
Duration: 2-3 weeks.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 4 per hour.
Light: Natural daylight or grow-light on a 12 hour cycle on/off cycle.
Flushing Interval: 10 days.

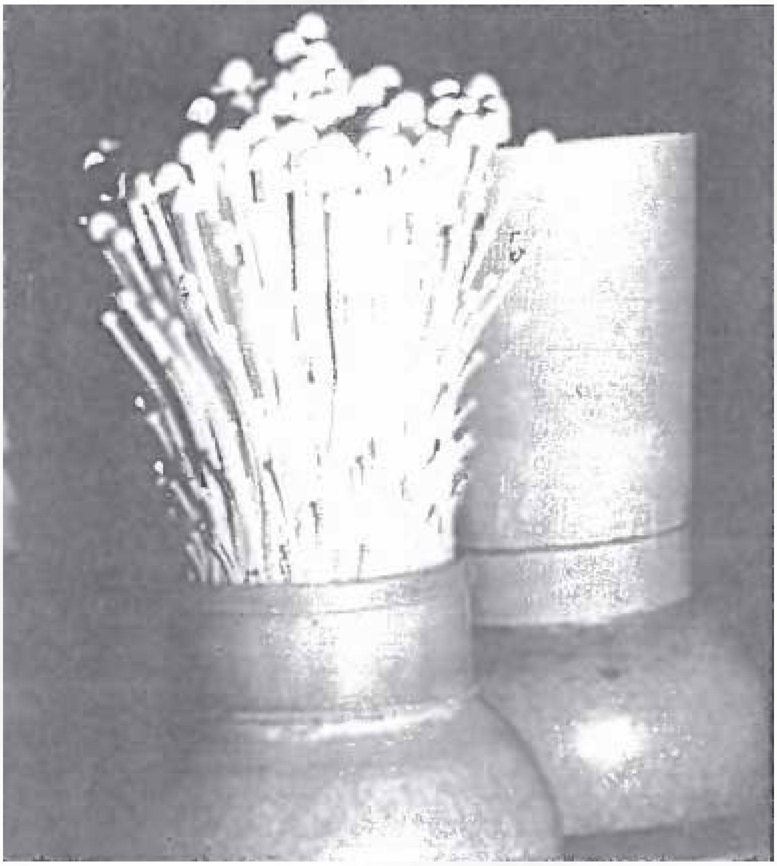

Figure 153 - *Flammulina velutipes* fruiting in plastic jar.

Yield Potential: Average commercial yields are 160-220 grams per 800 ml. bottle. Maximum yields are nearly 600 grams per 800 ml. bottle.

Moisture Content of Mushrooms: 92% water; 8% dry matter.

Nutritional Content: Reports vary from 18% to 31% protein (dry weight); 107 milligrams of niacin per 100 grams dry weight. F. Zadrazil (1979) found that colonization of straw by this species decreases its digestibility for use as fodder. This contrasts with the effects of *Pleurotus* and *Stropharia rugoso-annulata* whose presence on straw markedly increases its digestibility. Like many wood degrading fungi, an anti-tumor antibiotic has been isolated from *F. velutipes* and is appropriately called flammulin.

Comments: *F. velutipes* tends to form mycelial "pellets" soon after colonizing a substrate. This phenomenon makes liquid culture techniques more difficult. Japanese researchers found that the addition of 5% corn starch and 2% malt to a liquid solution inhibits the formation of these troublesome pellets. Curiously, fruitings on sawdust/bran beds can be precipitated when pieces of a fruitbody are added to this solution. Shiio *et al*. (1974) found that one could induce the early formation of fruitbodies with a technique whereby fresh pieces of *Flammulina velutipes* are mixed directly into liquid spawn and then introduced into the sawdust/bran medium. Not only was the fruiting process accelerated, the spawning period was cut in half and yield was nearly quadrupled over a year's time. Using this same technique with *Pleurotus ostreatus*, yields were increased over and above the norm by a factor of three. Total production in either case, equalled as much as ¼ of the substrate on a dry weight basis. An analogous technique was developed by Urayama (1972) who discovered that cell-free extracts of fresh *F. velutipes* mushrooms introduced to cultures of distantly related species caused fruitbody formation.

Genetic Characteristics: Basidia tetrapolar (4-spored), forming haploid spores; bifactorially heterothallic. Single spore isolates capable of producing sterile fruitbodies. Dikaryons are faster growing and characterized by clamp connections. Mycelium can produce oidia, self sectioning chains of cells with similar functions as spores. See Chapter XV.

For further information consult: H. Tonomura, 1974. "*Flammulina velutipes*" in *The Biology and Cultivation of Edible Mushrooms*. Academic Press, New York.

SPECIES: *Lentinus edodes* (Berk.) Sing.

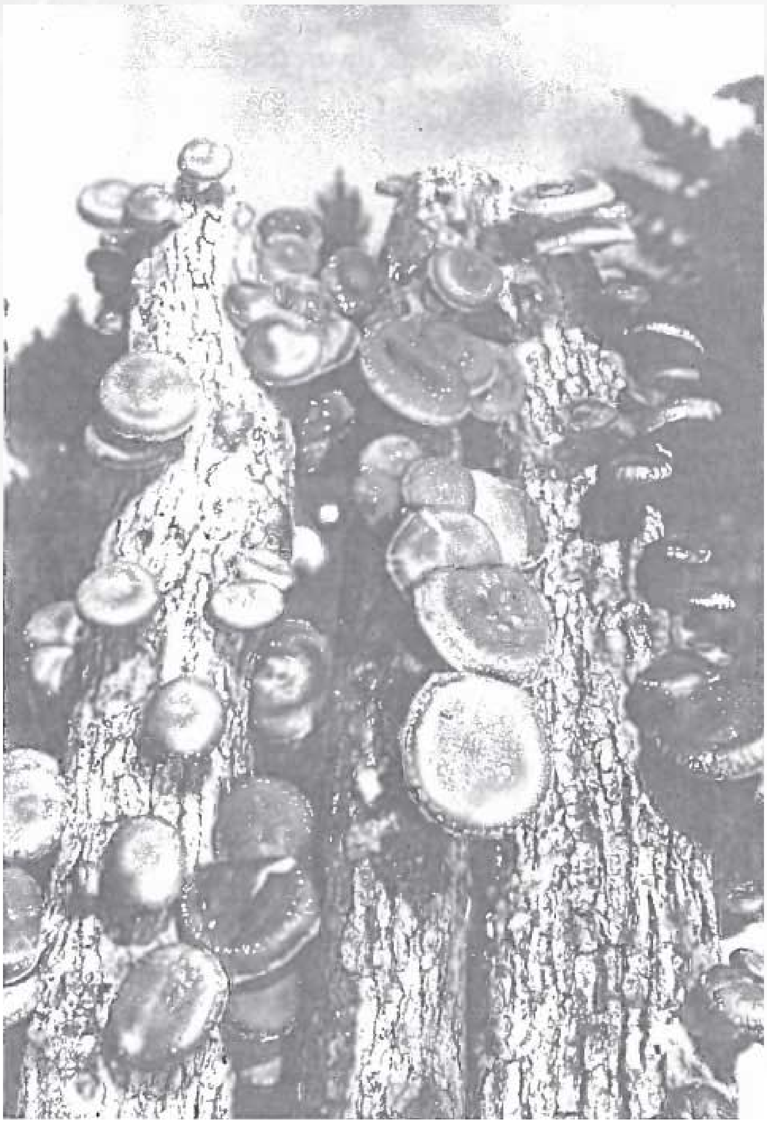

Figure 154 - *Lentinus edodes*, the shiitake mushroom, fruiting on oak logs.

STRAINS: Numerous strains of *Lentinus edodes* are available from commercial and private stocks. The American Type Culture Collection, which sells cultures to educational organizations and research facilities, has stock cultures of several wild and domesticated strains. Strains are often distinquished by their preferences for fruiting in colder or warmer temperature zones.

COMMON NAMES: The Shiitake Mushroom; The Japanese Black Mushroom; and The Chinese Black Mushroom. (The name shiitake comes from the association of this mushroom to the shiia tree, a member of the genus *Pasania*).

LATIN AND GREEK ROOTS: *Lentinus* comes from "lentis" or lens-shaped for the form of the cap and *edodes* signifies the edibility of this species.

GENERAL DESCRIPTION: Cap pale to dark reddish brown, convex, becoming broadly convex to nearly plane in age. The cap margin is typically inrolled when young. The cap surface is covered with whitish veil remnants, especially along the margin. The flesh is firm, pliant, easily drying and reconstituting. The gills are whitish, close to crowded, often with serrated edges. The stem is centrally attached to the cap, short, very tough and adorned with scattered fibrillose remnants of the partial veil. Its spores are whitish in mass.

NATURAL HABITAT: A wood decomposer, typically saprophytic. *Lentinus* species are common on the dead tissue of deciduous trees, mainly Fagaceae (oak, chestnut, shiia [*Pasania*] and beech). In nature, they particularly prefer oaks. Fruiting in the fall, early winter and spring, this species is indigenous to Japan, China and other countries in the temperate zone of the Indo-China region.

L. edodes - Growth Parameters

Mycelial Types: Rhizomorphic to linear.

Spawn Medium: Pre-soaked wooden dowels or a 4:1 sawdust/bran mixture. See Chapter III.

Fruiting Substrate and Method of Preparation: Oak or alder logs, 4-6 inches in diameter, are sawed into 3 foot lengths. These logs should be cut in the spring or fall to maximize sap content and can be inoculated immediately. (Some growers prefer to season their logs in shaded, open air stacks for one month prior to inoculation). Before inoculating, logs should be cleaned of any lichen or fungal growths.
Alternative fruiting substrates include alder or oak sawdust and bran mixed 4:1 with a moisture content of 60% and sterilized at 15 psi for 1-1½ hours. Fortified rye grass straw has also been used as a sterile fruiting medium. (See Chapter III).

Spawn Run:

Relative Humidity: 60-75% for logs; 90% for sawdust.
Substrate Temperature: Fast growth at 77°F. (Temperatures above 95°F. and below 41°F. stop mycelial growth).
Duration: 6-12 months for cut logs; 30-60 days for sawdust blocks.
CO_2: None established; no controls needed using these methods.
Fresh Air Exchanges: Stacks in open air sufficient. (Recent innovations show that logs stacked in a vertical configuration and covered with straw and plastic to maintain even temperatures result in faster spawn running in an outdoor environment. Within a controlled greenhouse, the logs need not be covered. The contact between the log surfaces should be minimized to prevent competitor molds and lichens from forming).
pH Optima: 5-6.
Light: None required.

Type of Casing: None needed.

Pinhead Initiation:

Initiation Technique: Submerge logs and blocks in cold water for 24-72 hours.
Relative Humidity: 95%.
Air Temperature: 59-68°F.
Duration: 7-14 days after soaking.
CO_2: Not applicable.
Fresh Air Exchanges: If within a greenhouse, 2-4 per hour.
Light: Ambient natural light or optimally 10 lux in the 370-420 nanometer range.

Cropping:

Relative Humidity: 85-90%.
Air Temperature: 59-68°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 2-4 per hour or sufficient to meet CO2 and/or cooling requirements.
Duration: 3-5 years on oak logs; 2-3 years on alder.
Harvest Stage: Directly before the incurved margin straightens and the cap expands to plane.
Flushing Interval: Outdoor methods generate 2 flushes per year (fall and spring); indoor methods can produce up to 4 flushes depending on the soaking/initiation schedule.
Light: Same as above.

Yield Potential: Average commercial yields are 2-3 lbs (fresh weight) of mushrooms per log.

Moisture Content of Mushrooms: 85% water; 15% dry matter.

Nutritional Content: 10.0-17.5% crude protein (dry weight) and 55 milligrams of niacin per 100 grams dry weight.

Comments: Compounds in this mushroom have anti-cholesterol effects. Chihara (1979) reported that lentinan, a water soluble polysacharide in *L. edodes*, was "found to almost completely regress the solid type tumors of sarcoma-180 and several kind (sic) of tumors...". The work of others (Cochran, 1978; Tokita *et al*., 1972; Tokuda and Kaneda, 1979) have similarly described the beneficial properties of this fungus. (See Appendix III).

Although the standard method of cultivation involves oak logs, recent experiments employing sawdust or rye grass based "synthetic" mixtures have proved that *Lentinus edodes* can be grown on a variety of substrates. In a recent article, Han et alia (1981) report the results of growth experiments with shiitake mini-logs composed of 90% broadleaf sawdust, 10% rice bran and 0.2% $CaCO_3$. Supplements that increased mycelial growth more than rice bran were yeast powder (2.0%), soybean meal (5.0%), milk powder (2.0%) and molasses (1.5%). The fastest mycelial growth occurred when the moisture content of the logs was balanced to 50-60%. In tests on fruiting and yield the following data were compiled:

> Once mycelial growth is complete, highest yields were achieved if the vegetative cycle was prolonged 4-12 weeks, with the maximum yield at 12 weeks.
> At pin initiation, water bath periods of 48-72 hours increased the moisture content of the logs by 5-15% and yields by 50%.
> Cooling the logs for eight days at 60-62°F. following 48 hours of soaking gave the highest yields.
> Using 0.1 % N hydrochloride to adjust the pH of the water bath from 4.5-7.0, a pH of 5.0 produced the most primorida and mature mushrooms.
> At a light intensity of 550 lux, yields were highest. The addition of the hormones NAA (5ppm), gibberellin (l0ppm), ethylene chlorohydrin (2000x) and colchicine (8000x) as well as yeast powder (0.1%) to the water bath increased yields.

Nevertheless, the traditional log method remains the most commercially feasible at this time and the one best suited to home cultivation.

Genetic Characteristics: Basidia tetrapolar, forming four haploid spores; heterothallic. Dikaryons with clamp connections. See Chapter XV.

SPECIES: *Lepista nuda* (Bull. ex Fr.) Cooke

= *Clitocybe nuda* (Fr.) Bigelow and Smith
= *Tricholoma nudum* (Fr.) Kummer

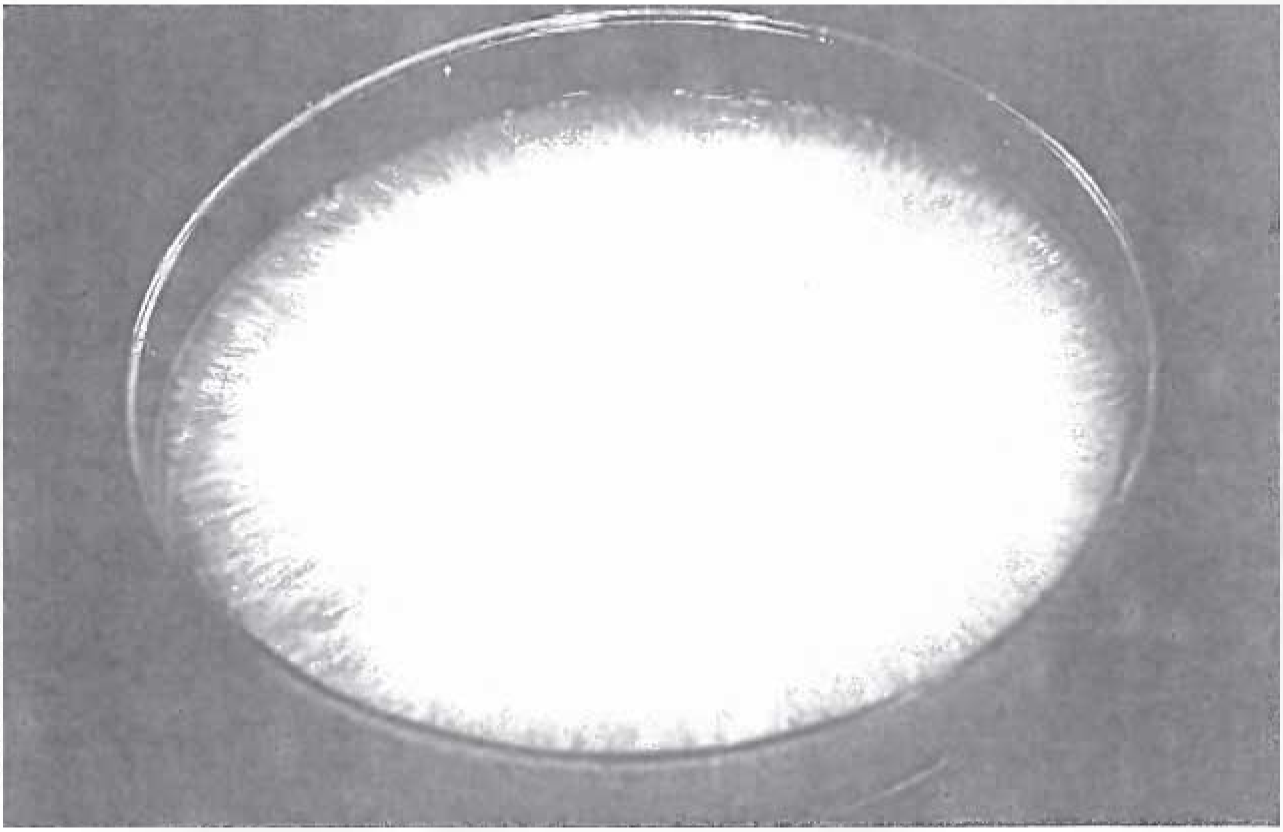

Figure 155 - Mycelium of *Lepista nuda*.

STRAINS: Available from commercial and private stocks. The American Type Culture Collection has several strains. Although few spawn companies sell strains of *L. nuda*, tissue and spore cultures are easily obtained from wild specimens. Nevertheless, there are a limited number of productive strains currently in circulation.

COMMON NAME: The Blewit.

LATIN AND GREEK ROOTS: *Lepista* comes from the greek "lepis" which means scale. On the other hand, the species epithet nuda comes from "nudus" or naked. The name *Lepista nuda* constitutes a contradition of terms, literally translating as the scaly smooth mushroom.

GENERAL DESCRIPTION: Cap typically violet when fresh, becoming buff brown in drying; smooth, without hairs; dry; convex or broadly convex to plane in age. The cap margin is inrolled or incurved when young and simply decurved at maturity. The gills are a pale violet color, sometimes developing brownish hues in age and are adnexed or ascending in their attachment to the stem. The stem is equal overall but bulbous at the base and covered with fine fibrils over much of its surface. Fruifbodies can be moderately large when mature. A partial veil is absent. The spore deposit is pale pinkish tan.

NATURAL HABITAT: Commonly occurring in the summer to late fall across much of the temperate regions of North America and Europe. This species is found in and around decomposing piles of sawdust, in conifer duff, amongst leaves and in mature compost piles.

L. nuda - Growth Parameters

Mycelial Types: Linear to cottony and usually with purplish to violet hues. (See Color Photo 3).

Spawn Medium: A 4:1 sawdust/bran mixture or rye grain spawn. See Chapter III.

Fruiting Substrates: Horse manure/straw compost mixed with 10% fresh straw at spawning; leaf mulch/sawdust mixtures.

Spawn Run:

Relative Humidity: 90+%.
Substrate Temperature: Fastest growth at 70-75°F. Temperature maxima and minima: 40°F. and 86°F. respectively.
Duration: 25-60 days for complete colonization.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.
Light: Incubation in total darkness.

Type of Casing: Standard peat based casing. An option is the addition of shredded leaf material and activated charcoal to 10% of total mass. Balance to a pH of 7.0.

Pinhead Initiation:

Relative Humidity: 95%.
Air Temperature: 55-65°F.
Duration: 7-14 days.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Light: Ambient natural light or optimally 10 lux in the 370-420 nanometer range. (Light requirements have not yet been established for this species, and until that time, light stimulation should be presumed as a prerequisite for fruiting.)

Cropping:

Relative Humidity: 85-90%.
Air Temperature: 55-65°F.
Duration: 24-52 weeks.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Harvest Stage: While the mushroom caps remain convex.
Flushing Interval: 10-14 days.
Light: Same as above.

Yield Potential: Data very limited. Yields of one and a quarter pounds per square foot in 14 weeks have been reported by Visscher (1981). (Recent studies show that yields can be increased substantially, although no maxima have yet been established.)

Moisture Content of Mushrooms: 88-90% water; 10-12% dry matter.

Nutritional Content: No data available.

Comments: Several contradictions about the fruiting requirements for this species are apparent. Although

Wright and Hayes (1979) reported that immature horse manure/straw composts supported the most vigorous mycelial growth, the work of previous researchers indicates that the best fruitings occurred on "spent" compost that has been colonized for a year or more. Fruitbodies also form on spawned leaf mulch mixed with sawdust. The fruiting mechanism may, in part, be controlled by bacterial flora associated with leaf mulch and the decomposition process.

Singer (1963) reported that mycelium implanted in beds of horse manure/straw compost for 7-14 months produced mushrooms directly after the appearance of rhizomorphs. J. Garbaye *et al*. (1979) published data indicating that the supplementation of natural patches with a NPKCa mineral fertilization induced large fruitings of *L. nuda* as well as *Boletus edulis* and *Lepiota rachodes*, two unrelated species of culinary distinction.

Alexander Smith (1980) remarks that this mushroom should not be eaten raw, but only after cooking. European books have reported that this mushroom contains thermobile hemolysin, a compound that degenerates red blood cells. Although this mushroom has been responsible for scattered poisonings when quantities have been eaten, the effects have been relatively minor and the toxin is easily destroyed by cooking or parboiling. *Lepista nuda* is, however, a mushroom with many positive attributes. Its striking color, firm texture and good taste recommend this species as one of high culinary appeal.

Some commercial production of *L. nuda* is ongoing in Europe. Nevertheless, this mushroom is not, as of yet, a species with yields substantial enough to warrant commercial production in this country. It is a mushroom more suited to the interests of home cultivators and natural culture techniques.

Genetic Characteristics: Basidia tetrapolar, forming four haploid spores; heterothallic. Dikaryons with clamp connections. See Chapter XV.

SPECIES: *Panaeolus cyanescens* Berkeley and Broome

= *Copelandia cyanescens* (Berk. & Br.) Sing.

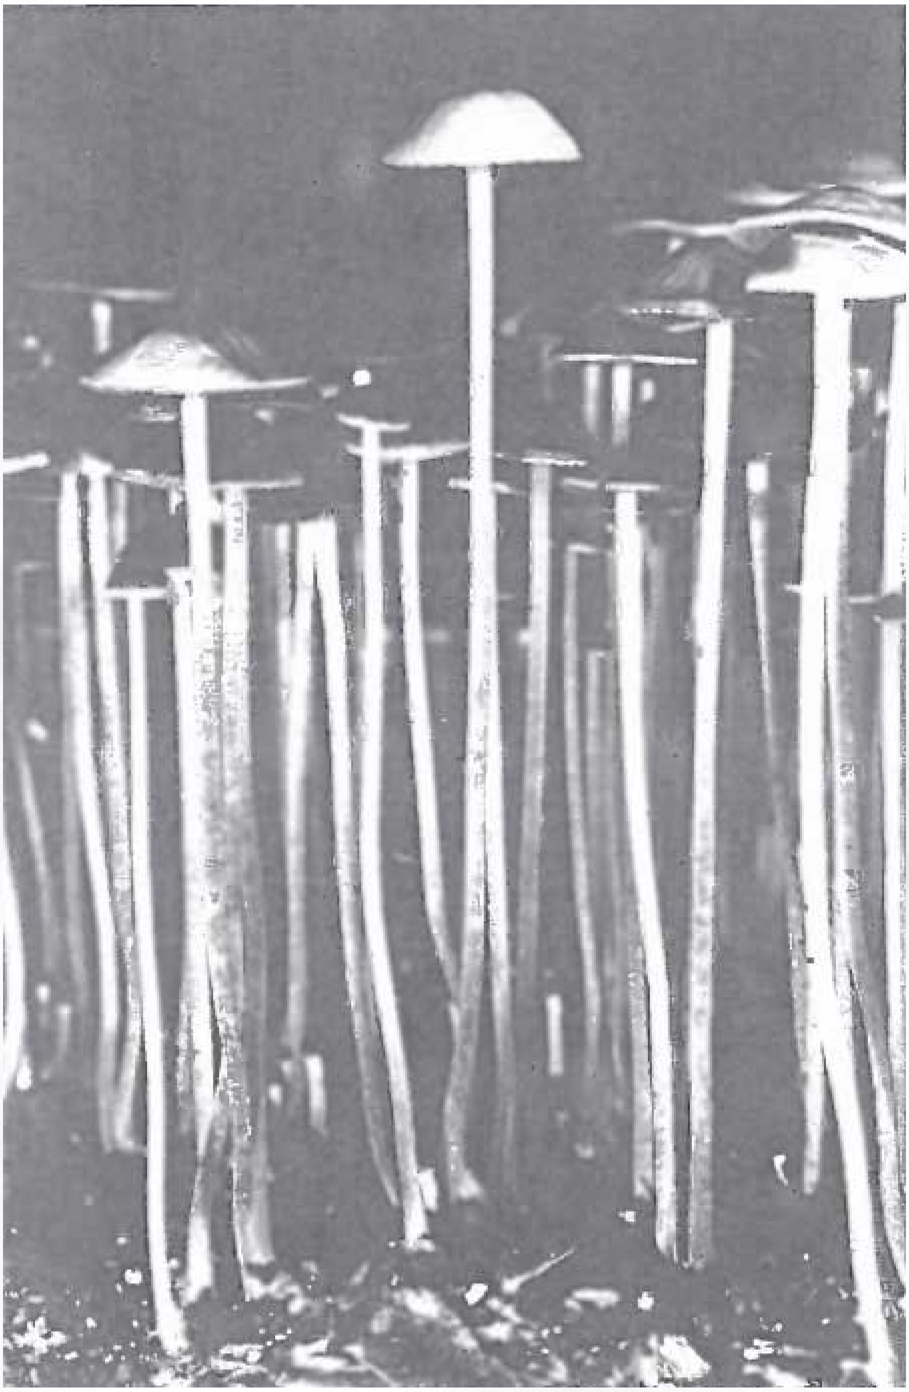

Figure 156 - *Panaeolus cyanescens* fruiting on cased straw.

STRAINS: Hawaiian. Mexican.

COMMON NAME: Pan cyan.

GREEK ROOT: *Panaeolus* is Greek for "all variegated", in reference to the spotted appearance of the gills. The species name *cyanescens* comes from "cyaneus" or blue for the color the flesh becomes upon bruising.

GENERAL DESCRIPTION: Cap 15-40 mm. broad. Hemispheric to campanulate to convex or broadly convex at maturity. The margin is initially shortly translucent striate when wet, opaque when dry. The cap is light brown at first, becoming pallid grey in drying, eventually pallid to white, often covered with spores. The gills are adnexed in their attachment, close, thin, with two or three tiers of intermediate gills and mottled grayish black at with spore maturity. The stem is 85-120 long x 15-30 mm. thick and equal to bulbous at the base, tubular, often grayish towards the apex, pale yellowish overall, and flesh colored to light brown towards the base. The flesh readily turns bluish where bruised. A partial veil is absent. Its spores are dark violet-black.

NATURAL HABITAT: Scattered to numerous on dung, in well manured grounds, grassy areas, meadows, or pastures. Known from Hawaii and Mexico. Two other Panaeoli, close to *P. cyanescens* macroscopically and microscopically, grow in western Washington and in Florida.

P. cyanescens - Growth Parameters

Mycelial Types: Linear to cottony mycelia; white to off-white, sometimes bruising bluish where injured.

Spawn Medium: Rye grain. See Chapter III.

Fruiting Substrates: Pasteurized wheat straw; horse manure/straw compost.

Method of Preparation: Chopped wheat straw pasteurized in a hot water bath at 160° for 20-30 minutes, cooled and spawned or horse manure/straw compost prepared according methods outlined in Chapter V.

Spawn Run:

Relative Humidity: 90+%.
Substrate Temperature: 79-84°F.
Duration: 7-12 days.
CO_2: 10,000 ppm or higher.
Fresh Air Exchanges: 0 per hour.

Type of Casing: Standard peat based casing whose preparation is described in Chapter VIII. Layer to a depth of ½-1 inch.

Post Casing/Pre-pinning:

Relative Humidity: 90+%.
Substrate Temperature: 79-84°F.
CO_2: 10,000 ppm or above.
Fresh Air Exchanges: 0 per hour.
Light: Incubation in darkness.

Primordia Formation:

Relative Humidity: 95+%.
Air Temperature: 75-80°F.
CO_2: 5,000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Light requirements: Diffuse natural or fluorescent grow-lights.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 75-80°F.
CO_2: 5,000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Harvest Stage: When the caps are convex.
Flushing Interval: 5-7 days.
Light: Diffuse natural or grow-lights.

Yield Potential: Not yet established.

Moisture Content: 90-92% water; 8-10% dry matter.

Comments: This rapidly growing species fruits readily on pasteurized straw provided a thin layer of casing is applied (½ inch). No more than one week passes from the time of casing to the first flush. Although the fruitbodies are small, the flushes are typically abundant. The degree of bluing seems to vary with the strain and substrate.

SPECIES: *Panaeolus subbalteatus* Berkeley and Broome

= *Panaeolus venenosus* Murrill

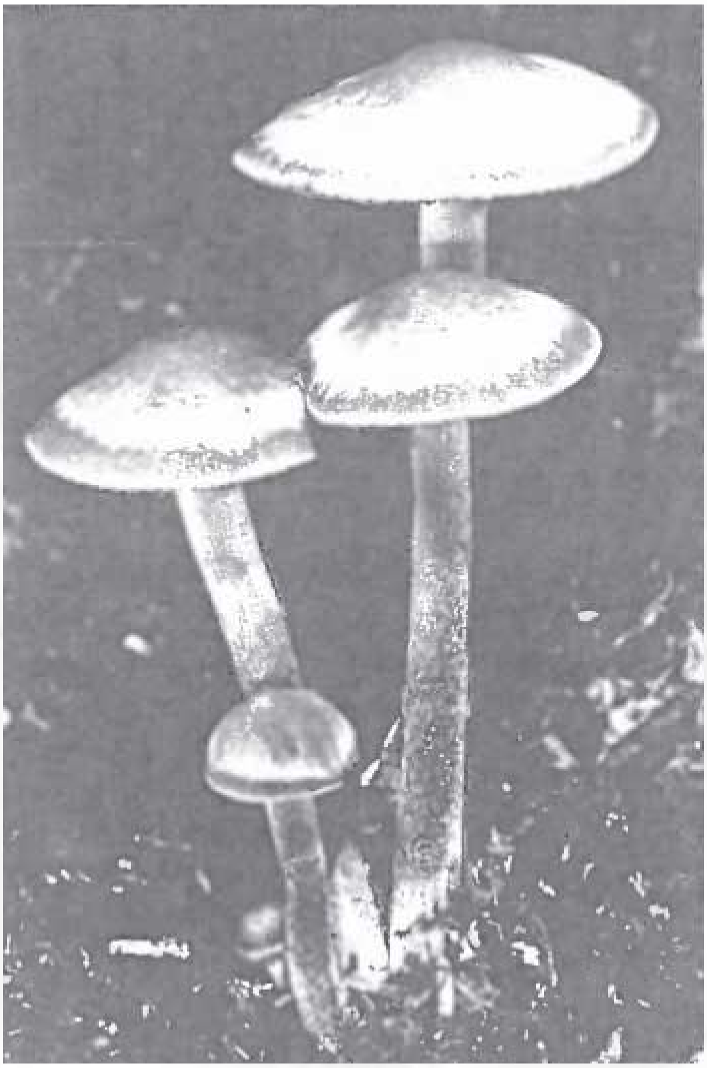

Figure 157 - *Panaeolus subbalteatus* fruiting outdoors on horse manure-wood chip compost.

STRAINS: Fruiting strains are easily obtained from wild specimens.

COMMON NAME: The Belted Cap *Panaeolus*.

GREEK ROOT: *Panaeolus* is Greek for "all variegated" in reference to the spotted appearance of the gills. The species name *subbalteatus* comes from the conjunction of the prefix "sub-" meaning almost or somewhat and "balteatus" or belt-like, for the characteristic color zonation that forms along the margin of the cap in drying.

GENERAL DESCRIPTION: Cap 35-50 mm. broad at maturity. The cap is convex to campanulate, then broadly convex and finally expanding to nearly plane with a broad umbo. The color is cinnamon brown to orangish cinnamon brown, fading to tan in drying with a dark brown encircling zone along the cap margin. The gills are attached to the stem, broader at the center and with three tiers of intermediate gills inserted. The gill color is brownish and spotted, with the edges remaining whitish, becoming blackish overall from spore maturity. The stem is 50-60 mm. long by 4 mm. thick at maturity and is brittle, hollow, fibrous, and enlarges towards the base. The color is reddish toned beneath a fine sheath of minute whitish fibrils, darkening downwards or when touched. The stem base often bruises bluish. On the cap, bluing is rarely seen.

NATURAL HABITAT: Scattered to numerous on stable leavings from horses; in horse dung; or in well manured grounds. This species is widely distributed across the North American continent and throughout temperate regions of the world.

P. subbalteatus - Growth Parameters

Mycelial Types: Cottony mycelia noted; whitish to off-white in color.

Spawn Medium: Rye grain.

Fruiting Substrate: Horse manure compost, pasteurized wheat straw.

Method of Preparation: Horse manure/straw compost or pasteurized wheat straw prepared according to methods outlined in Chapters V & VI respectively.

Spawn Run:

Relative Humidity: 90+%.
Substrate Temperature: 80-86°F.
Duration: 7-12 days.
CO_2: 10,000 ppm or higher.
Fresh Air Exchanges: 0 per hour.

Type of Casing: Casing optional. If used, make up a standard peat based casing whose preparation is described in Chapter VIII. Layer to a depth of ½ to 1 inch.

Post Casing/Pre-pinning:

Relative Humidity: 90%.
Substrate Temperature: 80-86°F.
CO_2: 10,000 ppm or above.
Fresh Air Exchanges: 0 per hour.
Light: Incubate in darkness.

Primordia Formation:

Relative Humidity: 95+%.
Air Temperature: 75-80°F.
CO_2: 5,000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Light: Diffuse natural or grow-lights.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 75-80°F.
CO_2: 5,000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Harvest Stage: When the caps have expanded to nearly plane.
Light: Diffuse natural or grow-lights.

Yield Potential: Not yet established.

Moisture Content: 90-92% water; 8-10% dry matter.

Comments: *Panaeolus subbalteatus* is a fast running and an early fruiting mushroom that easily grows in controlled environments. Possessing low levels of psilocybin and/or psilocin, the fruitbodies are small compared to other cultivated mushrooms. Hence, it has not been as popular with home cultivators as for instance, *Psilocybe cubensis*.

Given the fact that *Panaeolus cyanescens* fruits well on pasteurized wheat straw, *Panaeolus subbalteatus* is likely to fruit on that substrate as well. Pollock (1977) fruited this species on cased crimped oat spawn. Undoubtedly, *Panaeolus subbalteatus* can be grown on a wide variety of substrates.

Short term "natural culture" of this mushroom is also possible although yields are much lower than those attained in a controlled indoor growing environment. Horse manure/straw compost arranged in outdoor beds can be inoculated with mycelium from wild patches or grain spawn can be used.

Panaeolus subbalteatus is considered a "weed mushroom" by commercial *Agaricus* growers and its presence suggests under-composting and/or excessive moisture. This species once had the reputation, albeit undeserved, of being poisonous - thus the synonym *Panaeolus venenosus*.

SPECIES: *Pleurotus ostreatus* (Jacq. ex Fr.) Kummer

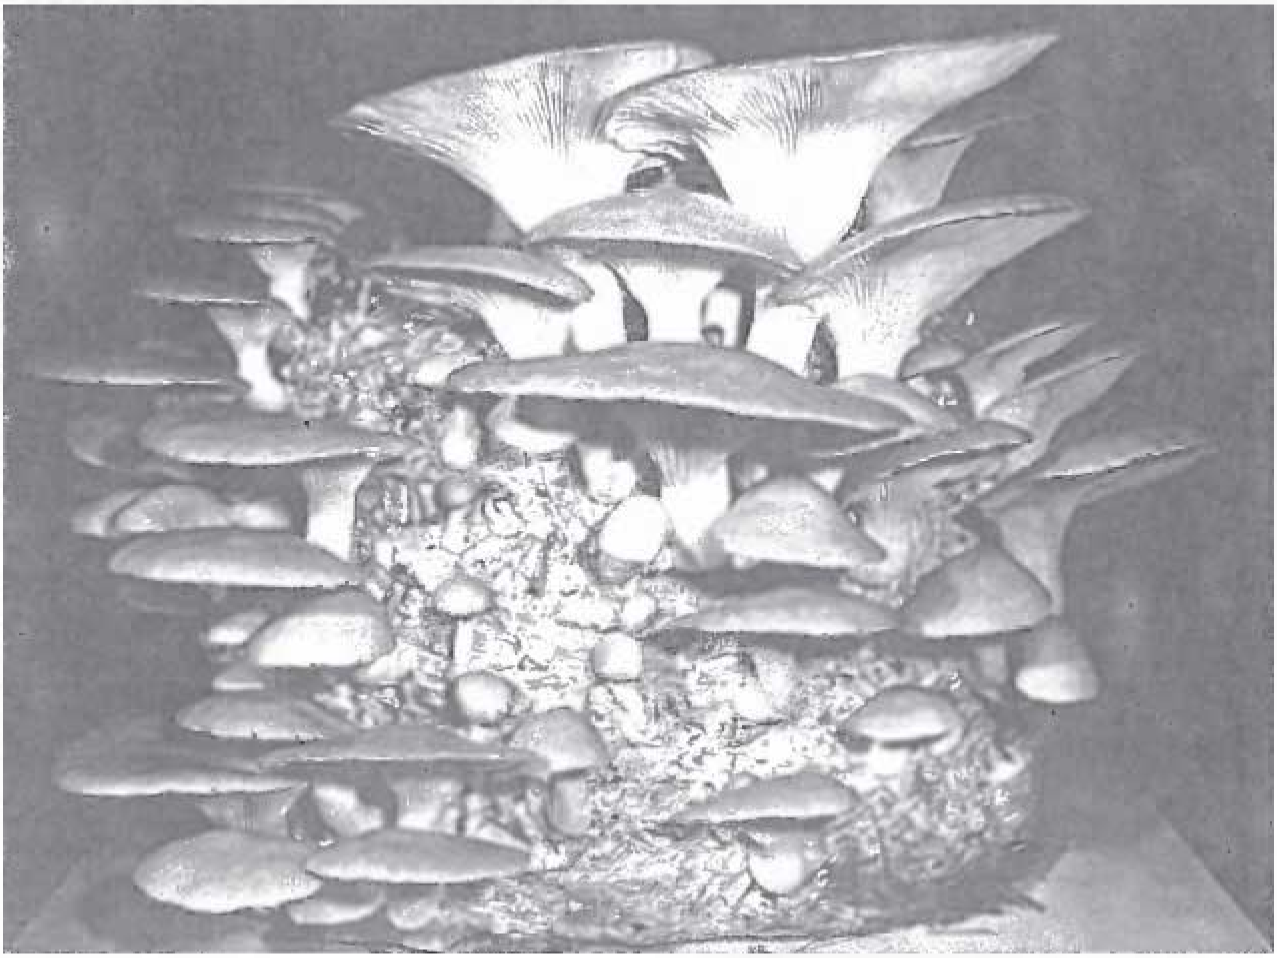

Figure 158 - Fully mature *Pleurotus ostreatus* mushrooms fruiting on straw.

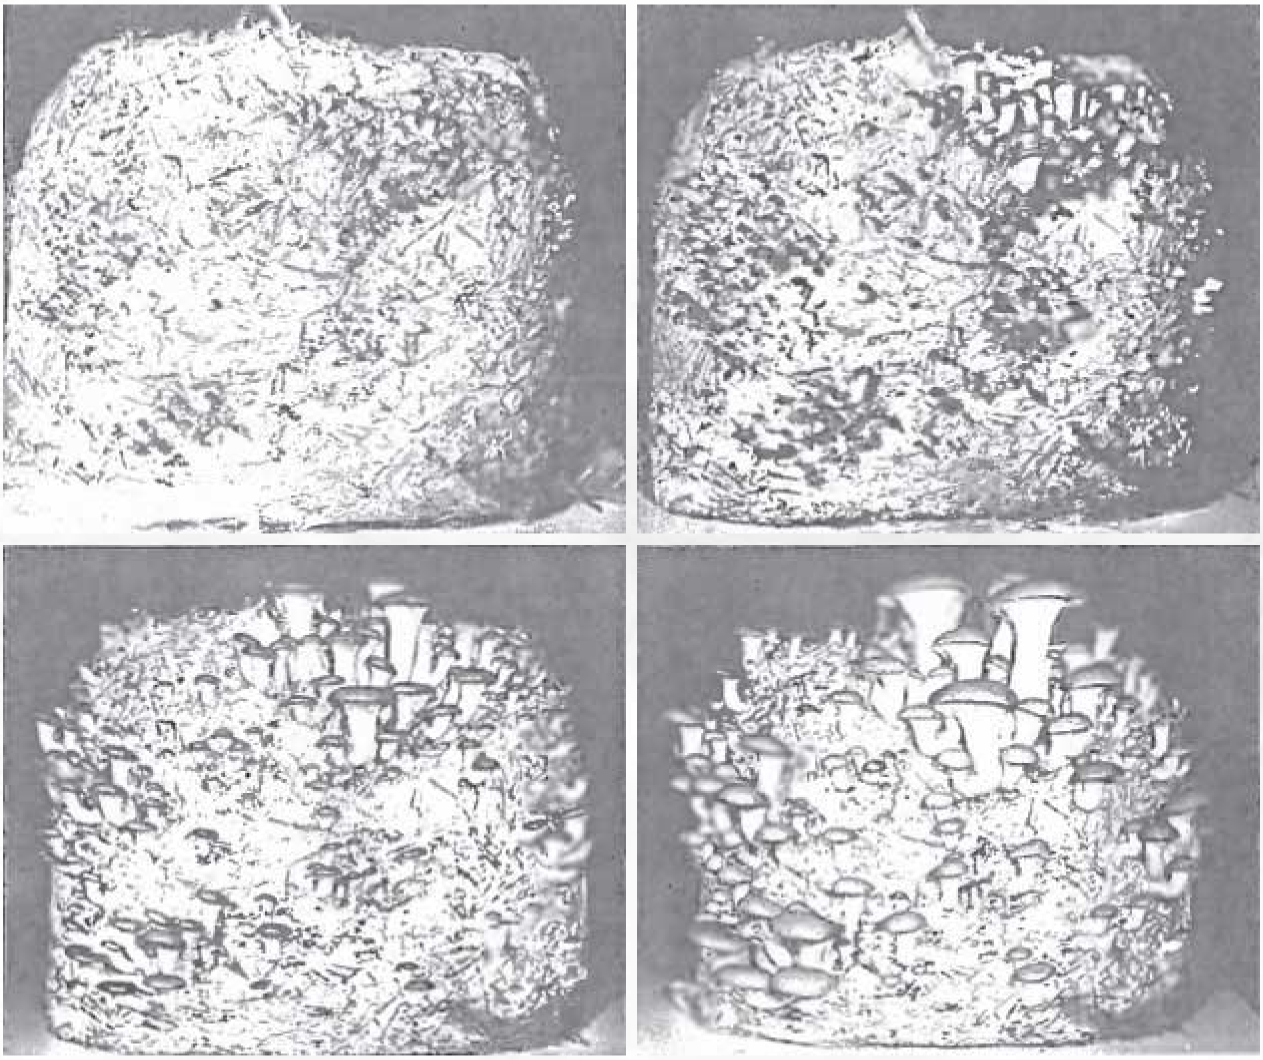
STRAINS: Strains of *Pleurotus ostreatus* are available from commercial and private stocks. The American Type Culture Collection, which sells cultures to educational organizations and research facilities, has stock cultures of several wild and domesticated strains. Somycel's-3004 is the standard strain used by the European *Pleurotus* industry and is synonymous with ATCC's-38546.

COMMON NAME: The Oyster Mushroom.

LATIN AND GREEK ROOTS: *Pleurotus* comes from the greek "pleuro" which means formed laterally or in a sideways position, referring to the lateral position of the stem relative to the cap. The species epithet *ostreatus* refers to its oyster shell-like appearance and color.

GENERAL DESCRIPTION: Cap tongue shaped, maturing to a shell shaped form, 50-150 mm. in diameter; whitish to gray to blue gray overall. (Color is a light determined factor in this species). The flesh is thin and white. The margin is even and occasionally wavy. The gills are white, decurrent and broadly spaced. The stem is attached in an off-centered fashion and is short at first and absent in age. Its spores are whitish to lilac gray in mass.



Figures 159-162 - Four day developmental sequence of *Pleurotus ostreatus* fruiting on wheat straw.

NATURAL HABITAT: A wood decomposing, saprophytic or parasitic fungus. *Pleurotus ostreatus* grows abundantly on standing and fallen alder, cottonwood and maple. This species is especially numerous in river valleys and fruits in the fall, early winter and spring across much of temperate North America.

P. ostreatus - Growth Parameters

Mycelial Types: Fast growing rhizomorphic to linear mycelia noted. Color is typically whitish.

Spawn Medium: Rye grain. See Chapter III.

Fruiting Substrate and Method of Preparation: Cereal straw (normally wheat) balanced to a 75% moisture content. The straw, chopped or whole, is pasteurized by submerging in a 160°F. water bath for 30-45 minutes. An alternative method utilizes live steam pasteurization at 140°F. for 6 hours. In Japan, *Pleurotus* is grown on a mixture of hardwood sawdust and bran (4 parts to 1, 65% moisture and a pH of 6.8-7.0). This mixture is sterilized for 1-2 hours at 15 psi. Being a primary decomposer, *Pleurotus* grows on a wide variety of cellulosic wastes.

Spawn Run:

Relative Humidity: 90-100%.
Substrate Temperature: Fastest growth at 78-84°F. Thermal death occurs if mycelium is held above 104°F. for 48 hours.
Duration: 10-14 days for complete colonization.
CO_2: 20,000 ppm or 20% CO_2 by volume. (Growth is stimulated up to 28,000 ppm).
Fresh Air Exchanges: 0 per hour.
Light: Incubation in total darkness.

Type of Casing: None needed.

Pinhead Initiation:

Relative Humidity: 95%.
Air Temperature: 55-60°F.
Duration: 7-14 days.
CO_2: less than 600 ppm.
Fresh Air Exchanges: 4 per hour.
Light: Phototropic, most responsive to an exposure of 2,000 lux/hour for 12 hours/day. Grow-lux type fluorescent lighting is recommended. Diffuse natural light is sufficient.
Watering: Regular misting once to twice daily until fruitbodies are 30-40% of harvest size and then water as needed to prevent caps from cracking.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 60-64°F.
Duration: 5-7 weeks.
CO_2: less than 600 ppm.
Fresh Air Exchanges: 4-6 per hour or sufficient to meet CO_2 and/or cooling requirements.
Harvest Stage: Directly before incurved margin elevates to plane.
Flushing Interval: 10 days.
Light: Same as above.
Watering: Regular misting to prevent caps from cracking and to keep resting pinheads viable.

Yield Potential: Average commercial yields are 1 kilogram fresh weight of mushrooms per kilogram of dry weight of straw substrate.

Moisture Content of Mushrooms: 91% water; 9% dry matter.

Nutritional Content: Crude protein has been reported at 30.4 % of dry weight and 109 milligrams of niacin per 100 grams dry weight.

Comments: Biologically, *Pleurotus ostreatus* efficiently utilizes its substrate. Its ability to fruit on a single component substrate, to permeate the straw rapidly while tolerating high carbon dioxide levels and to produce abundant crops within a short time period, make *Pleurotus* ideal for home cultivation.

Of concern to cultivators growing in enclosed rooms is the abundant spore load generated by this species. *Pleurotus* spores cause allergic reactions amongst some workers and mycophagists. Sporeless strains are therefore desirable and are the object of current research. Eger (1974) noted the possibility that heavy spore concentrations from *Pleurotus* farms could infect surrounding woodlands.

Pleurotus ostreatus var. *florida*, a warmth loving relative, is also cultivated in Europe (Hungary) and shares many of the growth properties of *Pleurotus ostreatus*.

Genetic Characteristics: Basidia tetrapolar, producing 4 haploid spores; heterothallic. Clamp connections present. See Chapter XV.

For more information consult: F. Zadrazil, 1974. "*The Ecology and Industrial Production of Pleurotus ostreatus, Pleurotus florida, Pleurotus cornucopiae, and Pleurotus eryngii*" in Mushroom Science IX (Part I), The Mushroom Research Institute, Japan.

SPECIES: *Pleurotus ostreatus* (Jacq. ex Fr.) Kummer (Florida variety)

= *Pleurotus ostreatus* var. *florida* nom. prov. Eger
= *Pleurotus floridanus* Singer

STRAINS: Most strains of this mushroom originate from wild specimens cultivated in 1958 by S.S. Block of Gainesville, Florida. Eger compared the Florida strains with *Pleurotus ostreatus* from Michigan (supplied by Alexander Smith) and found them to be identical in form, taste, color and odor. Spore size and shape are also the same. Monokaryons arising from single spore germinations are completely cross fertile, suggesting that these two mushrooms are not separate species, but different strains within the same species.

The American Type Culture Collection, which sells cultures to educational organizations and research facilities, lists this mushroom under *Pleurotus ostreatus* as number #38538. This strain is Block's original. Eger returned to Florida with San Antonio in 1977 and recollected four more strains of *Pleurotus*, three of which were deposited with ATCC. They are respectively: F1 = ATCC #38539; F2 = #38540; F4 = #38541.

The Florida *Pleurotus* is available as commercial spawn from Somycel as #3025. The Swiss American Spawn Company sells a "low spore load" strain called P-3.

COMMON NAME: Pleurotus Florida. The Florida Pleurotus.

LATIN AND GREEK ROOTS: *Pleurotus* comes from the Greek "pleuro" which means formed laterally or in a sideways position, referring to the lateral position of the stem relative to the cap. The epithet Florida obviously refers to the locality where this mushroom was first collected.

GENERAL DESCRIPTION: Cap tongue shaped, maturing to a shell shaped form, 50-100 mm. in diameter; whitish to gray to pale yellow brown. (Color is a light and temperature determined factor in this species). The flesh is thin and white. The margin is even and occasionally wavy. The gills are white, decurrent and broadly spaced. The stem is attached in an off-centered fashion and is short at first and absent in age. Its spores are whitish to lilac gray in mass.

NATURAL HABITAT: A wood decomposing, saprophytic or parasitic fungus. *Pleurotus ostreatus* grows abundantly on standing and fallen alder, cottonwood and maple. This species is especially numerous in river valleys and fruits in the fall, early winter and spring in subtropical environs.

P. ostreatus (Florida variety) - Growth Parameters

Mycelial Types: Fast growing rhizomorphic to linear mycelia. Its color is typically whitish.

Standard Spawn Medium: Rye grain. See Chapter III.

Fruiting Substrate and Method of Preparation: Cereal straw (normally wheat) balanced to a 75% moisture content. The straw, chopped or whole, is pasteurized by submerging in a 160°F. water bath for 20-30 minutes. An alternative method utilizes live steam pasteurization at 140°F. for 6 hours.

In Japan, *Pleurotus* is grown on a mixture of hardwood sawdust and bran (4 parts to 1,65% moisture and a pH of 6.8-7.0). This mixture is sterilized for 1 hour at 15 psi. Being a primary decomposer, *Pleurotus* grows on a wide variety of wastes high in cellulose.

Spawn Run:

Relative Humidity: 90-100%.
Substrate Temperature: Fastest growth at 82-86°F. Thermal death occurs if mycelium is held above 104°F. for 72 hours.
Duration: 10-14 days for complete colonization.
CO_2: 20,000 ppm or 20% CO_2 by volume. (Growth is stimulated up to 28,000 ppm).
Fresh Air Exchanges: 0 per hour.
Light: Incubation in total darkness.

Type of Casing: None needed.

Pinhead Initiation:

Relative Humidity: 95%.
Air Temperature: 72-77°F.
Duration: 7-14 days.
CO_2: less than 600 ppm.
Fresh Air Exchanges: 4 per hour.
Light: Positive phototropism has been firmly established. 2,000 lux/hours for 12 hours/day is most stimulatory. Grow-lux type fluorescent lighting is recommended. Diffuse natural light is sufficient.
Watering: Regular misting (once to twice daily) of the substrate until the fruitbodies are 30-40% of harvest size.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 72-77°F.
Duration: 4-5 weeks.
CO_2: less than 600 ppm.
Fresh Air Exchanges: 4-6 per hour or sufficient to meet CO_2 and/or cooling requirements.
Harvest Stage: Directly before incurved margin expands to plane.
Flushing Intervals: 10 days.
Light: Same as above.
Watering: Misting recommended to prevent cracking of caps and to prevent resting primordia from drying.

Yield Potential: Average commercial yields for *Pleurotus ostreatus* var. *florida* are 1 kilogram fresh weight of mushrooms per kilogram of dry weight of straw substrate. *Pleurotus ostreatus* var. *florida* produces more mushrooms within a shorter period of time while attaining a similar total yield per dry pound of substrate than does *Pleurotus ostreatus*.

Moisture Content of Mushrooms: 91 % water; 9% dry matter.

Nutritional Content: Crude protein has been reported at 30.4% of dry weight and 109 milligrams of niacin per 100 grams dry weight.

Comments: The Floridan *Pleurotus ostreatus*, a warmth loving variety, is popular with growers in Europe (Hungary, France and Germany) and shares many of the growth characteristics of *Pleurotus ostreatus*. Its preference for warmer climes recommends this species for cultivation during the late spring through early fall whereas *P. ostreatus* is ideal for winter cultivation.

This mushroom, like its close cousin *P. ostreatus*, is perfect for the home cultivator. But, the Floridan *Pleurotus ostreatus* has a distinct advantage over *P. ostreatus* in that a "cold shock" is not needed for pinhead formation and the period from initiation to first flush is only 10 days compared to 20 days for *P. ostreatus*. Its ability to fruit on a singular substrate, to permeate the straw rapidly while tolerating high CO_2 levels and to produce abundant crops within a short time frame, makes *Pleurotus* an excellent species for small scale cultivation.

The taxonomy of this "species" is unsettled and contradictory. Dr. Rolf Singer places *P. floridanus* in the Section Lentodiellum whose species are characterized by deeply rooted metuloid pleurocystidia (sterile surface cells on the gill having incrustations) and have mycelia that do not sclerotize. On the other hand, he assigns *Pleurotus ostreatus* to the type section *Pleurotus* which lacks metuloid pleurocystidia and has hyphae that undergoes sclerotization. Since monokaryons from single spores are compatible between these two mushrooms, and because sporulating fruitbodies form as a result of their mating, it seems clear that these two mushrooms are one species sharing a common genetic heritage.

Of concern to cultivators is the abundant spore load produced by this mushroom, most noticeable within an enclosed growing environment. Some people suffer allergic reactions when coming into contact with *Pleurotus* spores. A small fraction of mycophagists are unable to eat *P. ostreatus* and allies without stomach upset. Hence, when eating these mushrooms for the first time, small portions are recommended.

Genetic Characteristics: Basidia tetrapolar, producing 4 haploid spores; heterothallic. Clamp connections present. See Chapter XV.

SPECIES: *Psilocybe cubensis* (Earle) Singer

= *Stropharia cubensis* Earle.
= *Stropharia cyanescens* Murr.
= *Stropharia caerulescens* (Pat.) Sing.
= *Naematoloma caerulescens* Pat.
= *Hypholoma caerulescens* (Pat.) Sacc. & Trott.

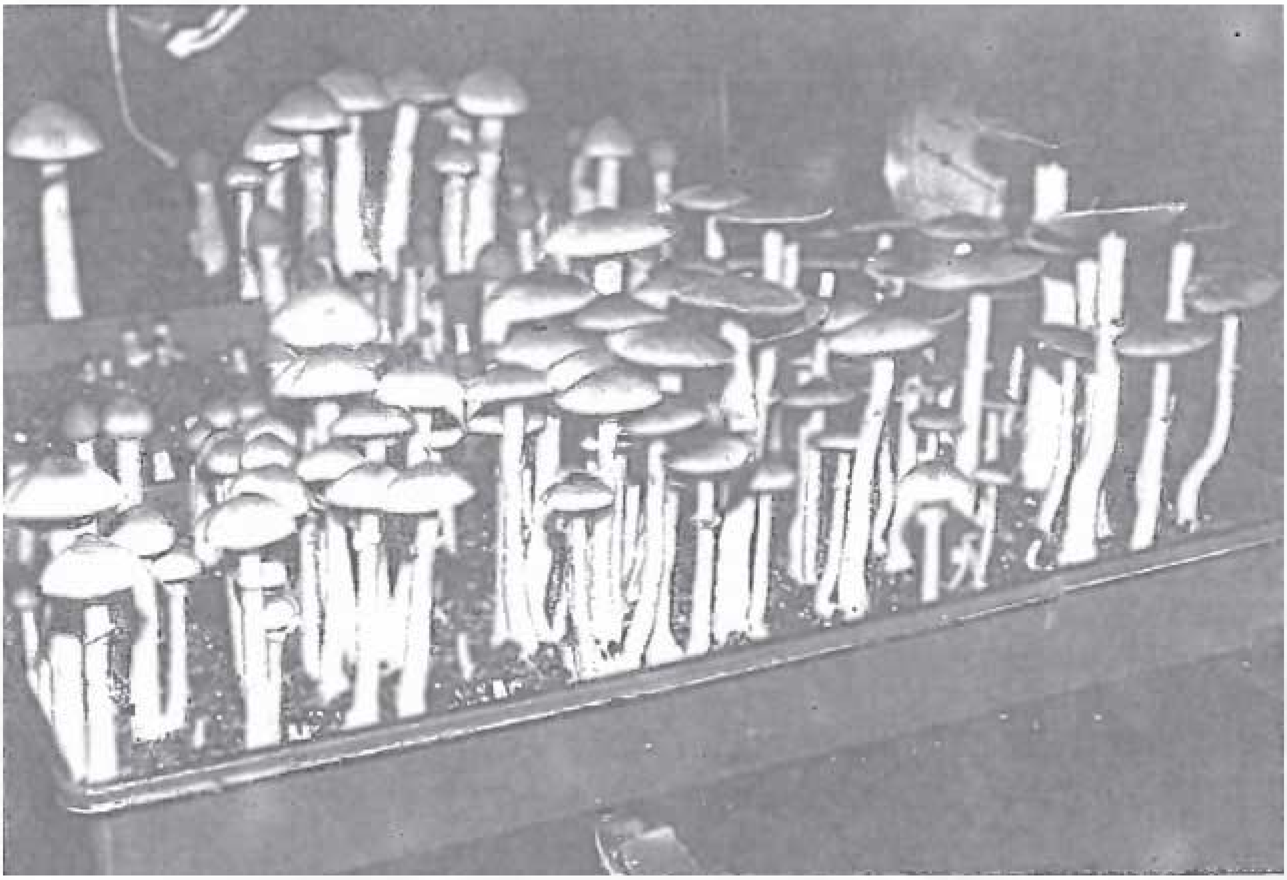

Figure 163 - *Psilocybe cubensis* fruiting on cased grain.

STRAINS: Strains of *Psilocybe cubensis* are available from private and commercial stocks. The American Type Culture Collection, which sells cultures to educational organizations and research facilities, has stock cultures of several wild strains. Note that the strains listed below are only some of those that are presently circulating. There are many more. Some strains may originate from the same region but have features not in agreement with those described here.

Amazonian: Medium to large mushrooms on rye grain; thick whitish stems; tenaciously attached to the casing.

Ecuadorian: Medium sized mushrooms on rye grain; hemispheric caps; abundant primordia former; high yielding on compost; thin whitish stems; easily picked.

Matias Romero: Medium to large mushrooms on rye grain; early fruiter; thick whitish stems and tenaciously attached.

Misantla: Medium sized mushrooms on rye grain; thin yellowish stems; tall standing and easily picked.

Palenque: Large mushrooms on rye grain; high yielding; and easily picked.

COMMON NAMES: San Isidro; Cubensis.

GREEK ROOT: *Psilocybe* comes from the Greek root "psilos" meaning bald head and *cubensis*, a name Earle assigned to this mushroom because it was first recognized as a new species from specimens collected in Cuba.

GENERAL DESCRIPTION: A medium to large size mushroom having a cap that becomes convex to plane in age and is usually pigmented chestnut brown to deep yellowish or golden brown. The cap surface is finely fibrillose, sometimes covered with scattered, fugacious, cottony scales that soon disappear. The partial veil is membranous, well developed and typically leaving a persistent annulus on the upper regions of the stem. The stem is often longitudinally striate, powdered above the annulus and often covered with dense fibrils below. Flesh bruising bluish or bluish green. Its spores purplish brown in mass.

NATURAL HABITAT: Naturally found in horse and cow pastures, in dung or in soil enriched with manure. *Psilocybe cubensis* is a widely distributed species that is found throughout tropical and subtropical zones of the world and is common in the pasturelands of the gulf coast of the southern United States and eastern Mexico.

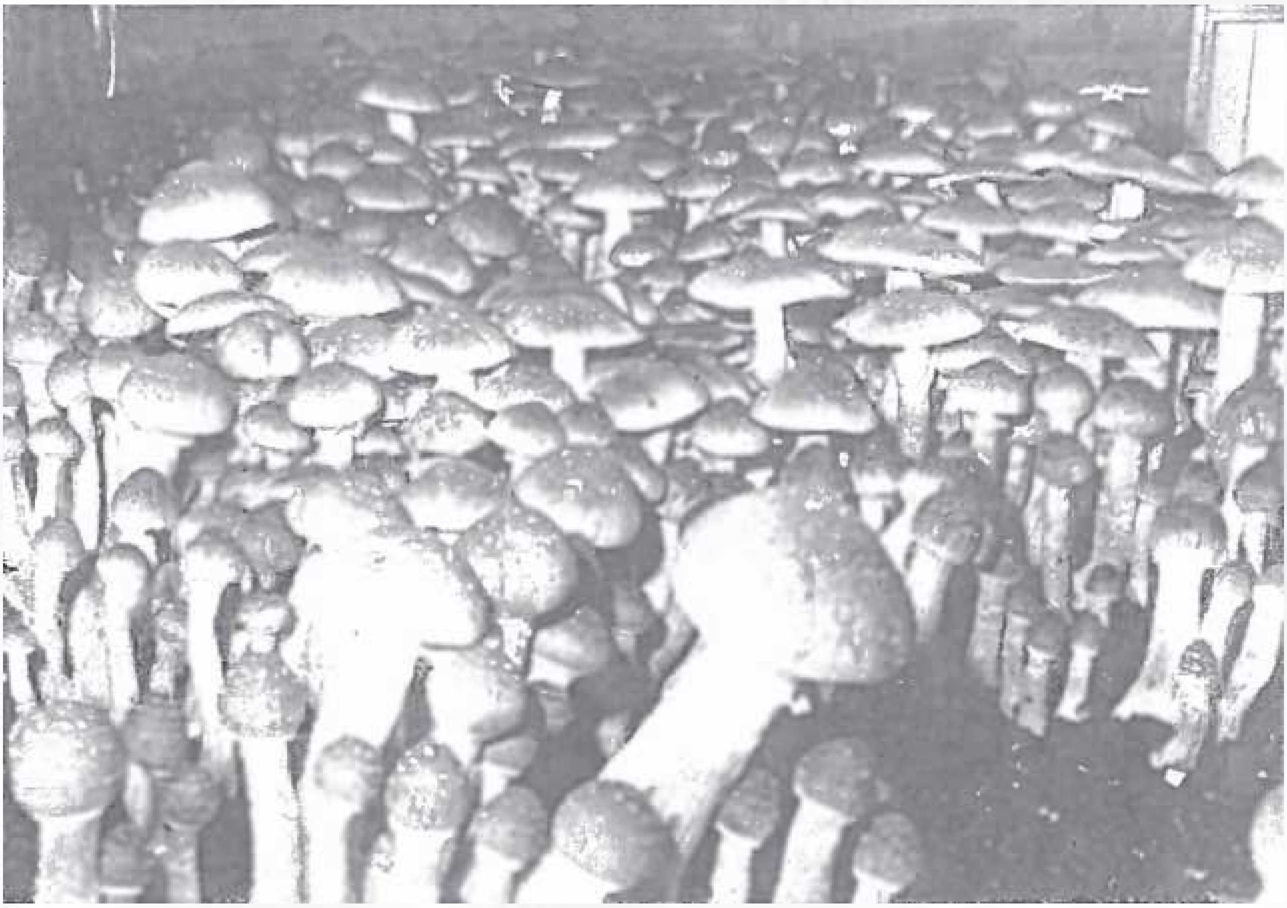

Figure 164 - *Psilocybe cubensis* fruiting on cased straw.

P. cubensis - Growth Parameters

Mycelial Types: Rhizomorphic to linear; whitish in overall color but often bruising bluish where injured.

Standard Spawn Medium: Rye grain. See Chapter III.

Fruiting Substrate: Rye grain; wheat straw; leached horse or cow manure; and/or horse manure/straw compost balanced to a 71-74% moisture content.

Method of Preparation: See Chapters III, V, and VI. Pasteurization achieved through exposure to live steam for 2 hours at 140°F. throughout the substrate. Straw or compost should be filled to a depth of 6-12 inches. Straw should be spawned at a rate of 2 cups/sq. ft.

Spawn Run:

Relative Humidity: 90%.
Substrate Temperature: 84-86°F. Thermal death limits have been established at 106°F.
Duration: 10-14 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Type of Casing: After fully run, cover with the standard casing whose preparation is described in Chapter VIII. Layer to a depth of 1-2 inches. The casing should be balanced to an initial pH of 6.8-7.2.

Post Casing/Prepinning:

Relative Humidity: 90+%.
Substrate Temperature: 84-86°F.
Duration of Case Run: 5-10 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.
Light: Incubation in total darkness.

Primordia Formation:

Relative Humidity: 95-100%.
Air Temperature: 74-78°F.
Duration: 6-10 days.
CO_2: less than 5000 ppm.
Fresh Air Exchanges: 1-3 per hour.
Light: Diffuse natural or exposure for 12-16 hours/day of grow-lux type fluorescent light high in blue spectra at the 480 nanometer wavelength. (See Chapters IV and IX).

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 74-78°F.
CO_2: less than 5000 ppm.
Fresh Air Exchanges: 1-3 per hour.
Flushing Pattern: Every 5-8 days.
Harvest Stage: When the cap becomes convex and soon after the partial veil ruptures.
Light: Indirect natural or same as above.

Yield Potential: Average yields are 2-4 lbs./sq.ft. over a 5 week cropping period. Maximum yield potential has not been established.

Moisture Content of Mushrooms: 92% water; 8% dry matter.

Nutritional Content: Not yet established.

Comments: One of the easiest mushrooms to grow, this species fruits on a wide variety of substrates within broad environmental parameters. As a primary and secondary decomposer, *Psilocybe cubensis* fruits well on untreated pasteurized straw and on horse manure/straw composts transformed by microbial activity. Sterilized grain typically produces smaller mushrooms than bulk substrates. Given the numerous substrates that support fruitings, *Psilocybe cubensis* is well suited for home cultivation.

Psilocybe cubensis cultivation was unheard of twenty years ago. Today, this species ranks amongst one of the most commonly cultivated mushrooms in the U.S. and soon the world. This sudden escalation in interest is largely due to the publication of several popular guides illustrating techniques for its culture.

Psilocybe cubensis is a mushroom with psychoactive properties, containing up to 1% psilocybin and/or psilocin per dried gram. The function of these serotonin-like compounds in the life cycle of the mushroom is not known.

Genetic Characteristics: Basidia tetrapolar (4-spored), forming haploid spores (1N); heterothallic. The mating of compatible monokaryons often results in fruiting strains. Clamp connections are present. See Chapter XV.

For further information consult: Oss, O.T. and O.N. Oeric, 1976. "*Psilocybin: Magic Mushroom Grower's Guide*" And/Or Press, Berkeley.

SPECIES: *Psilocybe cyanescens* Wakefield

= *Geophila cyanescens* (Maire) Kuhn. & Romagn.
= *Psilocybe mairei* Singer

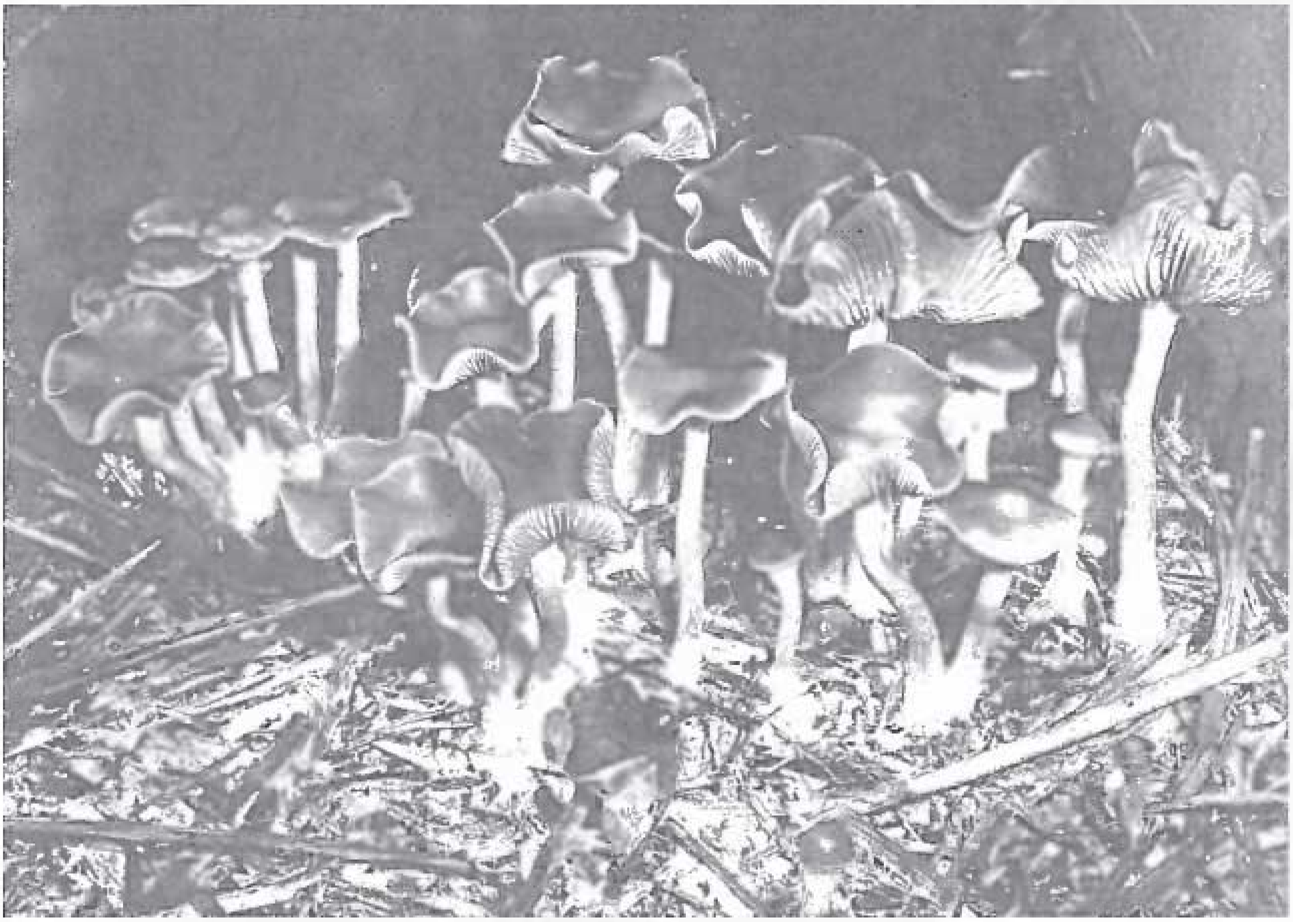

Figure 165 - Psilocybe cyanescens fruiting indoors in a tray of alder chips.

STRAINS: St. Clair.
Many wild strains can be adapted to cultivation.

COMMON NAMES: Cyan; Grandote.

GREEK AND LATIN ROOTS: *Psilocybe* comes from the Greek "psilos" or bald head. The species name *cyanescens* is from "cyaneus" or blue for the color reaction of the flesh upon bruising.

GENERAL DESCRIPTION: Cap 20-50 mm. broad, convex to broadly convex to plane in age with an elevated and undulating margin which is, in turn, translucent-striate. The cap surface is smooth and viscid when moist from a separable gelatinous pellicle ("skin"). The color is caramel brown, fading to yellow-brown to straw colored from the center. The gills are attached in an adnate to adnexed fashion, dull brown with whitish edges. The stem is 60-80 mm. long by 2-5 mm. thick, fibrous and enlarged towards the base. Its surface is smooth or powdered (pruinose). The stem color is whitish, silky and becomes blue where injured, with rhizomorphs protruding about the stem base. The partial veil is cortinate (cobweb-like), leaving little or no trace on the stem. Its spore print is dark purplish brown.

NATURAL HABITAT: Clustered in woody habitats; in soils high in the tissue of deciduous trees; or in tall rank grass. This species grows throughout the Pacific Northwest in areas well mulched by woody debris of deciduous and coniferous trees (typically not associated with bark). It has been reported from England and is thought to be broadly distributed throughout the European continent.

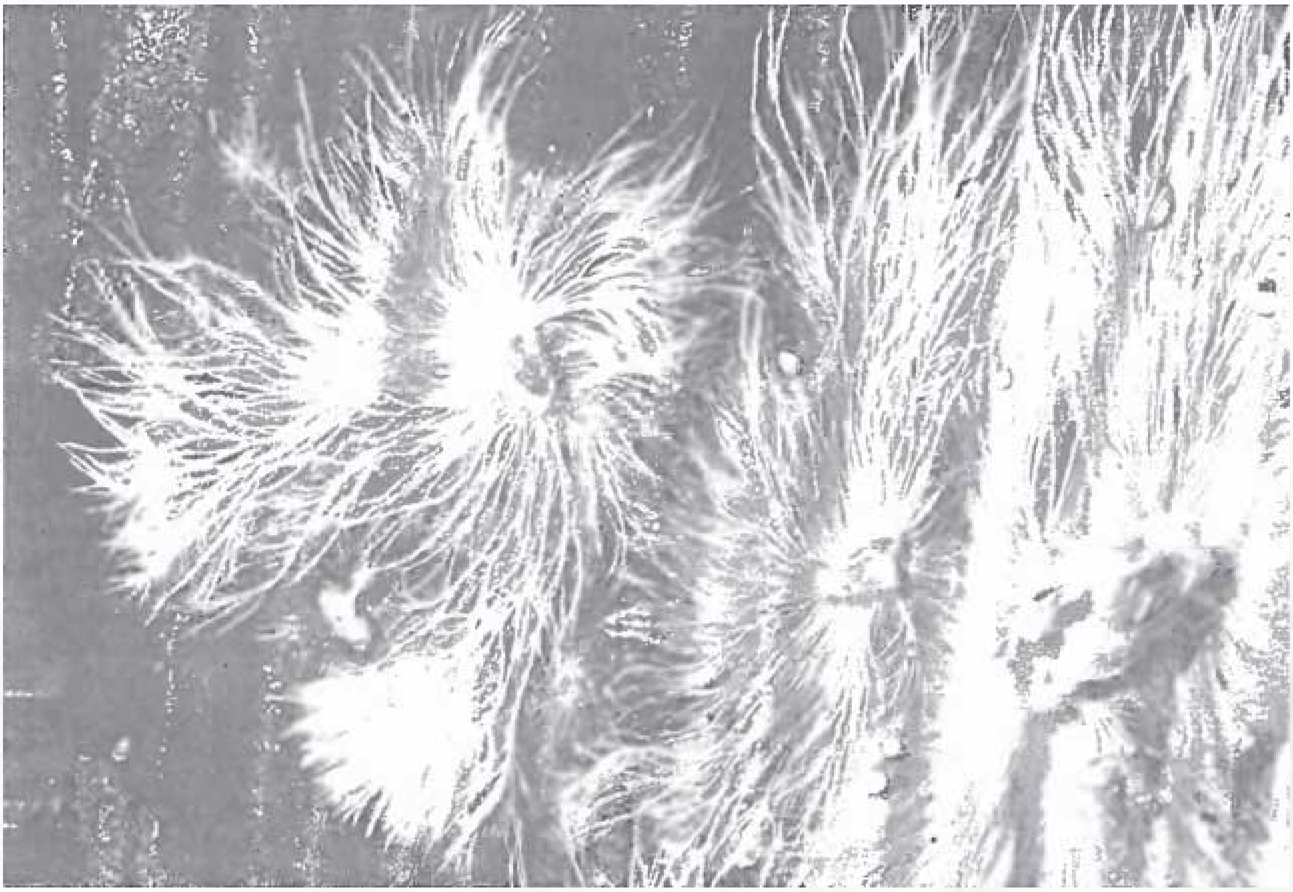

Figure 166 - *Psilocybe cyanescens* mycelium growing on soaked corrugated cardboard inoculated with grain spawn.

Psil. cyanescens - Growth Parameters

Mycelial Types: Rhizomorphic to closely linear; whitish in color.

Spawn Medium: Sawdust/bran or rye grain spawn.

Fruiting Substrate: A lignicolous species utilizing a number of wood types, most notably alder, maple and fir. It is able to grow on a wide variety of cellulosic wastes including newspaper and cardboard.

Method of Preparation: Branches and other small diameter wood are chipped into 1-3 inch pieces, preferably in the spring when the sap content is highest. This material is spawned with sawdust/bran (4:1) and made into prepared beds outdoors amongst ornamental shade plants (especially rhododendrons) or tall grass. Another method is to use sawdust/bran or rye grain spawn to inoculate soaked corrugated cardboard. When fully colonized, sheets of cardboard are laid at the bottom of trays which are then covered with a 2-4 inch layer of freshly cut alder chips. (Wood chips are far superior to sawdust as a fruiting substrate).

Spawn Run:

Substrate Temperature: 65-75°F.
Duration: 30-60 days.
Relative Humidity: 90+%

CO_2: 10,000 ppm or higher.
Fresh Air Exchanges: 0 per hour.

Type of Casing: None required.

Primordia Formation:

Relative Humidity: 95%.
Air Temperature: 50-60°F.
CO_2: 5000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Light requirements: Diffuse natural or grow-lights.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 50-60°F.
CO_2: 5000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Harvest Stage: When the caps become nearly plane.
Light: Diffuse natural or grow-lights.

Yield Potential: In natural outdoor culture on alder chips, 1 lb. wet weight per square foot in one growing season is easily obtained.

Moisture Content: 90-92% water; 8% dry matter in fruitbodies.

Comments: *Psilocybe cyanescens* is a primary decomposer, readily digesting newly cut alder and other deciduous woods. Considered the grandote of the Pacific Northwest, this species is both robust and potently psilocybian. Much sought after for its high psilocybin and psilocin content, it is a favored mushroom by those seeking entheogenic experiences.

Psilocybe cyanescens' adaptability to natural outdoor culture makes this species attractive to beginning and connoisseur cultivators alike. Virgin spawn can be collected from the wild and implanted in prepared beds (see Chapter VI) or spawn can be grown out on bran/sawdust or grain and inoculated directly onto unsterilized soaked corrugated cardboard. Grain spawn inoculated onto untreated wood chips is associated with a higher contamination rate than the same spawn implanted onto soaked cardboard, owing to the partial selectivity of the latter material.

Although fruitbodies can form on fresh sawdust, they do so reluctantly and belatedly. The fact that sawdust so readily loses its moisture may explain, in part, why *Psilocybe cyanescens* has difficulty fruiting on it.

Psilocybe cyanescens has a mycelium that is typically whitish and strandy (rhizomorphic). Tissue and spore cultures are easy to obtain. Outdoor colonies can be maintained for years with minimal effort and produce two to three flushes within a season.

See Color Photos 17 & 18.

SPECIES: *Psilocybe mexicana* Heim

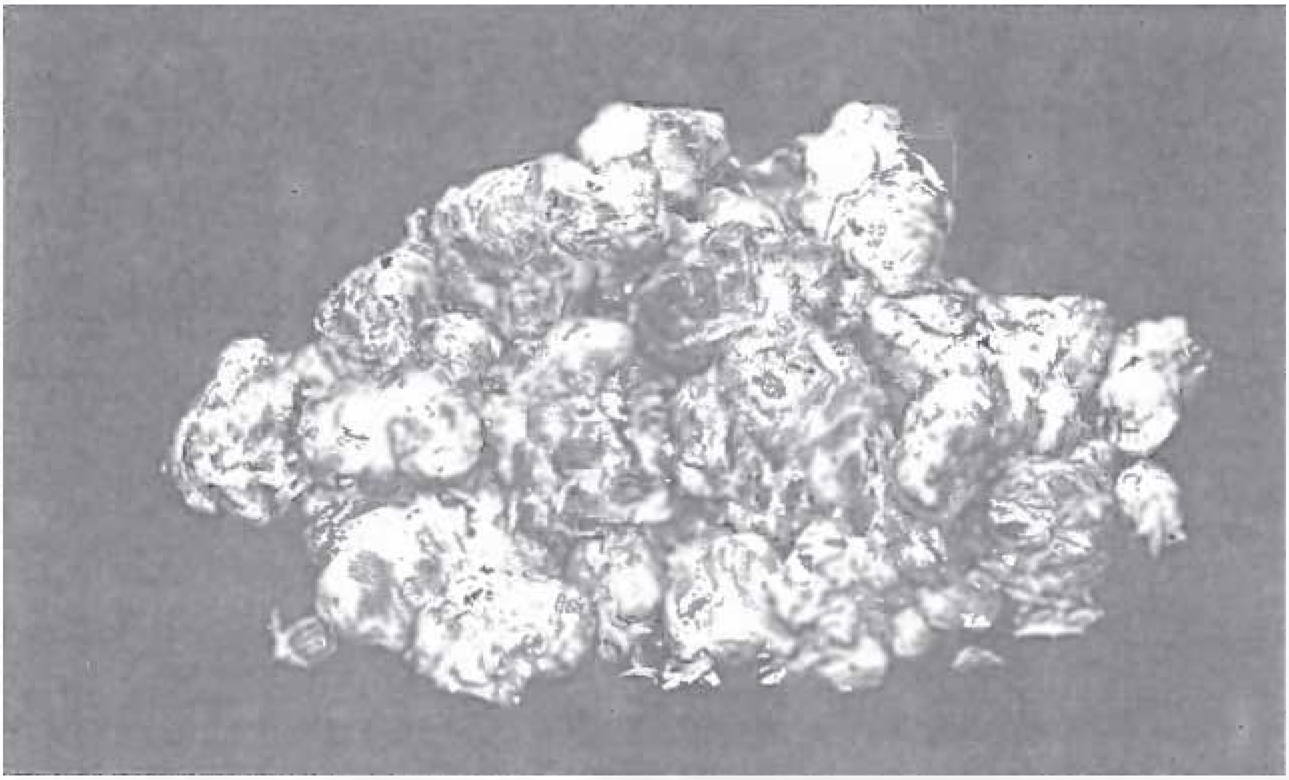

Figure 167 - Sclerotia of *Psilocybe mexicana* harvested from one cup of rye grass seed six weeks after inoculation.

STRAINS: Heim Strain,
Pollock Strain.

COMMON NAMES: Mushroom of the Gods; Teonanácatl or God's Flesh; Nize (Mazatec Name); and Pajaritos (Spanish Name).

GREEK ROOT: *Psilocybe* comes from the Greek "psilos" or bald head. The species name *mexicana* denotes the country in which this mushroom grows.

GENERAL DESCRIPTION: Convex to subumbonate, sometimes with a small umbo, expanding in age to plane or nearly so. The surface is smooth, translucent-striate two thirds to the disc. The cap color is brownish to orangish grey to straw brown, more yellowish to the disc. The gills are adnately attached, grey to dark purplish brown. The stem is equal, smooth, hollow, pale straw to brown to reddish yellow, darkening when injured but typically not bruising bluish. Its spores are dark violet brown in mass.

NATURAL HABITAT: Solitary to numerous in grassy areas, horse pastures and meadows although not occurring on dung. Distributed throughout subtropical regions in Mexico, common in the state of Oaxaca, and also known from Guatemala.

P. mexicana - Growth Parameters

Mycelial Types: Slightly rhizomorphic to finely linear; off-white to tan in color, sometimes with multicolored zones.

Spawn Media: Annual rye grass seed or rye grain.

Fruiting Substrates: Rye grass seed and to a lesser degree rye grain and pasteurized wheat straw. Few fruitbodies form on enriched malt agar media.

Method of Preparation: Rye grass seed combined with water in a 2:1 volumetric proportion, preferably soaked overnight and then sterilized for 1 hour at 15 psi. Wheat straw is pasteurized in a hot water bath at 160-170°F. for 30 minutes.

Spawn Run:

Relative Humidity: 90+%
Substrate Temperature: 75-81°F.
Duration: 10-14 days.
Relative Humidity: 90+%.
CO_2: 10,000 ppm or higher.
Fresh Air Exchanges: 0 per hour.

Type of Casing: Standard peat based casing whose preparation is described in Chapter VIII. Layer to a depth of ½-1 inch.

Post Casing/Pre-pinning:

Relative Humidity: 90+%.
Substrate Temperature: 75-81°F.
CO_2: 10,000 ppm or above.
Fresh Air Exchanges: 0 per hour.
Light: Incubation in darkness.

Primordia Formation:

Relative Humidity: 95+%.
Air Temperature: 71-74°F.
CO_2: 5,000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Light: Diffuse natural or fluorescent grow-lights for 12 hours daily.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 71-74°F.
CO_2: 5000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Harvest Stage: When the caps become nearly plane.
Light: Same as above.

Yield Potential: Not yet established. A petite mushroom. *Psilocybe mexicana* is an interesting species for the connoisseur. Because of the small stature of the fruitbody, one should expect low yields per square foot. Sclerotia formation on rye grass seed after two months is 50-70 grams per cup of seed.

Moisture Content: 90-92% water and 8% dry matter in fruitbodies; 70% water and 30% dry matter in sclerotia.

Comments: This species is most remarkable for its early formation of sclerotia - only three weeks after inoculation onto rye grass seed. Heim and Wasson (1958) considered sclerotia production in this species to be the most efficient method for the generation of biomass. Optimum temperature for sclerotia production was reported to be at 70-75°F. in darkness. Sclerotia on agar media peaked at 4.5% malt concentration. Heim and Wasson also found fruitbody production was maximized on agar media when the percentage of malt was balanced to .45%. Nevertheless, sclerotia form best on rye grass seed incubated in total darkness.

For further information consult: "*Les Champignons Hallucinogenes du Mexique*" by R. Heim and R. G. Wasson, 1958. Editions du Museum National D'Histoire Naturelle, Paris.

See Color Photographs 2 and 13.

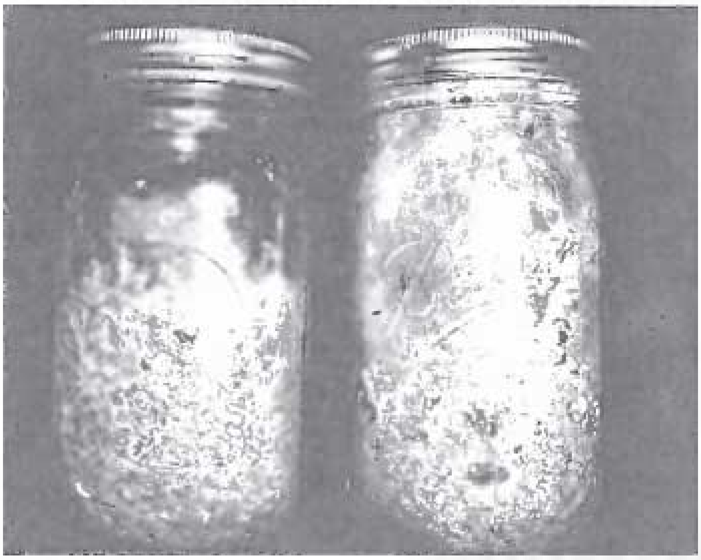

Figure 168 - Two quart jars at 10 days and 30 days after inoculation onto rye grass seed.

SPECIES: *Psilocybe tampanensis* Guzmán and Pollock

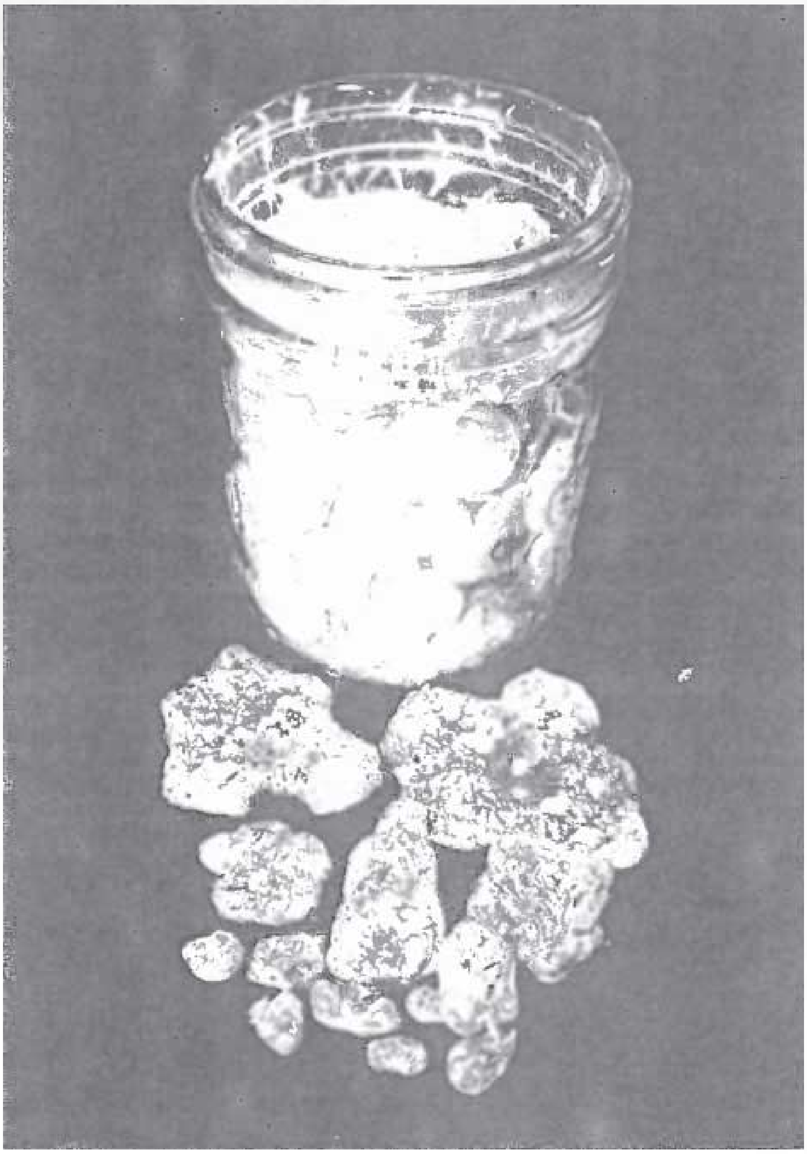

Figure 169 - Sclerotia of *Psilocybe tampanensis* harvested from one cup of rye grass seed six months after inoculation.

STRAINS: Pollock Strain.

COMMON NAMES: The Tampa Psilocybe; Pollock's Psilocybe. Sclerotia are called The New Age Philosopher's Stone or Cosmic Comote.

GREEK ROOT: *Psilocybe* comes from the Greek "psilos" or bald head. The species name *tampenensis* denotes the city near which this mushroom was first collected.

GENERAL DESCRIPTION: Cap convex to subumbonate, soon broadly convex to plane. The surface is smooth and the color is ochraceous brown to straw brown to grey brown. The gills are adnately attached, dark violet brown with whitish edges. The stem is 20-60 mm. long by 3-5 mm. thick, fibrous and enlarged towards the base. The stem surface is smooth to powdered (pruinose) and its color is yellowish brown to reddish brown overall, with whitish to bluish mycelium at or around the base. Its spores are dark purplish brown in mass.

NATURAL HABITAT: Solitary to scattered in sandy soils and meadows in Florida (near the city of Tampa). This species is known only from the type locality where one wild specimen was collected.

P. tampanensis - Growth Parameters

Mycelial Types: Finely linear to cottony; tan to brownish in color, often multicolored with brownish hues.

Spawn Media: Annual rye grass seed, wheat grass seed or rye grain.

Fruiting Substrate: Cased rye grass seed (and possibly rye grain); leached cow manure; some potting soils; and enriched malt agar media. This species will probably fruit on cased pasteurized wheat straw.

Method of Preparation: Rye grass seed combined with water in a 2:1 volumetric proportion, preferably soaked overnight. Sterilize for 1 hour at 15 psi. Wheat straw is pasteurized in a hot water bath at 160-170°F. for 20 minutes.

Spawn Run:

Relative Humidity: 90+%.
Substrate Temperature: 75-81°F.
Duration: 10-14 days.
CO_2: 10,000 ppm or higher.
Fresh Air Exchanges: 0 per hour.

Type of Casing: Standard peat based casing whose preparation is described in Chapter VIII. Layer to a depth of ½ to 1 inch.

Post Casing/Pre-pinning:

Substrate Temperature: 75-81°F.
Relative Humidity: 90+%.
CO_2: 10,000 ppm or above.
Fresh Air Exchanges: 0 per hour.
Light: Incubation in darkness.

Primordia Formation:

Relative Humidity: 85-92%.
Air Temperature: 71-74°F.
CO_2: 5000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Light requirements: Diffuse natural or grow-lights for 12 hours/day.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 71-74°F.
CO_2: 5000 ppm or below.
Fresh Air Exchanges: 2 per hour.
Harvest Stage: When the caps become nearly plane.
Light requirements: Diffuse natural or grow-lights for 12 hours/day.

Yield Potential: A petite species, *Psilocybe tampanensis* is noted for its sclerotia forming ability, approximately 10-30 grams (wet weight) per cup of rye grass seed over 12 weeks. Because of the small stature of the fruitbody, one should expect low yields per square foot in comparison to other more fleshy species of *Psilocybe*.

Moisture Content: 90-92% water and 8-10% dry matter in fruitbodies; 70% water and 30% dry matter in sclerotia.

Comments: This mushroom would not be known but for a single specimen collected by Steven Pollock and Gary Lincoff in September of 1977. Cultures taken from this wild specimen were marketed by Hidden Creek Inc. under the name of the "Cosmic Comote".

Sclerotia do not form until the fourth week (typically six to eight weeks) after inoculation of rye grass seed. To encourage sclerotia production only, incubate mycelia on rye grass seed at 75°F. in complete darkness.

For further information consult: "*Magic Mushroom Cultivation*" by Steven H. Pollock, 1977. Herbal Medicine Research Foundation, San Antonio, Texas (out of print).

See Color Photographs 4, 14 and 15.

SPECIES: *Stropharia rugoso-annulata* Farlow apud Murrill

= *Stropharia ferii* Bresadola
= *Naematoloma ferii* (Bres.) Singer

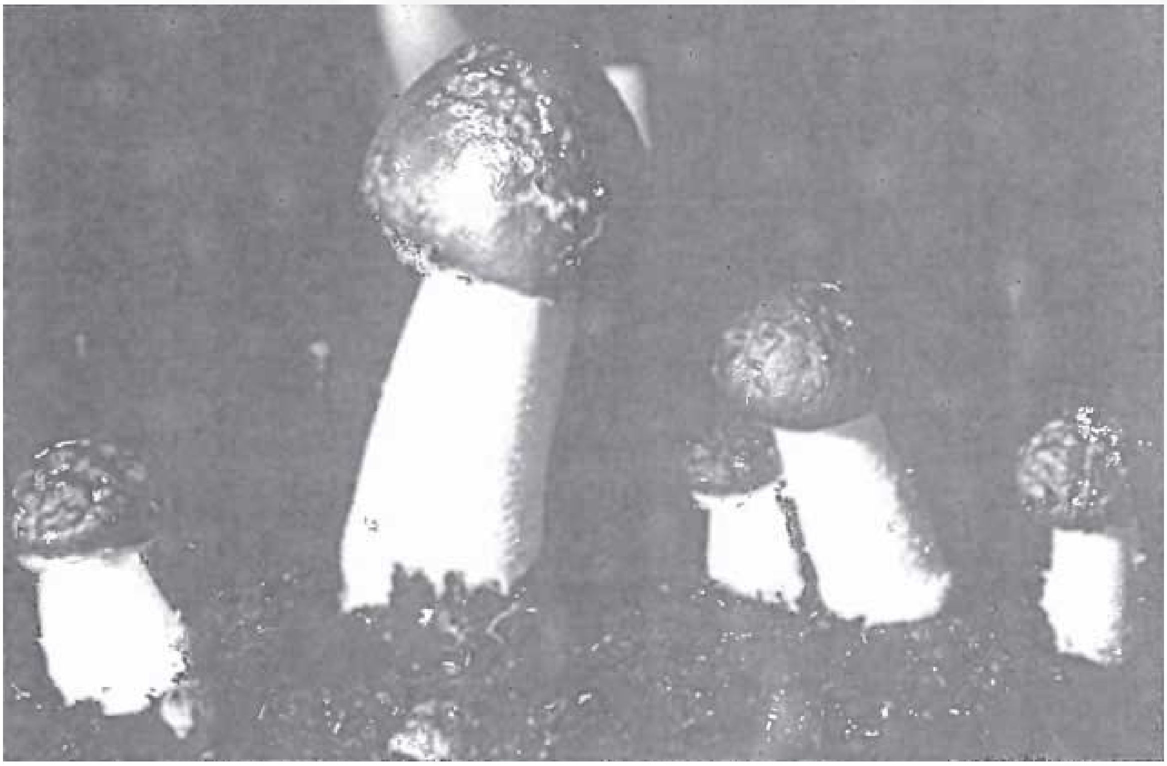

Figure 170 - Young fruitbodies of *Stropharia rugoso-annulata* fruiting on pasteurized straw cased with peat.

STRAINS: Gartenriese
Winnetou
Gelbschopf

The above listed strains are of European origin. Many strains of this species are available from culture banks, including those maintained by the American Type Culture Collection and Pennsylvania State Buckhout Laboratory. Strains are easy to obtain from the spores and tissue of wild specimens.

COMMON NAMES: The Wine Red Stropharia; The Giant Stropharia.

LATIN ROOT: *Stropharia* means "sword belt", so named for the belt-like ring on the stem. The species epithet *rugoso-annulata* comes from the combination of two Latin words: "rugosus" meaning wrinkled and "annulus" or ring.

GENERAL DESCRIPTION: A large, thick fleshed mushroom with a broadly convex cap measuring 50-400 mm. in diameter, darkly pigmented yellowish brown with distinct reddish tones. The partial veil is thick, membranous, leaving a persistent membranous ring on the stem on whose uppersides are tiers of gills. The stem is whitish and has rhizomorphs attached to its base. Its spores are dark purplish brown in mass.

NATURAL HABITAT: Occurring in gardens, in wood chips, on decomposing straw, in sawdust enriched soils and commonly in grounds where potatoes have been planted.

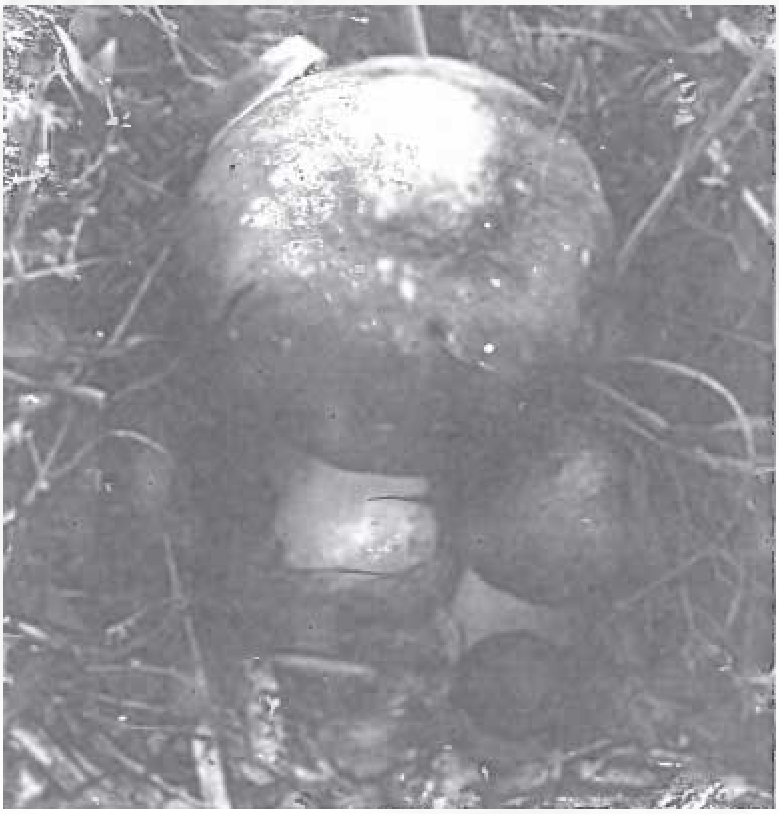

Figure 171 - Buttons of *Stropharia rugoso-annulata* fruiting outdoors in a bed of wood chips.

S. rugoso-annulata - Growth Parameters

Mycelial Types: Rhizomorphic to closely linear; whitish in color.

Standard Spawn Media: Rye grain or chopped wheat straw.

Fruiting Substrates: Cased wheat straw, whole or chopped, and balanced to a 71-74% moisture content. This species has been grown on a substrate of alder/maple chips mixed with mature horse manure using natural culture techniques.

Method of Preparation: Either chopped or whole straw is adequate, although permeation is more rapid on the former. (See Chapter VI on preparation of straw as a fruiting substrate). Pasteurization is achieved through the submersion of straw into a hot water bath at a temperature of 160°F. for 20-30 minutes. The straw, once pasteurized and inoculated, should be compacted and filled to a depth of 6-12 inches. Gramss (1979) noted that wheat straw supplemented with 25% Fagus sawdust enhanced yields. Watling (1980) reported, without elaboration, that fruitbodies form on a sawdust based medium. This species also fruits on unpasteurized straw although problems with insect pests and competitor molds are more pronounced.

Spawn Run:

Relative Humidity: 90+%.
Substrate Temperature: 76-82°F. Thermal death limits have been reported as low as 90°F. and -5°F.
Duration: 2-4 weeks.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.

Type of Casing: After fully run, cover with peat/humus (1:1) casing. Optimally, the casing should have a pH of 5.7-6.0. (Because calcium based buffers inhibit fruiting, adjust the casing's pH by increasing or decreasing amount of peat). Balance to a 70-75% moisture content. Layer to a depth of 1-2 inches. Humus should be pasteurized to kill nematodes, mites, and other parasites. Some strains form fruitbodies solely on a peat casing. (Mushrooms do not form, however, on sterilized casing. Hence, if the casing must be treated, steam pasteurization is recommended).

Post Casing/Prepinning:

Relative Humidity: 90+%.
Bed Temperature: 76-82°F.
Duration of Case Run: 10-12 days.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.
Light: Incubation in darkness.

Primordia Formation:

Relative Humidity: 95+%.
Air Temperature: 55-62°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Watering: Regular misting (once to twice daily) to help stimulate primordia formation.
Light: Indirect natural or exposure to grow-lux type fluorescent for 12 hours/day.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 55-62°F.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Flushing Interval: Every 10-15 days.
Harvest Stage: Directly before or as the partial veil tears. (Note that young mushrooms have a much better flavor than mature ones).
Light: Indirect natural or exposure to grow-lux type fluorescent for 12 hours/day.

Yield Potential: Average commercial yields are 2-3 lbs./sq.ft. over a 8 week cropping period. Maximum yields are nearly 6 lbs per square foot.

Moisture Content of Mushrooms: 92% water; 8% dry matter.

Nutritional Content: 22% protein (dry weight); 34 milligrams of niacin per 100 grams dry weight.

Comments: A mushroom recently cultivated in Europe (Germany, Czechoslovakia and Poland) by home growers in outdoor cold frames, the status of knowledge regarding the optimum growing parameters for this species remains in its infancy. For instance, Szudyga (1978) noted that fruitbodies form just as well at 50°F. and 68°F., a considerable fruiting range for any species.

After the cropping period ends, the spent straw is used as fodder for farm animals or is saved for future inoculations. The strain is kept kept alive by continous transfer onto fresh substrates. (See Chapter VI on natural culture). Propagating spawn in this way, however, is less assured than sterile methods.

Stanek (1974) reported that the introduction of several thermotolerant endospore-forming bacteria of the genus *Bacillus* (*B. subtilus*, *B. meseatericus* and *B. macerans*) to the casing not only inhibited attacks by competitors but also stimulated mycelial growth which presumably would enhance yields. Endospores of these bacteria survive pasteurization but not sterilization, and are abundant in soils. This discovery may explain why sterilized casings do not produce fruitbodies.

Genetic Characteristics: Basidia tetrapolar (4-spored), forming haploid spores; heterothallic. Clamp connections are present. See Chapter XV.

For further information consult: K. Szudyga, 1978. "*Stropharia rugoso-annulata*" in *The Biology and Cultivation of Edible Mushrooms* ed. by S.T. Chang and W.A. Hayes. Academic Press, New York.

SPECIES: *Volvariella volvacea* (Bull. cx Fr.) Sing.

STRAINS: Many strains of *V. volvacea* are available from commercial and private stocks. The American Type Culture Collection, which sells cultures to educational organizations and research facilities, has stock cultures of several wild and domesticated strains. Several commercial companies also sell strains of this species.

COMMON NAMES: The Paddy Straw Mushroom; The Chinese Mushroom.

LATIN ROOT: *Volvariella* is the conjunction of two words: "volvatus" which means having a volva or cup-like sheath and the suffix "-ellus" denoting smallness in size. The species name *volvacea* shares the same root as the genus.

GENERAL DESCRIPTION: Mushrooms whitish at first, becoming a dark tan as the veil tears and eventually a pale tan with age. Fruitbodies are relatively small when young, enveloped by a sheath-like universal veil, soon breaking as the fruitbodies mature and leaving an irregular cup-like sack at the base of the stem. The cap is egg shaped at first, soon hemispherical to convex and expanding to plane with age. Its spores are pinkish to pinkish brown in mass.

NATURAL HABITAT: Commonly occurring in decomposing straw in the Orient and in other subtropical regions of the world.

V. volvacea - Growth Parameters

Mycelial Types: Fast growing rhizomorphic to slow cottony mycelia noted. The color is typically white to grayish white.

Spawn Medium: Rice straw or rye grain. See Chapter III.

Fruiting Substrate and Method of Preparation: Traditionally grown on rice straw that has been composted for 1-2 days. More recently Hu (1974) found that a mixture of cotton wastes supplemented with wheat bran and calcium carbonate (5% and 5-6% by weight, respectively) and composted for 3 days, pasteurized for 2 hours at 140°F., conditioned for 8 hours at 125°F. and then gradually lowered to 77°F. over a 8-12 hour period, produced a higher yielding substrate than that of others previously used. A moisture content of 65-70% is recommended for rice straw and 70% for cotton waste mixtures. Chang (1978) recommended a combination of the two - with the rice straw/cotton waste in a proportion of 2:1 or 1:1 by weight.

Spawn Run:

Relative Humidity: 90+%.
Substrate Temperature: Fastest growth at 88-95°F.
Duration: 4-6 days for thorough colonization.
CO_2: 5000-10,000 ppm.
Fresh Air Exchanges: 0 per hour.
Light Requirements: Incubation in total darkness.

Type of Casing: None needed.

Pinhead Initiation:

Relative Humidity: 95+%.
Air Temperature: 82-88°F.
Duration: 4 days.
CO_2: less than 1000 ppm.
Fresh Air Exchanges: 2-4 per hour.
Light: Diffuse natural or direct grow-light fluorescent for 12-18 hours per day.
Watering: Regular misting once to twice daily.

Cropping:

Relative Humidity: 85-92%.
Air Temperature: 82-88°F.
Duration: 5-7 weeks.
CO_2: less than 600 ppm.
Fresh Air Exchanges: 2-4 per hour or sufficient to meet CO_2 and/or cooling requirements.
Harvest Stage: Directly before rupturing of the universal veil.
Flushing Intervals: 5-10 days.
Light: Same as above.
Watering: Regular misting to prevent caps from cracking and to keep resting pinheads viable.

Yield Potential: Average commercial yields on rice straw are 22-28 kilograms of fresh mushrooms per 100 kilograms of dry straw. Optimum yields on cotton waste compost are 25-35 kilograms per 100 kilograms of substrate. Maximum yields are nearly 45 kilograms on cotton waste compost.

Moisture Content of Mushrooms: 88-90% water; 10-12% dry matter.

Nutritional Content: Crude protein is reported at 21.2 % of dry weight; 91 milligrams of niacin per 100 grams dry weight.

Comments: In contrast to other species growing on straw, this mushroom does not compare favorably in terms of yield. The smaller crop figures are probably a result of the early picking of the mushroom fruitbodies, when they are most flavorful.

Several researchers have noted the difficulty of maintaining high yielding strains of this species for any length of time. Its mycelium seems to have a limited transfer potential and should be stored at moderate temperatures (50°F.). Cultures are frequently renewed through multispore germinations.

Volvariella volvacea is primarily grown in the Orient and is a warmth loving mushroom.

Genetic Characteristics: Basidia tetrapolar, producing 4 haploid spores; primary homothallic. Clamp connections are present. Chlamydospores form. See Chapter XV.

XII. CULTIVATION PROBLEMS AND THEIR SOLUTIONS: A TROUBLE SHOOTING GUIDE

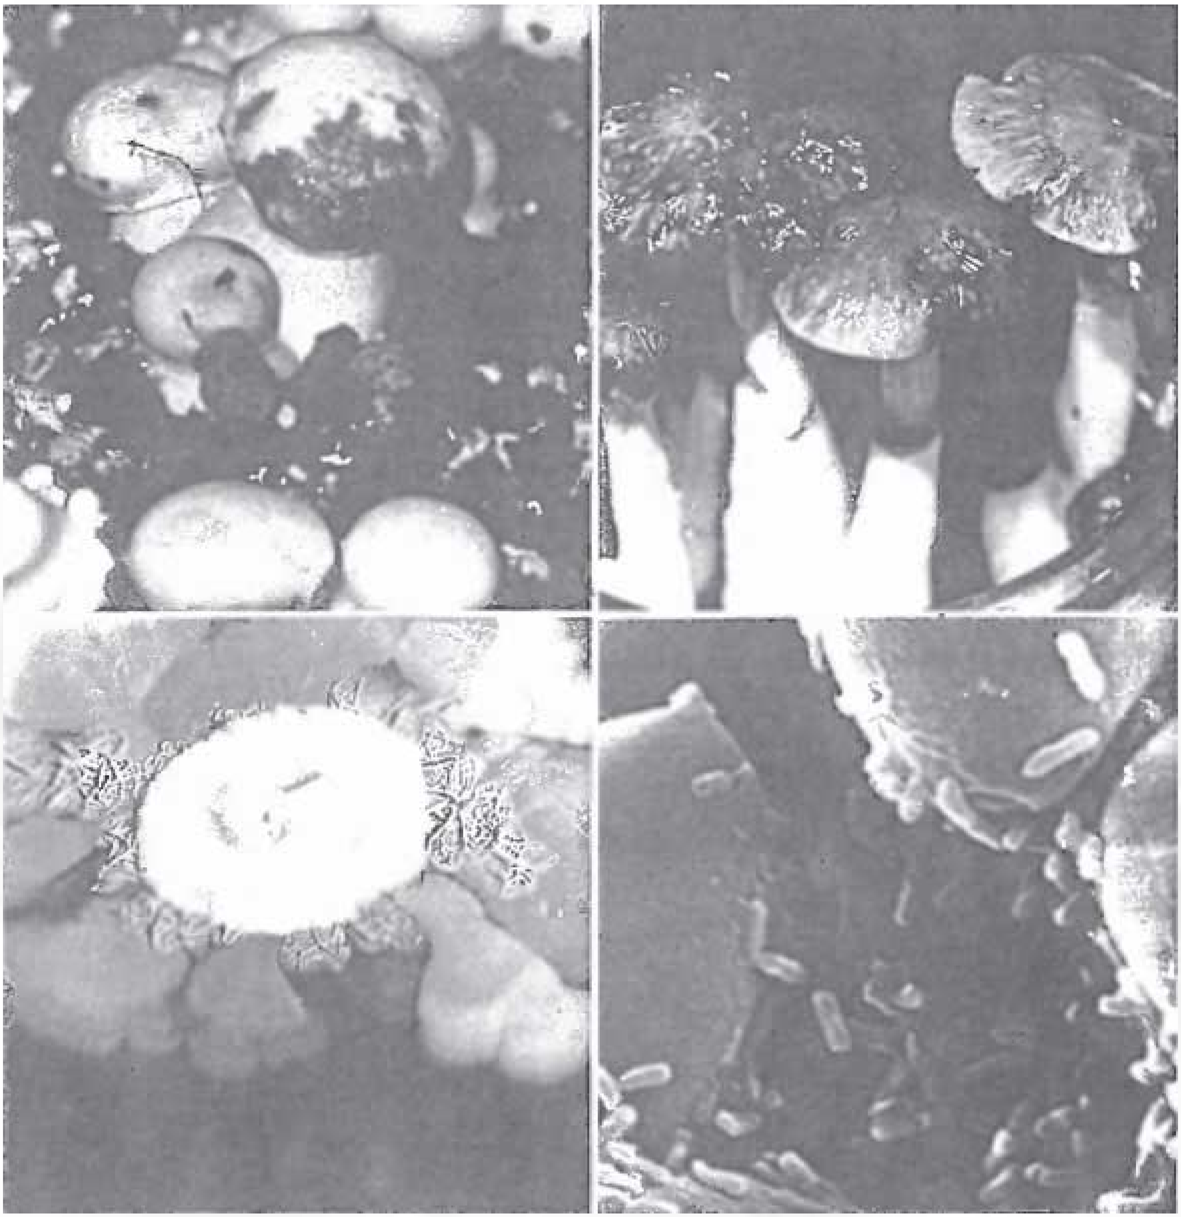

Figure 172a,b,c,d. - The results of bacterial contamination.

Many first-time cultivators fail to grow mushrooms for the simplest of reasons. Often times the slightest error in technique sets into motion a series of events that drastically influence the outcome of the crop. Whenever conducting sterile technique, making spawn, preparing compost or cropping mushrooms, wise cultivators follow a routine that has proven successful in the past. Once a consistent methodology has been established, new variations are introduced, one at a time, to gauge their effect.

Problems intrinsic to mushroom culture have been encountered by most everyone attempting to grow mushrooms. The following trouble-shooting guide lists problems, causes and solutions according to their frequency of occurrence and has been organized into five categories:

1. **Sterile Technique**: media (agar and grain) preparation, spore germination, tissue culture and spawn-making.
2. **Compost Preparation**: raw materials, characteristics of composts at different stages, Phase I and Phase II.
3. **Spawn Running**: colonization of compost and bulk substrates.
4. **Case Running**: application, colonization by mycelium, pre-pinning strategy.

5. **Mushroom Formation and Development** (Pinning to Cropping): strategy for pinhead formation, maturation and harvesting.

Identify the problem, locate it on the list, read its possible causes, refer to the solutions available, and if indicated, turn to the chapter noted in parentheses. Good luck, pay attention to detail and may your problems be few.

Sterile Technique

Agar Culture

PROBLEM	CAUSE	SOLUTION
Media fails to solidify.	Insufficient quantity of agar or distribution thereof.	Thoroughly mix media before pouring.
Media boils out of vessel or flask containing it.	Excessive escape of steam from pressure cooker.	Do not vent pressure cooker until reaching 1 psi. Grease pressure cooker seals with thin film of petroleum jelly. For pressure cookers using 5, 10, 15 lb weights, do not operate so steam escapes.
Contamination occurs in petri dishes after pouring media but before inoculation.	High contaminant spore load in lab. Improper media preparation technique. Contaminated pressure cooker (bacteria).	Clean, paint lab. Install laminar flow hood. Allow pressure cooker to cool in sterile setting before opening. Sterilize pressure cooker for 24-48 hours at 15 psi.
No growth from spores or tissue transferred.	Wrong type of media. Wrong pH. Old or dehydrated spores. Scalpel or loop too hot. Sugar in media caramelized.	See media preparation. See media preparation. Soak in sterilized water for 12-24 hours. Cool tool before contacting spores or tissue. Lower sterilization pressure and temp. to recommended levels.
Contamination occurs around point of transfer onto agar media.	Inoculum (spores or tissue) contaminated. Inoculation tools not sterile.	Obtain "cleaner" spores or take a tissue culture from a fresher specimen, or inoculate as many plates as possible, saving only those not becoming contaminated. Autoclave tools, soak in alcohol, flame sterilize before using.
Rhizomophic mycelia becomes cottony, slow growing. Fruitings diminish. Strain appears to be degenerating.	Senescence, strain aging.	Retrieve stock cultures and reactivate a strain of known vigor. Alternate media so that gene expression is not selected by a limited chemical matrix.
	Mutating. Sugar in media caramelized. Media containing mutagens.	Cook agar media at lower temp. and pressure, between 12 and 15 psi.
	Insufficient jelling agent causing mycelium to grow subsurfacely and appear cottony.	Add more agar or thoroughly mix media before pouring petri dishes.

Grain Culture

PROBLEM	CAUSE	SOLUTION
Glass spawn jars broken when pressure cooker is opened.	Pressure cooker cooled too rapidly. Change in temp. too abrupt.	Allow cooker to descend to room temp. gradually.
	Jars too tightly packed.	Allow space so jars can expand.
	Jars defective or cracked.	Check for cracks or defects. Obtain new jars.
	Wrong type of jars.	Replace with canning or autoclavable type.
Grain jars difficult to shake.	Too much grain in container.	Reduce grain to recommended levels.
	Too much water relative to grain.	Follow recommended formulas.
	Measuring cups not accurate.	Calibrate measuring cups with a graduated cylinder.
Grain "spontaneously" contaminates before inoculating or opening pressure cooker.	Introduction of alien spores upon cooling.	Cool-down in sterile environment or in front of laminar flow hood.
	Survival of bacterial endospores despite autoclaving.	Replace source of grain or presoak grain for 24 hours before autoclaving.
Agar wedge sticks to glass when grain jar is shaken.	Agar media too thin, either from evaporation or from shallow pouring.	Use mycelium covered media before substantial evaporation occurs. Pour more media into each petri dish initially.
Little or no growth after mycelial wedge has been transferred.	Grain too hot when inoculated.	Allow to cool to room temperature before inoculating.
	Grain too dry.	Balance according to recommended recipes.
	Mycelium not evenly distributed.	Vigorously shake spawn jar after transfer of agar wedge and again 3-5 days after inoculation.
	Incubated at wrong temperature.	Buffer with calcium carbonate according to species being cultured.
	pH wrong.	See recommended spawn incubation temperatures in Chap. XI.
	Wrong spawn medium.	Use media recommended for that species.
Poor strain.	Contaminated strain.	Discard strain. Obtain purer strain, make up more grain media and clean laboratory.
No growth on grain after inoculated with liquid culture/stirrer technique.	Too many individual hyphae (cells) severed.	Stirred for too long. No more than 5 seconds is recommend for high speed laboratory-type blenders to produce fragmented chains of hyphae.
	Bacteria.	Replace mycelia with pure strain, free of bacteria. Be sure tools and water are sterile before inoculation.
	Poor strain.	Cottony type mycelia is slow growing. Replace with rhizomorphic or faster growing strain.
	pH	Follow recommended recipes. See Chap. II.
	Water too hot.	Allow to cool before inoculating.

Contamination after transfer of mycelium.	High contaminant spore count in laboratory.	Clean lab before inoculations. Maintain high standards hygiene.
	Tools not sterile.	Autoclave tools, soak in alcohol, flame sterilize before inoculation.
	Mycelium being transferred has high resident load of contaminant spores.	Obtain cleaner strain or spawn of better purity.
Mycelium fails to grow out through entire spawn jar.	Insufficient shaking of grain after inoculation.	Thorough shaking after double-wedge transfer, combined with re-shaking four days after inoculation.
	Mycelium inhibited by contamination (usually bacteria). Externally or internally introduced.	Inoculate more sterilized grain using a pure strain and following standard practices for doing so. See Chap. II.
Top kernels in spawn jar not colonized by mycelium.	Top kernels dehydrated from excessive evaporation.	If using porous filter discs, limit evaporation. Or use only in conjunction with narrow mouthed jars.
Spawn jar discolored with yellowish droplets of fluid.	Spawn jar incubated for an overly long period of time, at higher than optimum temperatures, or both, causing the exudation of metabolites ("sweat") and the build-up of fluids in which bacteria thrive.	Incubate at temperature and for period of time recommended for species being cultivated.

Compost Preparation

Phase I

PROBLEM	CAUSE	SOLUTION
Compost does not heat up, remains under 140°F.	Undersupplemented.	Check compost formula. Check Nitrogen content of raw materials.
	Pile too open, airy.	Compress pile sides. Protect pile from strong winds.
	Moisture content too high or low.	Balance moisture to 70%.
	Insufficient pile mass.	Increase total raw materials.
Compost generates no ammonia.	Undersupplemented.	Check compost formula calculations. Check Nitrogen content of raw materials.
Compost anaerobic.	Moisture content too high.	Balance moisture to 70%.
	Straw too short; pile too dense.	Carefully monitor raw materials and adjust pile size as materials compact.
	Pile sitting too long between turns.	Turn more frequently.
Compost decomposing unevenly.	Improper turning procedures.	Move inside of pile to outside and vice versa.
	Variable starting materials.	Horse manure or straw should all be in the same state of decomposition at the start of composting.
Compost greasy.	Gypsum quantity too low.	Add more gypsum.
	Starting materials too old.	Use only fresh, undecomposed starting materials.
Compost too wet or too dry at filling.	Incorrect water addition or timing.	Check moisture content of pile before each turn.
Straws still bright and shiny at filling.	Phase I too short.	Continue composting.
Compost short and black at filling.	Phase I too long.	Shorten Phase I.

Phase II

PROBLEM	CAUSE	SOLUTION
Compost will not heat up.	Supplementation rates too low.	Check compost formula calculations.
	Compost too mature.	Shorten Phase I.
	Oversupply of fresh air.	Reduce fresh air supply.
	Air to bed ratio too great.	Add more beds or trays and fill with more compost.
	Compost too wet.	Compost should be 70% at filling.
Compost temperature erratic.	Irregular fresh air supply.	Fresh air supply should be constant. Make volume changes slowly and as needed to stablize temp.
	Room environment not monitored enough.	Check room every 4-6 hours.
Compost temperature uneven.	Containers filled unevenly.	Fill all containers with equal amounts of compost and to the same depth.
	Uneven supplement distribution in Phase I.	Be sure supplements are evenly mixed and are not concentrated in small pockets.
	Faulty air system design.	Air system should insure even temp. throughout the room.
Compost temp. too high after pasteurization.	Inadequate supply of fresh air.	Increase fresh air.
	Pasteurization too long.	Pasteurize for 2 hours at 140°F.
Compost temp. drops too low after pasteurization.	Prolonged fresh air supply.	Anticipate drop in compost temp. and reduce fresh air before reaching conditioning temp.
	Pasteurize at a lower temp. for more time.	Low temperatures preserve more microorganisms that prevent temp. from falling rapidly.
Prolonged ammonification.	Oversupplementation with nitrogen.	Reduce nitrogen supplements.
	Prolonged time at temp. over 130°F.	Keep temp. under 130° after pasteurization. Use low temp. ranges during conditioning.

Spawn Running

PROBLEM	CAUSE	SOLUTION
Spawn grows slowly or not at all.	Inferior spawn.	Check spawn making procedures. Review strain storage methods. Test strain purity by inoculating agar plates.
	Degenerative or inviable strain.	Always test untried strains in "miniculture" trials prior to inoculation into bulk substrates. Switch to a strain of known viability.
	Residual ammonia in compost.	Prolong Phase II conditioning until litmus paper test shows no color change.
	Improper Phase I or Phase II.	Review composting section.
	Substrate moisture content too high.	Compost should be 64-66% water; straw should be 70-75% at spawning.
	Fly or nematode infestation.	Check pasteurization time and temperature.
	Mycelium lacks oxygen.	Be sure the container has provisions for air exchange.

Molds present during spawn run.	Improper Phase I or Phase II.	Review composting section. Check contamination section for identification and factors predisposing to mold growth.
Inky Caps (*Coprinus sp.*) occur during spawn run.	Residual ammonia in compost.	Prolong Phase II conditioning until litmus paper test no change.
Mites or nematodes present.	Insufficient pasteurization.	Pasteurize 2 hrs. at 140°F.
	Compost with dense overwet areas.	Review composting and filling procedures.
	Unclean substrate containers or spawning tools.	Containers and tools should be disinfected before use.

Case Running

PROBLEM	CAUSE	SOLUTION
Mycelium fails to run through the casing layer.	Temperature too high or too low.	Incubate at optimum temp. for mycelial growth.
	pH improperly adjusted.	Test pH before application. Adjust with limestone buffer (with one exception). Consult Chap. XI on the correct pH for each species.
	Casing to wet or too dry.	Test moisture before application. Apply at 90% of capacity (70-75% moisture).
	Unsatisfactory casing materials.	Review preparation of casing in Chap. VIII.
	Weak mycelial growth in substrate.	Review techniques for substrate preparation in appropriate chapter.
	Substrate contaminated.	Check substrate for molds and nematodes before casing.
Casing dries out after application.	Growing room humidity too low.	Increase humidification. Increase frequency of watering, or cover with plastic.
	Fan speed too high. Too much airflow.	Decrease fan speed. Maintain slow, easy circulation.
Uneven mycelial growth into casing.	Casing materials poorly mixed.	Thoroughly mix casing ingredients to insure an even blend.
	Unevenly applied casing.	Redistribute or apply casing to an even depth.
	Uneven mycelial growth into substrate underlying casing.	Thoroughly and evenly spread spawn throughout substrate at inoculation.
Mycelium covers the casing but forms few primordia.	"Overlay" caused by prolonged mycelial growth into the casing layer.	Patch the casing. Begin initiation sequence sooner. If dealing with a slow pinning strain be careful that the evaporation rate off the casing surface is not excessive.
Mycelium overlays the casing and then "mats", becoming flattened and impervious to water. No primordia form.	Improper watering and/or too low humidity in the external environment. Evaporation rate too extreme.	Scratch and/or re-case. Maintain 95% humidity at pinning. Reduce evaporation rate. If watering, mist lightly and evenly.
Mycelium runs through the casing and then disappears.	Die Back Disease (Virus).	Discard and begin anew with a virus-free strain. See Chap. XIII.
Dense white matted zones form on casing.	Stroma.	Select strains not predisposed to stroma formation (those without fluffy sectors). Reduce CO_2.
	Contaminant (*Scopulariopsis*).	pH too high. Compost improperly prepared. See Chapters V, XIII.

Mushroom Formation and Development

Pinhead Initiation

PROBLEM	CAUSE	SOLUTION
Mycelium fails to form primordia.	Monokaryotic strain with low or no fruiting ability.	Start again with new tissue isolate or isolate from multispore germination.
	Humidity too low.	Keep humidity at 95% during pinning.
	CO_2 too high.	Reduce CO_2 by introducing fresh air.
	Temperature too high.	Decrease air temp. to the fruiting range.
	Insufficient light.	Illuminate cropping surface for 12 hours/day.
Primordia form early.	Uneven casing depth.	Apply casing at an even depth and patch areas where mycelium appears prematurely.
	Early light stimulation.	Incubate culture in darkness until ready to pin.
	Temperature too low.	Incubate at optimum temp. for mycelial growth and then drop temp. for pinning.
	CO_2 levels too low.	Maintain airtight room and recirculate air until ready to pin.
Primordia formation uneven.	Uneven casing depth.	Patch shallow areas as mycelium appears until growth is even.
	Uneven moisture in casing.	Water casing evenly and carefully.
	Casing surface partially damaged from heavy watering.	Keep casing surface open and porous through proper misting techniques.
	Uneven environmental conditions within the growing room.	Review air system design.
Pinheads fail to form abundantly.	Casing layer moisture too low or too high.	Adjust moisture level in casing to 70-75% for pinhead formation.
	Casing layer pH imbalanced.	Adjust pH to levels recommended in Chap. XI for the species being cultivated.
	Magnesium in limestone buffer too high (above 2%).	Some species are inhibited by minerals in the casing layer, especially the magnesium in dolomitic limestone. Use a low magnesium lime, less than 2%.
	CO_2 too high.	Lower CO_2 to recommended levels. (Some species fruit poorly in high CO_2 environments).
	Insufficient light.	Photosensitive species require several hours of light stimulation per day for pinhead formation.
	Improper pinhead initiation strategy.	See Chapter IX.
	Defective strain.	Replace with strain of known viability.
	Nematode infestation.	See Chapter XIV.

Pinheads form but fail to mature.	Insufficient nutrient base.	Review substrate materials and formulas. Follow those that are recommended for the species being cultivated.
	Excessive CO_2 levels.	Reduce CO_2 to recommended levels.
	Humidity to high.	Reduce humidity to 85-92%.
	Insufficient fresh air.	Increase fresh air input to 2-4 room exchanges per hour.
	Strain idiosyncrasy.	Replace with a strain having better fruiting capabilities.
	Fly, nematode or other contaminant inhibiting development.	Review contaminant control procedures. Check source and quality of casing materials. Check mixing procedures.
	Excessive loss of moisture from casing.	Maintain sufficient moisture (70-75%) in the casing through daily mistings if required.

Cropping

PROBLEM	CAUSE	SOLUTION
Low yielding first flush.	Poor pin set.	Review pinning procedures and growing parameters for the species being grown.
	Substrate low in nutrients.	Review substrate materials and formulas.
Few mushrooms develop fully, many abort.	Uneven pinning.	Remove early developing pins.
	Lack of nutrients.	Review substrate materials and formulas.
	Temperature too high.	Maintain air temp. within cropping range.
	Parasitized by contaminant.	See Chapters X and XIII. Follow procedures for encouraging cropping, not contamination.
Mushrooms have long stems and small underdeveloped caps.	CO_2 too high.	Increase fresh air input.
	Insufficient lighting.	Evaluate lighting system and type of light used.
Mushrooms develop but abnormally.	Parasitized by contaminant.	Eliminate stagnant air pockets in the growing environment. See Chap. IV.
	Excessive CO_2. Improperly balanced growing environment.	Lower CO_2 to recommended levels. Maintain air circulation, temp. and humidity at recommended levels. See Chap. X.
	Exposure to mutagenic chemicals (insecticides, detergents, chlorine, etc.)	Limit exposure of mushrooms to such chemicals.
	Lack of adequate light for fruitbody development.	Increase light exposure to 12 hours per day. See Chapters IV and IX.
	Strain idiosyncrasy.	Switch to strain of known fruiting ability.

XIII. THE CONTAMINANTS OF MUSHROOM CULTURE: IDENTIFICATION AND CONTROL

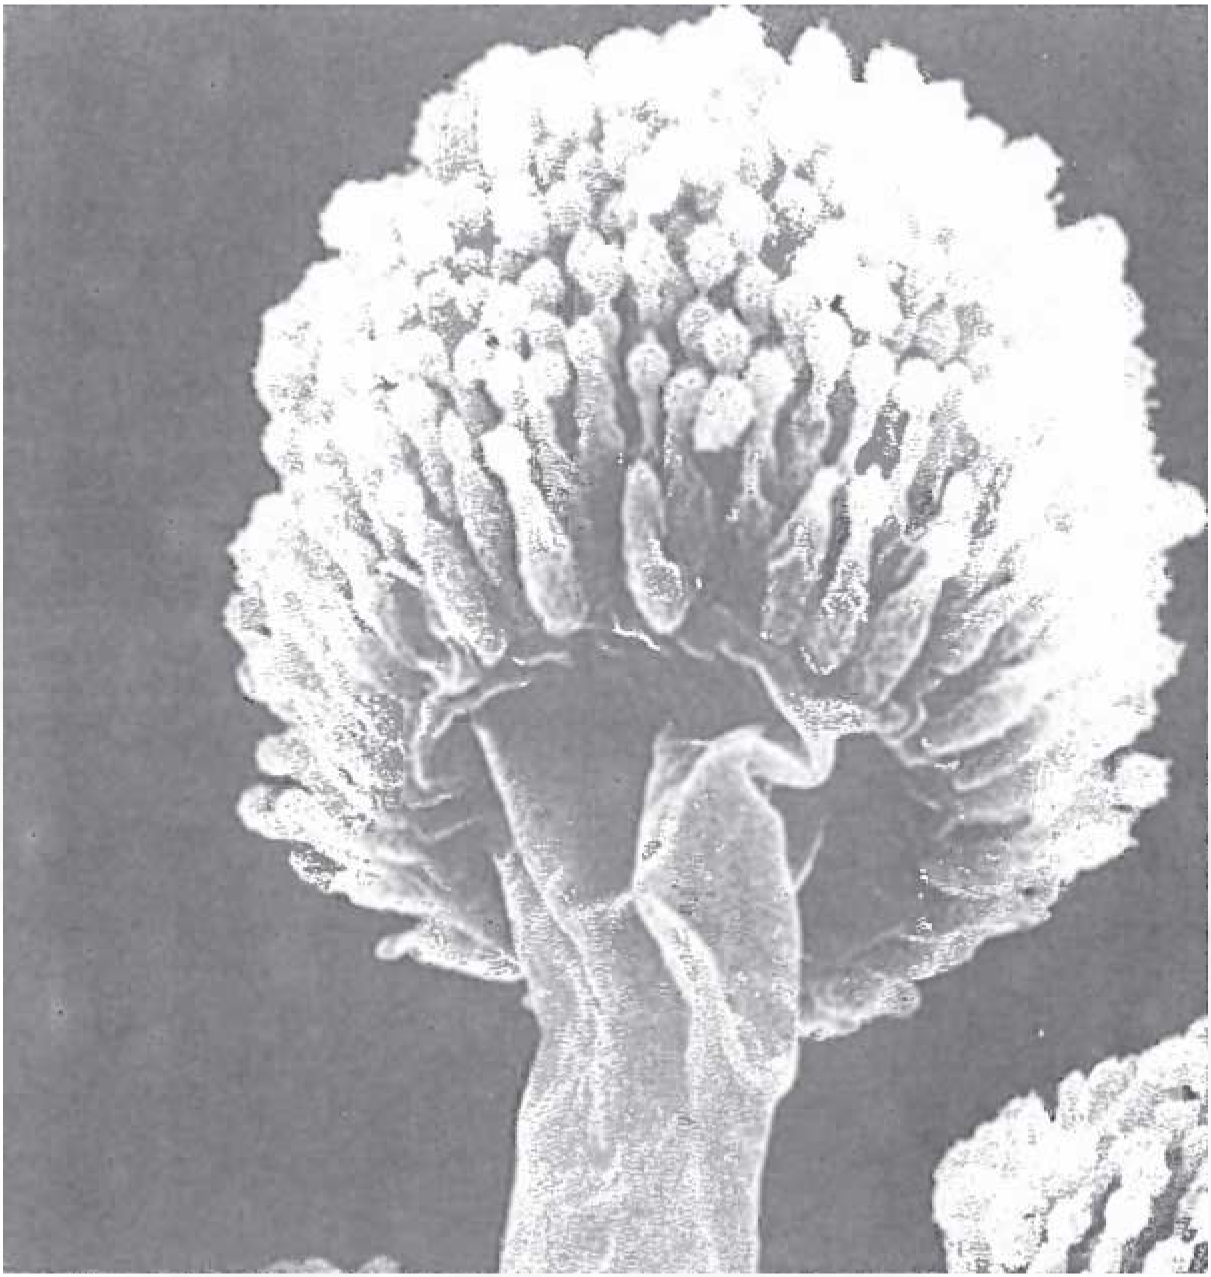

Figure 173 - Sporulating structure of *Aspergilus* mold.

The contaminants are so named solely because they are undesired. If one were trying to culture *Penicillium* and spores of an *Agaricus* or *Psilocybe* settled onto the agar media and germinated, the resulting mycelia would be the so-called "contaminant." The contaminants in mushroom culture, however, are primarily molds, bacteria, viruses and insects. The pathway by which a disease is introduced, known as the **vector** of contamination, can be used to trace the contaminant back to its site of origin using simple deduction. By observing how a contaminant affects the mushroom crop and by carefully noting the conditions in which it flourishes, a cultivator can soon identify its cause.

Earlier in the book, the five most probable vectors of contamination were identified as:

1. the cultivator.
2. the air.
3. the substrate to be inoculated.
4. the mycelium that was being transferred.

5. the inoculating tools, equipment, containers, facilities, etc.

Different contaminants are associated with different stages of mushroom cultivation. Contaminants in agar culture most often come from airborne spores. Grain cultures contaminate from airborne spores and from a source which many cultivators fail to identify: the grain used in spawn making which is laden with spores of imperfect fungi, yeasts and bacteria. (See Ivanovich-Biserka, 1972). In compost culture, the major contributors to contamination are the materials used, the spawn, the workers or the facilities. This is not to say that contaminants can not be introduced by other means; these are the most probable sources of contamination given the cultivator has followed generally accepted procedures for mushroom culture.

Tracking down the source of contamination is not difficult. For instance, the photographs below show two media filled Petri dishes contaminated with a *Penicillium* mold. Although the contaminant may be the same, the source of contamination is likely to be quite different. The plate in Fig. 174 has a mold colony growing directly beside the wedge of mycelium that was transferred. The plate in Fig. 175 shows contamination along the outer periphery. Here is a clear example illustrating how contamination spreads.

The left plate became contaminated when the mycelium was transferred, suggesting the mold was associated with the previous culture. The right Petri dish contaminated from airborne spores which entered as the culture was incubating, judging by the proximity of the mold colonies to the outer edge. Air movement within the "sterile" laboratory most likely wafted spores towards the media plate and some penetrated the minute spaces between the lid and the base. Within the still air environment of the Petri dish, spores settled nearest to their point of entry, germinated and began resporulating, soon to be visible as a green mold. One would, therefore, implement the measures of control accordingly.

Often times the source of contamination is not obvious. Beginners are at a particular disadvantage because every contaminant they encounter is "new". With each crop, problems arise requiring novel solutions. If a certain method of cultivation has been repeatedly successful in the past and suddenly an unfamiliar contaminant appears, identifying the vector can be much more difficult. Only when the cultivator can pinpoint the variables leading to the introduction of that contaminant can appropriate counter-measures be applied. Frequently what seems to be an inconsequential alteration in technique at one stage leads to a radical escalation of the contamination rate at later stages.

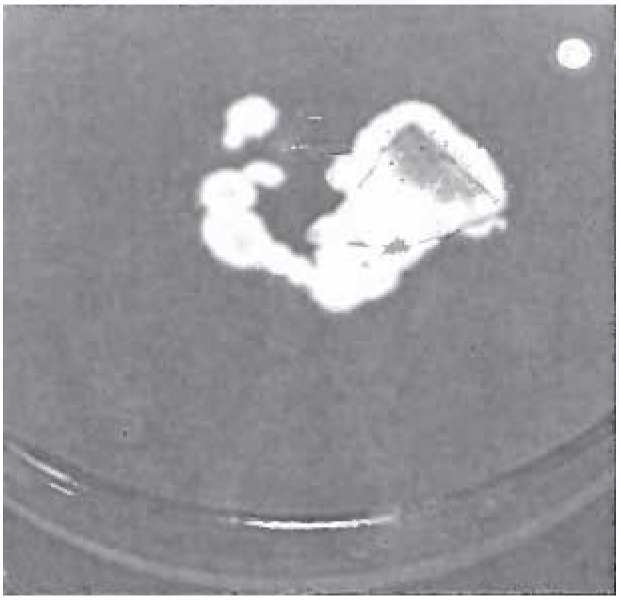

Figure 174 - *Penicillium* mold near to transferred wedge of mushroom mycelium.

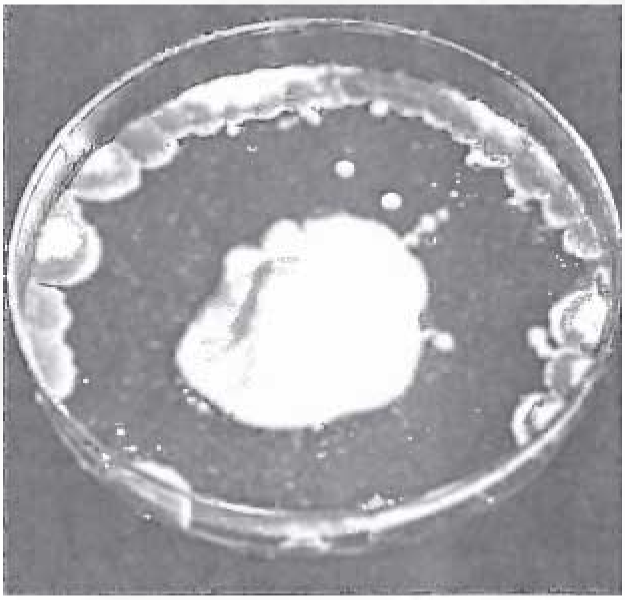

Figure 175 - *Penicillium* mold along outer periphery of Petri dish.

Since contamination at any phase of cultivation occurs for specific reasons, the contaminants can be the cultivator's most valuable guide for teaching one what NOT to do. If the problem causing organism is identified and if the recommended measures of control are carefully followed, a conscientious cultivator will avoid those conditions predisposing to that one competitor and, incidentally, many others. In effect, skill in mushroom culture is tantamount to skill in contamination control.

Molds and bacteria do not grow well in a climate specifically adjusted for mushrooms. Although both mushrooms and contaminants prefer humid conditions, the latter thrive in prolonged stagnant air environments whereas mushrooms do not. The differences are frequently subtle - amounting to only a few percentage points in relative humidity and slight adjustments to the air intake dampers in the growing room.

The contaminants can be divided into two well defined groups. Those attacking the mushrooms are called **pathogens** while those competing for the substrate are labeled **indicators** or **competitors**. (Mushroom pathogens are either molds, bacteria, viruses or pests; indicators are always fungi of some sort). In general, mushroom pathogens are not as numerous as the competitor molds, though they can be much more devastating.

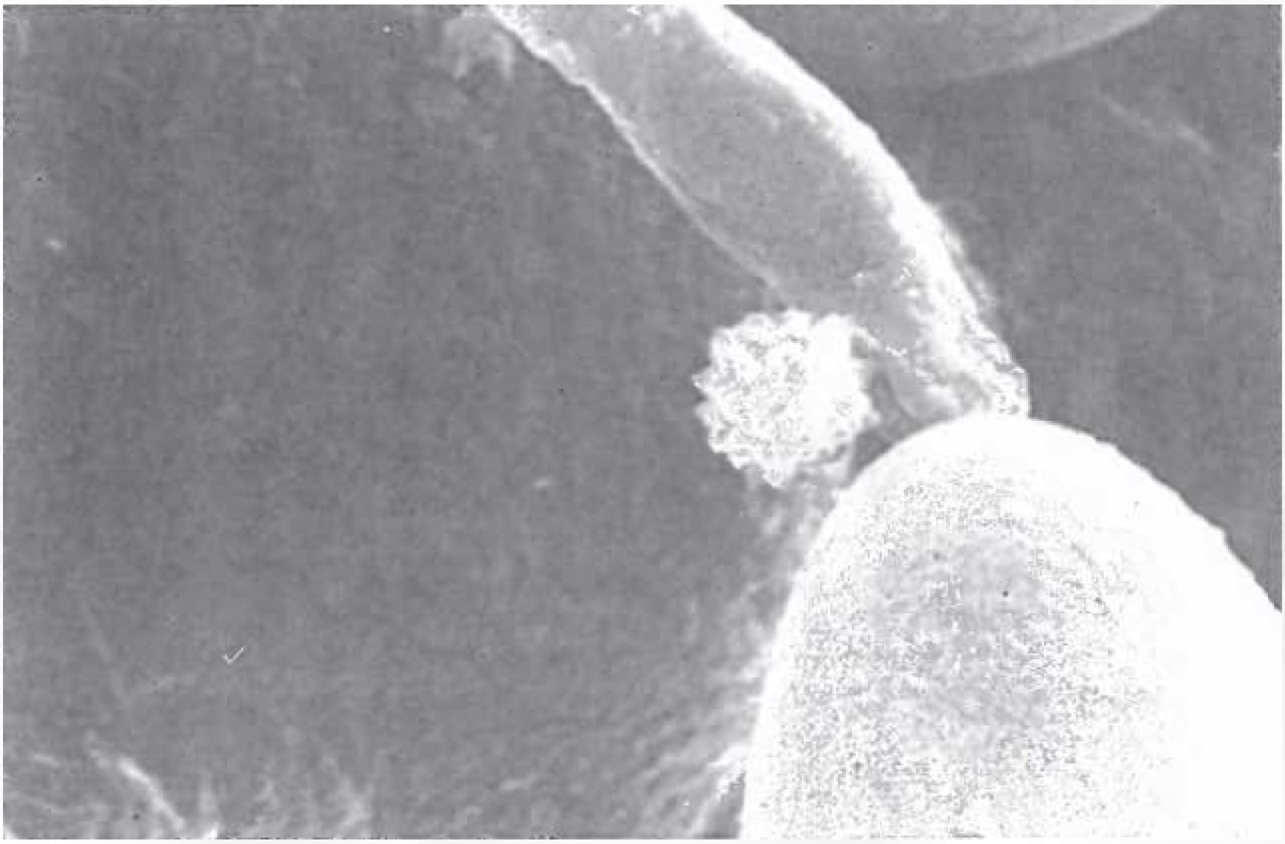

Figure 176 - High magnification scanning electron micrograph of *Aspergilus* spore beside germinating spore of *Psilocybe cubensis*.

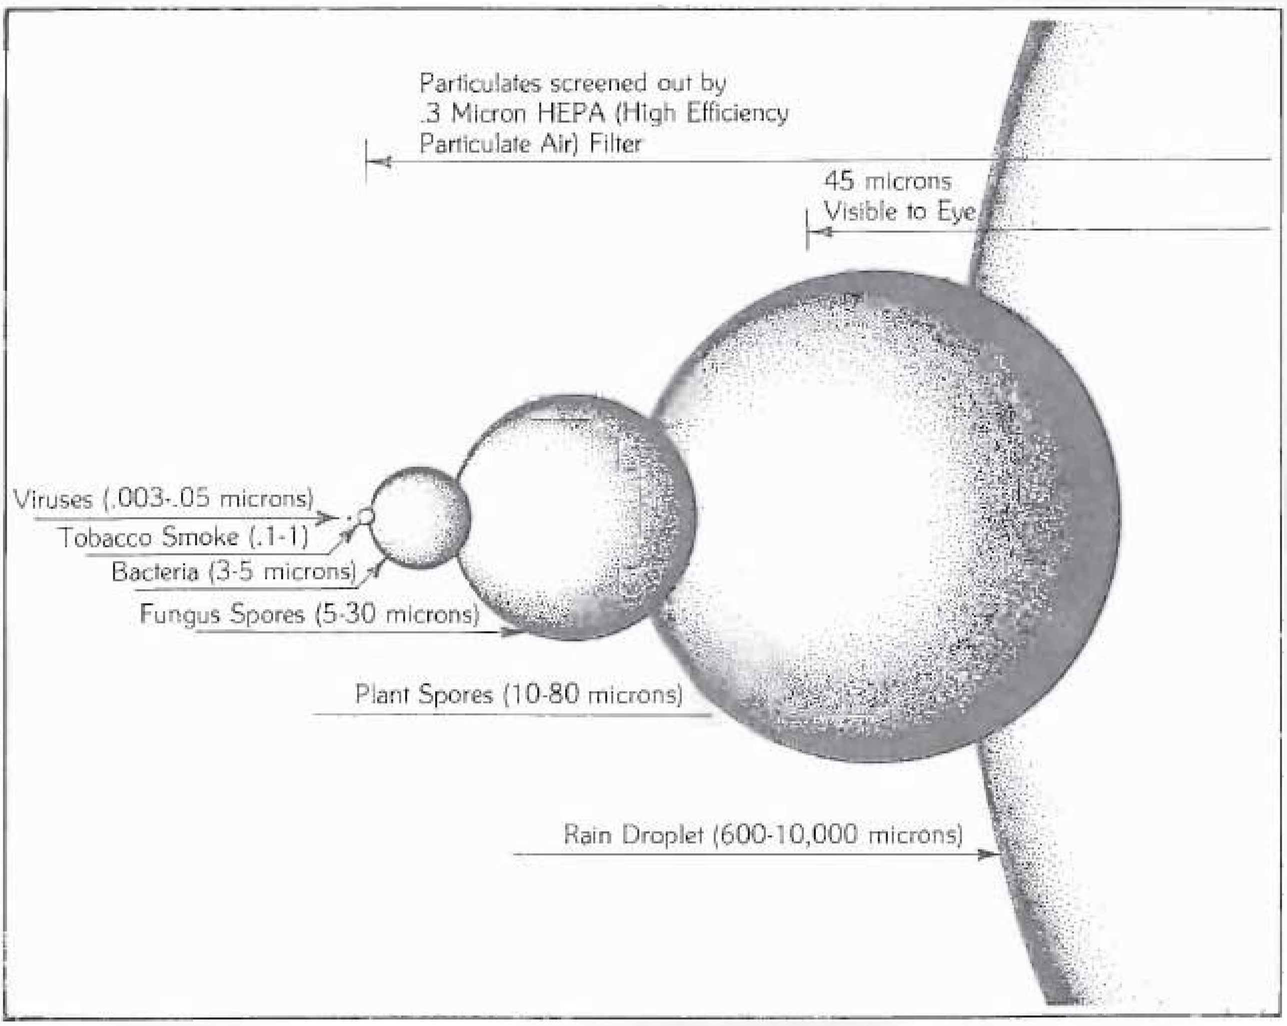
Not all molds and bacteria are damaging to the mushroom crop. To the contrary, several are beneficial. These can not be called true "contaminants" since cultivators try to promote, not hinder, their growth. To the beginner, however, they resemble real contaminants and therefore must be included in this chapter. Examples of yield enhancing organisms are several thermophilic fungi and bacteria, including:

Humicola
Torula
Actinomyces
Streptomyces
Select *Pseudomonas* and *Bacillus* species

These organisms are encouraged during the preparation of compost or during spawn run and are rarely seen in agar or grain culture. Since they can not accurately be termed contaminants, the aforementioned groups are not in the following key though they are fully discussed in the ensuing descriptions.

Fungi, bacteria and viruses can be roughly delimited according to their size. All but viruses can be defected by the home cultivator. Viruses can prevent fruiting, malform the mushroom fruitbody, and expose the crop to further infestations from other pathogens. Since detecting viruses is beyond the means of home cultivators, they have also been excluded from this key.

RELATIVE SIZES OF THE CONTAMINANT GROUPS		
Organism	**Size (in microns)**	**Method of Detection**
Viruses	.01 - .20	X-ray defraction, transmission electron microscopy and ultracentrifuge. Typically attached to other larger particles, occurring within cells, or are present in large conglomerate colonies. Often associated with bacteria.
Bacteria	.40 - 5.0	Detected by electron microscopy, light microscopy and ultracentrifuge. Large colonies visible to unaided eye. Sometimes associated with mushroom spores or mycelium.
Fungi	2.0 - 30.0	Detected by light microscopy. Large colonies visible to unaided eye. Associated with a larger spore generating structure, often chain-like in form.



Particulates screened out by
.3 Micron HEPA (High Efficiency
Particulate Air) Filter
45 microns
Visible to Eye
Viruses (.003-.05 microns)
Tobacco Smoke (.1-1)
Bacteria (3-5 microns)
Fungus Spores (5-30 microns)
Plant Spores (10-80 microns)
Rain Droplet (600-10,000 microns)

Figure 177 - Diagram illustrating comparative sizes of airborne particulates.

What follows is a rudimentary key to the major contaminant groups encountered in mushroom cultivation with the exception of insects and viruses which are discussed in later sections. Though thousands of species of fungi exist in nature, only a small fraction are repeatedly seen in the course of mushroom culture. Hence, this key is limited to that small sphere of microorganisms and does not propose to be an all encompassing guide to the molds. Nevertheless, this key should prove to be a valuable resource for anyone interested in improving their cultivation skills. Some contaminants are keyed out more than once if occurring in various habitats, or if exhibiting significant color changes. Since color has some emphasis in this key and that feature can be substrate specific, the authors presume the agar medium employed is 2% malt based, the spawn carrier is rye grain or sawdust/bran, and the fruiting substrate is one outlined in this book.

Once led to a particular genus, refer to its description. If in doubt, a quick look under a medium power (400 X) microscope should readily discern one contaminant from another. If the contaminant can be identified but its source can not, turn the chapter entitled **Cultivation Problems and Their Solutions**. One or more of the common names have been listed under each competitor. Good luck, be meticulous in your observations and strictly adhere to the recommended measures of control.

Contaminants encompassed by this key:

Alternaria
Aspergillus
Bacillus
Botrytis
Chaetomium
Chrysosporium
Cladosporium
Coprinus
Dactylium
Epicoccum
Fusarium
Geotrichum
Monilia
Mucor
Mvcelia Sterilia
Mycogone
Neurospora
Papulospora
Penicilium
Pseudomonas
Rhizopus
Scopulariopsis
Sepedonium
Trichoderma
Trichothecium
Verticillium
Yeasts

A Key to the Common Contaminants of Mushroom Culture

This key is easy to use. Simply follow the key lead that best describes the contaminant at hand. When the key terminates at a specific contaminant, turn to the descriptions immediately following this key and then refer to the photographs and any related genus mentioned. To confirm the identity of any contaminant, compare its sporulating structures with the accompanying microscopic illustrations and/or micrographs.

1a	Contaminant parasitizing the mushroom fruitbody (a pathogen).	2
1b	Contaminant not parasitizing the mushroom fruitbody (an indicator).	7
2a	Contaminant causing mushrooms to become watery, slimy, or to have lesions from which a liquid oozes but not covered with a powdery or downy mycelium.	3
2b	Contaminant not as above but covering mushrooms with a fine powdery or mildew-like mycelium.	4
3a	Droplets forming across the cap and stem but lacking sunken lesions. Mushrooms eventually reduced to a whitish foamlike mass.	Causal organism not known "Weepers"
3b	Cap not as above but first having brownish spots that enlarge, deepen, and in which a grayish brown slime forms. Mushrooms eventually disintegrate into a dark slimy, oozing mass.	*Pseudomonas tolassii* Bacterial Blotch Bacterial Pit
4a	Contaminant eventually sporulating as a green mold on the mushroom. Usually preceded by an outbreak of green mold on the casing layer.	*Trichoderma virkie* *Trichoderma koningii* "Trichoderma Blotch"
4b	Not as above.	5
5a	Contaminant appears on the casing soil as a fast running grayish cobweb-like mycelium, enveloping mushrooms in its path. (Spores usually three or more celled and 20 x 5 microns in size. If two celled, not acorn-shaped).	*Dactylium dendroides* "Cobweb Mold"
5b	Contaminant attacking the mushroom but usually not appearing on the casing layer. (Spores single celled or if two celled, resembling a roughened acorn and measuring much less than above).	6
6a	Contaminant appears on the casing soil as a fast running grayish cobweb-like mycelium, enveloping mushrooms in its path. (Spores usually three or more celled and 20 x 5 microns in size. If two celled, not acorn-shaped).	*Mycogone perniciosa* "Wet Bubble"
6b	Contaminant afflicting young mushrooms as described above but those parasitized not exuding amber fluid when cut open. Stem in more mature mushrooms often splitting and peeling, causing the mushrooms to tilt. (Spores one celled.)	*Verticillium malthousei* "Dry Bubble"
7a	Contaminant in the form of another mushroom whose cap deliquesces (melts) into a blackish liquid with age.	*Coprinus* spp. "Inky Cap"
7b	Contaminant not as above	8
8a	Contaminant becoming pinkish to reddish to purplish colored in age.	9

8b	Contaminant not as above.	14
9a	Occurring on compost or the casing layer.	10
9b	Occurring on nutrient agar media and on grain.	11
10a	Mycelium fast growing, aerial, and never having a frosty texture. Pinkish with spore maturity. (Spores unicellular with nerve-like ridges longitudinally arranged and ellipsoid).	*Neurospora* sp. "Pink Mold"
10b	Mycelium slow growing, appressed, and developing a frosty texture. Often becoming cherry red. (Spores cylindrical and lacking nerve-like ridges).	*Geotrichum* "Lipstick Mold"
11a	Mycelial network of contaminant not well developed, not clearly visible to the unaided eye, often slime-like.	12
11b	Mycelial network of contaminant well defined and easily discernible to the naked eye, not slime like.	13
12a	More frequently seen in agar culture. (Spores produced by simple budding, ovoid, single celled).	The Yeasts see *Cryptococcus*
12b	More frequently seen in grain culture. (Spores produced on a short conidiophore, sickle shaped, and multicelled).	*Fusarium* "Yellow Rain Mold"
13a	Mycelium fast growing and aerial. (Spores with nerve-like ridges and ellipsoid).	*Neurospora* "Pink Mold"
13b	Mycelium typically slow growing and appressed. (Spores two celled, without ridges, and pear-shaped).	*Trichothecium* sp. "Pink Mold"
14a	Contaminant slime-like in form.	15
14b	Contaminant mycelium-like or mold-like in form.	17
15a	Non-motile (not moving spontaneously). Spores relatively large, 4-20 microns in diameter. Not affected by bacterial antibiotics such as gentamycin sulfate.	The Yeasts (see *Cryptococcus* and *Rhodotorula* under *Torula*)
15b	Motile (moving spontaneously). Spores relatively minute, rarely exceeding 2 microns in diameter. Growth prevented by bacterial antibiotics such as gentamycin sulfate.	16
16a	Cells rod-like in shape. Gram positive (retaining a violet dye when fixed with crystal violet and an iodine solution).	*Bacillus* "Wet Spot"
16b	Cells variable in shape. Gram negative (not retaining a violet dye when fixed with crystal violet and an iodine solution).	*Pseudomonas* "Bacterial Blotch"
17a	Contaminant mold greenish with spore maturity.	18
17b	Contaminant mold blackish with spore maturity.	20
17c	Contaminant mold brownish with spore maturity.	24
17d	Contaminant mold yellowish with spore maturity.	25
17e	Contaminant mold whitish with spore maturity.	28
18a	Forming small burrs and usually olive green in color. (Spores lemon shaped, enveloped in a sac-like structure (a perithecium)).	*Chaetomium olivaceum* "Olive Green Mold"
18b	Not as above.	19
19a	Molds typically blue-green in color. (Conidiophore diverging at apex into multiple chains of lightly pigmented single celled spores).	*Penicillium* spp. "Blue Green Mold"
19b	Molds typically true green to yellow green in color. (Condiophore swollen at apex and bulb-like (capitate), around which multiple chains of lightly pigmented single celled spores extend).	*Aspergillus* spp. "Green Mold"
19c	Molds forest green in color. (Conidiophore easily disassembling in wet mounts and difficult to observe under the microscope. Spores single celled, lightly pigmented, and encased in a mucous-like substance).	*Trichoderma* spp. "Forest Green Mold"

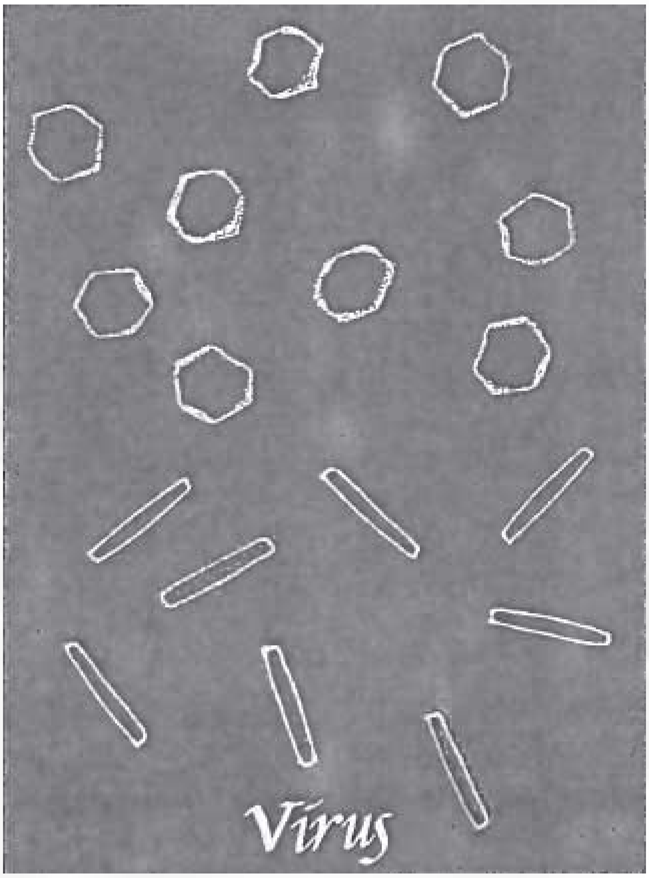
19d	Molds blackish green in color. (Conidiophores branching into few forks at whose ends darkly pigmented spores form, often two celled.)	*Cladosporium* spp. "Blackish Green Mold"
20a	Mold colony appressed, resembling a dark Penicillium-like mold, but not aerial.	21
20b	Mold colony aerial, not Penicillium-like.	22
21a	(Spores elongated and ornamented with ridges, generaly exceeding 20 microns in length and 5 microns in diameter).	*Alternaria* spp. "Black Mold"
21b	(Spores spherical, not ornamented with ridges, generally less than 5 microns in diameter).	*Aspergillus* spp. "Black Mold"
22a	Most frequently seen on compost. Resembling black whiskers. (Forming a conidiophore that diverges into multiple stalks at whose ends are chains of darkly pigmented spores).	*Doratomyces stemonitis* spp. "Black Whisker Mold"
22b	Most frequently seen in agar and grain culture. Resembling a forest of dark headed pins. (Forming a sporangiophore consisting of single stalk at whose end a ball-like sporulating structure is attached).	23
23a	Conidiophore appearing swelled at apex; partially covered by a sporulating membrane.	*Rhizopus* "Black Bread Mold" "Black Pin Mold"
23b	Conidiophore not swelled as above; apex totally covered by sporulating membrane.	*Mucor* "Black Pin Mold"
24a	Mold developing small bead-like masses of cells (easily visible with a magnifying lens). Never producing cup-like fruitbodies. (Darkly pigmented cells clustered on a mycelial mat; spores lacking).	*Papulospora byssina* "Brown Plaster Mold"
24b	Mold not developing the ball-like clusters of the above. Sometimes producing cup-like fruitbodies. (Spores produced in bunches in a grape-like fashion).	*Botrytis* "Brown Mold"
25a	Mold forming a corky layer between the casing layer and the compost, and mat-like. (Spores borne on short vase shaped pegs).	*Chrysosporium luteum* "Yellow Mat Disease" "Confetti"
25b	Mold not forming a corky layer and appearing mat-like. (Spores not borne in the manner above).	26
26a	Not occurring on compost. (Conidiophores short, arising from cushion shaped cells. Spores, if reticulated, appear to be composed of several tightly compacted cells).	*Epicoccum* "Yellow Mold"
26b	Frequently seen on compost but not exclusively so. (Conidiophores not as above. Spores appearing unicellular)	27
27a	Spores large, exceeding 5 microns in diameter, and of two types. Some spherical and spiny, forming singly at the end of individual hyphal branches; others vase shaped arising singly or in loose clusters from an indistinct, hyphal-like conidiophore).	*Sepedonium* "Yellow Mold"
27b	Spores small, less than 5 microns in diameter, ovoid, forming on chains arising from a head-like structure positioned at the apex of a long stalk.	*Aspergillus* spp. "Yellow Mold"
28a	Appearing as a dense plaster-like or stroma-like mycelium. (Condiophore brush shaped (penicillate)).	*Scopulariopsis* "White Plaster Mold"
28b	Mycelium not plaster-like. (Conidiophore not brush shaped (penicillate)).	29
29a	Spores forming from hyphae in chains.	*Monilia* "White Flour Mold"
29b	Spores absent, not forming from hyphae.	*Mycelia Sterilia* (see also: *Mucor* and *Sepedonium*).

Virus (Die-Back Disease)

Common Name: Die-back Disease; La France Disease, Mummy.

Habitat and Frequency of Occurence: An infrequent and difficult to detect disease. Their habitats are other larger particles or organisms.

Medium through which contamination is spread: Primarily from infected mycelium or from the spores of diseased mushrooms. Dieleman-van Zaayen (1972) found that the most common way virus spreads is through the anastomosing ("merging") of healthy mycelia with infected mycelia that was leftover from previous crops. Once anastomosed, the virus particles spread throughout the mycelial network of the new mycelium.



Measures of Control: Thorough disinfection of the growing room between crop rotations by steam heating for 12 hours at 158-160°F.; the installation of high efficiency spore filters to screen particulates exiting the growing environment; the disinfection of floors and hallways leading to and from the growing room with 2% chlorine solution; and picking diseased mushrooms while the veil is intact before spores have the opportunity to spread. Isolation of infected crops from adjacent rooms or those newly spawned helps retard the spread of this disease. Other measures of control include the placement of disinfectant floor mats to prevent the tracking in of virus-carrying particles on worker's shoes and the maintenance of strict hygienic practices at all times, particularly between crops.

Macroscopic Appearance: On nutrient agar media, infected mycelia slows or nearly abates in its rate of growth as the disease progresses throughout the mycelial network. When running through the casing layer, large zones one to three feet in diameter remain uncolonized. In some cases the mycelia, once present, disappears from the surface. Fruitbodies may not form at all, or when they do, the mushrooms are typically deformed (dwarfed or aborted), often with watery or splitting stems, and brown rot. The caps prematurely expand to plane. Virus infected cultures can exhibit any combination of the above described symptoms.

Microscopic Characteristics: Particles typically ovoid to polyhedral, measuring 25 or 34 nanometers. Elongated particles measure 19-50 nanometers. Virus particles dwell within hyphal cells or on the surfaces of spores. They are detectable only through transmission electron microscopy or ultracentrifuging.

History, Use and/or Medical Implications: Responsible for many plant, animal and human diseases. Typically viruses are associated with larger carrier particles, particularly bacteria.

Comments: Virus is most likely introduced during or directly after spawning. Infected farms experience losses up to 70%. First reported from Europe, measures of control and prevention have been developed and successfully tested by the Dutch. Most notably, virus spreads by attaching itself to mushroom spores which then become airborne. Virus also spreads through the contact of healthy mycelia with diseased mycelia. Afflicted mushrooms are soon exploited by a host of other parasites, making a late and accurate diagnosis of this contaminant difficult.

Undoubtedly, virus is the cause of what many have noted as "strain degeneration". Heat treatment of infected strains grown on enriched agar media at 95°F. for three weeks has been suggested as one remedy for curing diseased mycelia. (See Candy and Hollings, 1962 and Rasmussen *et al*., 1972).

Van Zaayen (1979) and others have noted that *Agaricus bitorquis* seems resistant to virus disease even when inoculated with in vitro particles. Another species of *Agaricus*, called *Agaricus arvensis*, exhibits similar virus resistant qualities.

Virus-like particles have also been found in *Lentinus edodes* by Mon et alia (1979) but do not adversely affect fruitbody formation or development. These same researchers reported that this species' viruses can not be transmitted to other mushrooms or plants, a fact they attributed to the interferon producing properties of the shiitake mushroom. No work with infected strains of *Psilocybe* are known. Only a fraction of wild mushrooms harbor virus-like particles.

Actinomyces (Firefang)

Class: *Actinomyces*

Order: *Actinomycetales*

Family: *Actinomycetaceae*

Common Name: Firefang

Greek Root: From "actino" meaning rayed or star-like and "myces" or fungus, in reference to its characteristic appearance when colonizing straw or straw/manure compost.

Habitat & Frequency of Occurrence: Many species thermophilic; thriving in the 115-135°F. temperature range and commonly found in decomposing straw, horse and cow manures. *Actinomyces* are important soil constituents. They thrive in aerobic, well prepared mushroom composts.

Medium Through Which Contamination Is Spread: Primarily air; secondarily the straw used in compost preparation.

Measures of Control: Generally no controls are necessary during compost preparation. However, *Actinomyces* can cause spontaneous combustion in wet, compacted straw. Covering stored baled straw from excess water absorption should be adequate protection from *Actinomyces* and the thermogenic reactions they cause.

Macroscopic Appearance: Grayish to whitish speckled colonies, readily apparent on dark composted straw.

Microscopic Characteristics: Composed of an extensive, fine hyphal network that rarely branches. Rod-like spores form when the filaments break at the cell wall junctions. The filamentous hyphae and spores are minute, measuring only 1 micron in diameter. Within each cell, no well defined nucleus is discernible. Lacking differentiated spore-producing bodies, *Actinomyces* are Gram-positive.

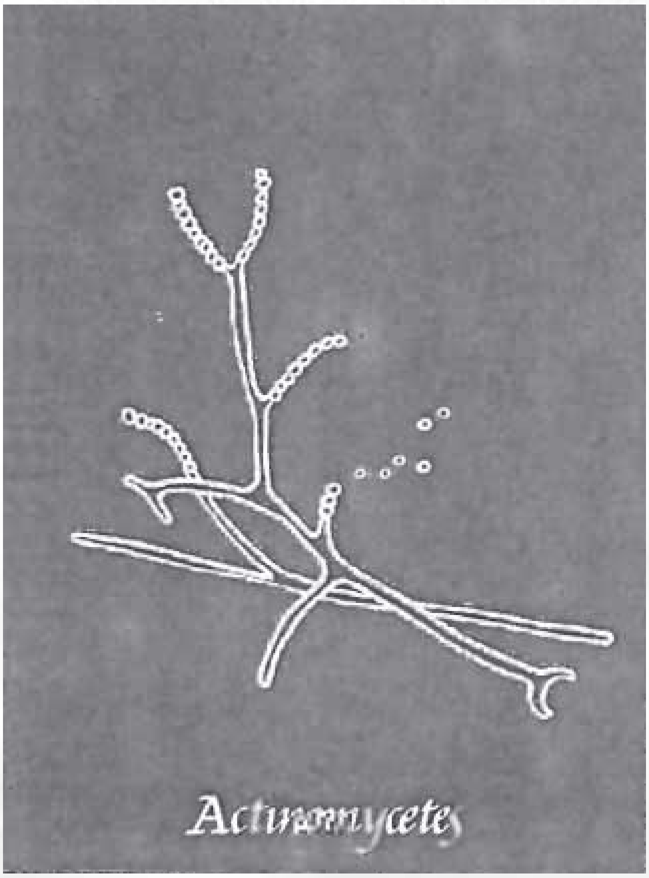


Figure 178 - Drawing of Actinomyces.

History, Use, and/or Medical Implications: Few species pathogenic. Amongst agricultural workers in the same position, males are three times more susceptible to this bacterium than females (see Cruickshank *et al*., 1973). Two notable species causing serious diseases (actinomycosis) of the skin and oral cavity in humans are *Actinomyces bovis* and *Actinomyces israelii*. Generally, these species behave as secondary infectious organisms. Penicillin is often used for treatment. Actinomycin, a potent antibiotic compound interfering with RNA synthesis, is derived from this group of bacteria.

Although the likelihood of mushroom growers contracting actinomycosis is remote, workers spawning compost are exposed to high concentrations of *Actinomyces* spores and often report less severe, temporary allergic reactions. Therefore, the use of a filter mask when spawning large volumes of compost is advisable.

Comments: The *Actinomyces* resemble both bacteria and fungi and have alternately been called one or the other. Presently, the prevailing belief is that they are filamentous (Gram-positive) bacteria because they are prokaryotic (lacking a defined nucleus), are inhibited by bacterial antibiotics and not affected by fungal antibiotics;, and lack the chitin-like compounds so typical of the true fungi. The hyphal filaments of *Actinomyces* are one fifth to one tenth as thick as those of true fungi.

Actinomyces are commonly called Firefang for their ability to cause spontaneous combustion of decomposing materials. (Spontaneous combustion is prevented by proper composting practices.) Many of these bacteria/fungi are true thermophiles and can live aerobically or anaerobically. *Actinomyces* is the major microorganism selected to colonize the compost during Phase II. When the finished compost is spawned, *Actinomyces* are consumed by the mushroom mycelia.

See also *Streptomyces*. See Color Photo VIII.

Bacillus (Wet Spot)

Class: *Schizomycetes*

Order: *Eubacteriales*

Family: *Bacillaceae*

Common Name: Wet Spot; Sour Rot.

Latin Root: From "bacilliformis" meaning rod-like, in reference to its characteristic shape.

Habitat & Frequency of Occurrence: Living within a broad range of habitats. *Bacillus* grows on almost anything organic that is moist and is surrounded by oxygen. It is particularly common in soils.

Medium Through Which Contamination Is Spread: Primarily through the air; secondarily through water, grain, soils, composts, insects, tools and workers.

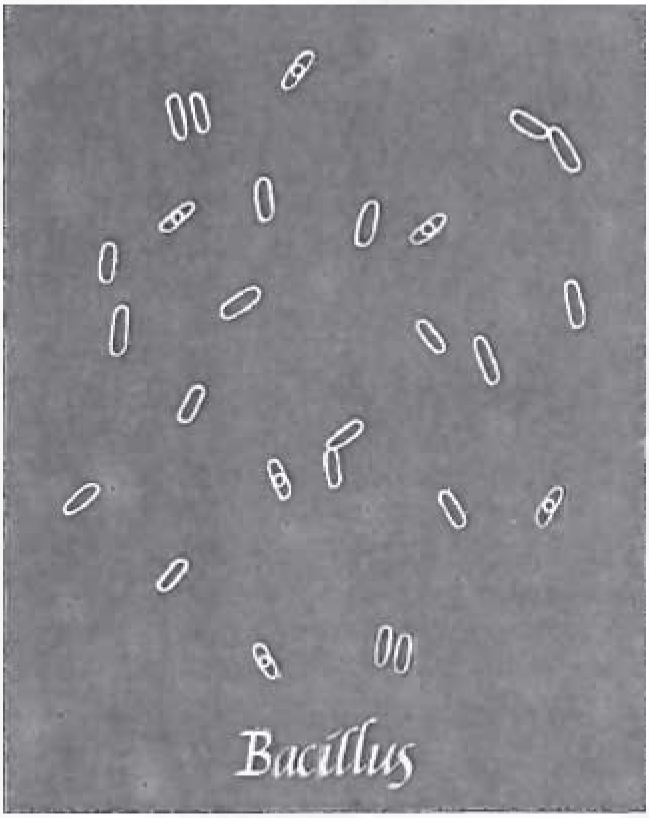

Figure 179 - Drawing of endospore forming *Bacillus* cells as they appear through a microscope and without special stains.

Measures of Control: Air filtration through high efficiency particulate air filters; thorough sterilization of grain; and proper storage and use of relatively "clean" grains. The addition of antibiotics to agar media (gentamycin sulfate, penicillin, streptomycin, aureomycin, etc.) hinders or prevents the growth of these contaminants. Endospores are neutralized by exposure to moist heat, such as the steam generated within a pressure cooker at temperatures of 250°F. and 15 psi pressure for a full hour. Temperatures as low as 140°F. kill the vegetative parent cells but not the endospores they form.

Macroscopic Appearance: A dull gray to mucus-like brownish slime characterized by a strong but foul odor variously described as smelling like rotting apples, dirty socks or burnt bacon. *Bacillus* makes uncolonized grain appear excessively wet, hence the name "Wet Spot". Pallid to whitish ridges along the margins of individual grain kernels characterize this contaminant.

Microscopic Characteristics: Rod-like or cylindrical in shape, measuring 0.2-1.2 microns in diameter and 1-5 microns in length. When wet mounts are viewed through a microscope, *Bacilli* excitedly wriggle back and forth. Species move by the vibrating action of flagella ("hairs") that outline each cell. These flagella are difficult to observe microscopically without using specific staining techniques. *Bacilli* are encapsulated by a thin but firm slime and conglomerations of cells give infected grain a slimy appearance. *Bacillus* primarily reproduces through simple cell division. In times of adverse environmental conditions, especially heat, a single hardened spore forms within each parent cell body. These endospores show an extraordinary resistance to heat, are low in water content and are unaffected by drying. Species in this genus are Gram positive.

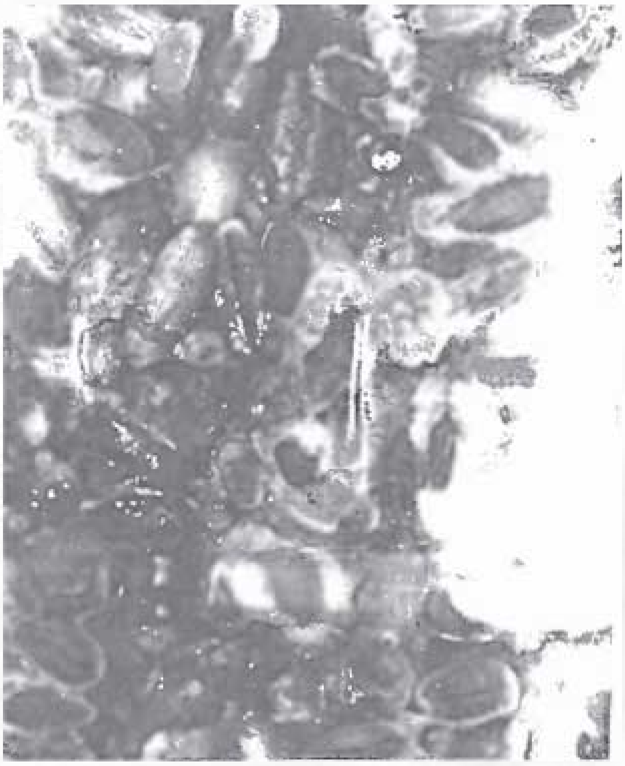

Figure 180 - *Bacillus*, the Wet Spot bacterium, as it appears on grain.

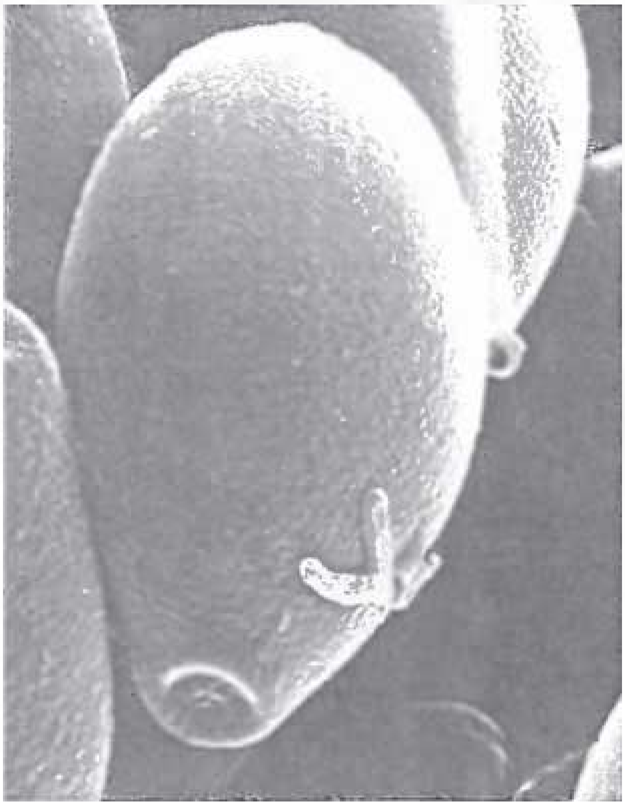
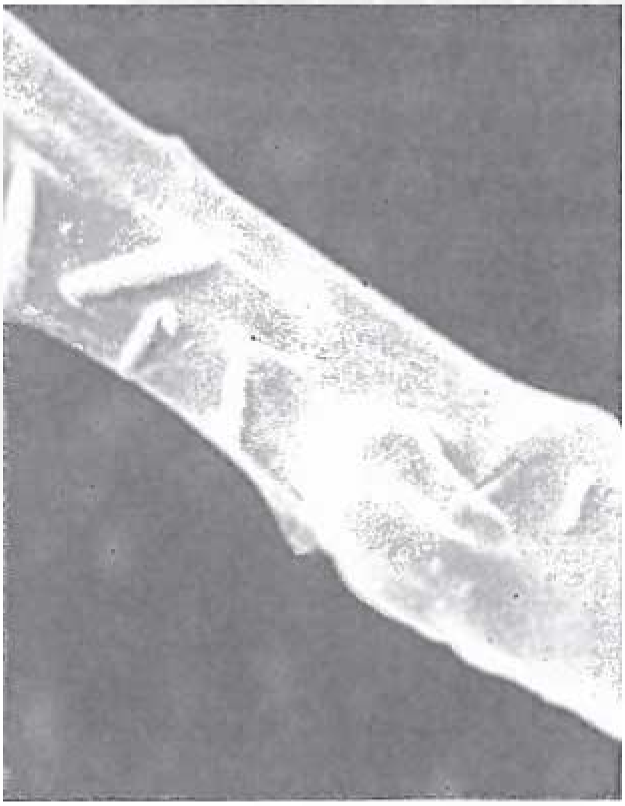
Figure 181 - Scanning electron micrograph of rod shaped bacteria on a spore of *Panaeolus acuminatus*.

Figure 182 - Scanning electron micrograph of rod shaped bacteria on mycelium of *Psilocybe cubensis*.





History, Use, and/or Medical Implications: The most notable species in the genus is *Bacillus anthracis*, the cause of the hideous Anthrax disease that killed several thousand sheep when an United States Army experiment went awry in Utah during the 1950s. Home cultivators are, however, unlikely to be exposed to this species. Most endospore forming bacteria are not virulent. *Bacillus subtilis*, the bacterium spoiling grain spawn, is being developed to replace *E. coli* as a recombinant-DNA fermentor. *Clostridium* is a genus similar to *Bacillus* except that it is anaerobic. That genus is reknowned for one toxic species in particular: *C. botulinum*, the cause of botulism.

Comments: A pernicious and tenacious competitor, *Bacillus* contamination is the most difficult to control. At room temperature, a single cell reproduces every 20 minutes and will multiply into nearly a million daughter bacteria in only seven hours. In another seven hours each one of those million bacteria divide into a million more cells. Thus, in less than fourteen hours, one trillion bacteria evolve from a single parent cell!

The phenomenonal reproductive capability of *Bacillus* and other bacteria poses a formidable threat to the spawn maker. Although parent cells are easily destroyed, their endospores are not. Under dry conditions, endospores form in increasing numbers as temperatures rise to 130°F. In boiling water (212°F.), endospore viability markedly decreases. (Ninety percent of *Bacillus* spores are killed in only one minute at 212°F.). At the higher temperatures and pressures within an autoclave the survivability of *Bacillus* spores falls well below 1%. Nevertheless, this 1% seriously obstructs any attempt at grain culture given *Bacillus*' rapid reproductive capability. This problem is compounded if the bacteria count in the grain is initially high.

In one study (Shull and Ernst, 1962), the thermal death time (TDT) of an exposed *Bacillus stearothermophilus* population of 1,300,000 endospores was pinpointed at 250°F. for 13 minutes. (In a pressure cooker at sea level, 250°F. corresponds to 15 psi). Food researchers concerned with food-spoiling bacteria (particularly *Clostridium*) have shown that endospore endurance to heat is directly related to the amount of calcium in the host substrate. Once formed, endospores can sit dormant for extended periods of time. Even endospores removed from the stomachs of mummies have proved viable after hundreds of years.

Although an autoclave may read a certain temperature, the grain within the spawn containers may be well below that reading. To guarantee adequate steam penetration, the water in pressure cookers should be brought to a boil for 5 minutes before closing the vent valve. Furthermore, bacteria within the spawn container are partially protected from the sterilizing influence of steam by the structural cavities of the grain medium. This delay in steam penetration time is especially characteristic of large, heavily packed autoclaves.

Despite the fact that autoclaving for one hour at 15 psi is sufficient to kill most contaminants, grain having initially high bacteria populations may require sterilization at higher temperatures and for prolonged periods of time. Autoclaving quart jars for 1 hour at 270°F. (which is equivalent to 27 psi) is sufficient to neutralize grain heavily infested with endospore forming bacteria. If converting a standard home pressure cooker for this purpose, contact the manufacturer about stress limitations and follow all safety recommendations.

If "sterilized" rye grain spontaneously contaminates with bacteria before inoculation and the grain is the cause, it is best to replace the grain with a cleaner one than to undergo the expense and time of double sterilization. Some spawn laboratories regularly precook their grain for approximately 2 hours in water at a low boil. Excess water is allowed to drain from the grains which are then placed into the spawn container and sterilized at standard time and pressure.

The most practical method for eliminating bacterial endospores involves soaking the grain at room temperature 24 hours prior to sterilization. Endospores, if viable, will germinate within that time frame and then be susceptible to standard sterilization procedures. And, new endospores won't form in the moist environment of the resting jar of grain.

Bacillus subtilis var. *mucoides* is the common bacterium responsible for spoiling spawn media. If allowed to proliferate, this contaminant wreaks havoc in a spawn laboratory, necessitating a complete shut-down of operations. Spores and even strains of mushroom mycelium can become hosts for *Bacillus*, carrying bacteria on their hyphae (see Figs. 181 & 182), and then contaminating any media onto which the mushroom mycelia is transferred.

Many bacteria are rod-shaped and the term bacillus has been loosely used to describe them. The genus concept of *Bacillus*, however, has been narrowed considerably with time; *Bacillus* is now defined as Gram positive rod-like, aerobic bacteria that form spores.

According to Park and Agnihotri (1969), *Bacillus megaterium* stimulates primordia formation in certain strains of *Agaricus brunnescens* (*bisporus*). (See Appendix II for a futher discussion on the influence of bacteria on fruiting). Another species, *Bacillus thermofibricolous*, if introduced at spawning, inhibits the growth of competitor molds in rice bran/sawdust spawn prepared for shiitake cultivation according to Steineck (1973).

See also *Pseudomonas*.

Pseudomonas (Bacterial Blotch & Pit)

Class: *Schizomycefes*

Order: *Pseudomonadales*

Family: *Pseudomonaceae*

Common Name: Bacterial Blotch; Bacterial Pit.

Greek Root: From "pseudes" meaning spurious, false or deceptive and "monas" meaning one or a single unit, in reference to the variable forms of this single celled bacterium.

Habitat & Frequency of Occurrence: Ubiquitous in all soils and abounding in aqueous habitats. *Pseudomonas tolaasii* commonly parasitizes mushrooms that remain wet over a prolonged period of time.

Medium Through Which Contamination Is Spread: Primarily water; secondarily through grain, soils, composts, flies, mites, nematodes, tools and workers.

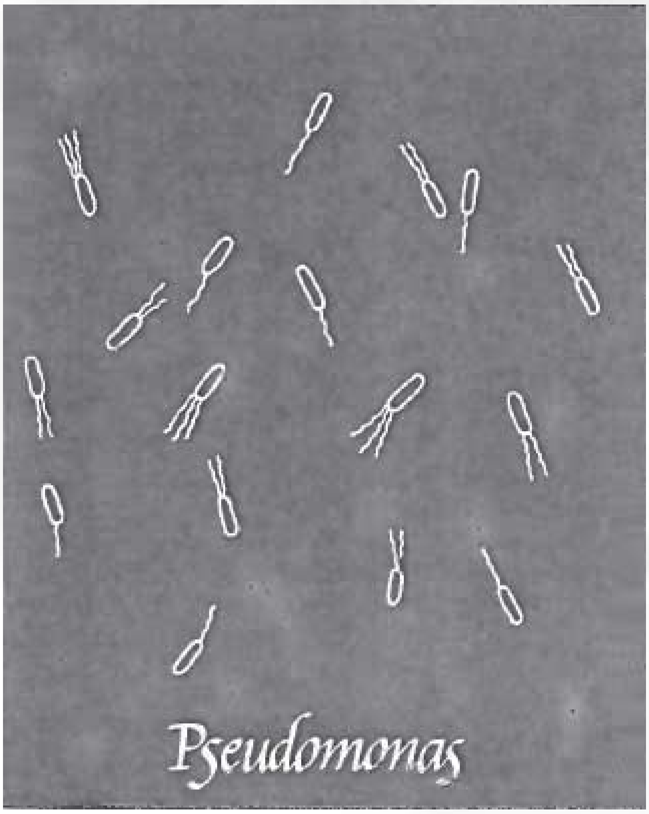


Figure 183 - Drawing of *Pseudomonas*, a genus of variably shaped bacteria that have hair-like flagella at their ends.

Measures of Control: Use of mildly chlorinated water (150-250 ppm) or water free of high bacteria counts. This contaminant can easily be prevented by: isolating and properly disposing of infected fruitbodies; eliminating excessively high humidity levels during cropping (greater than 92%); and preventing stagnant air pockets through a good air circulation system. Maintaining a sufficient evaporation rate lessens the likelihood of these bacteria infecting the fruitbodies.

Macroscopic Appearance: Yellowish spots or circular or irregular lesions; superficial; rapidly reproducing on wet mushrooms; and becoming chocolate brown and slimy with age. This bacterium has a dull gray to mucus-like brownish slime. It also has a mildly to strongly unpleasant odor.

Microscopic Characteristics: Cylindrical (bacilli) and spherical (cocci) forms characterize this genus. Cells are extremely variable in shape, measuring 0.4-0.5 x 1.0-1.7 microns. Typically the bacterial cell has one or more flagella ("motile hairs") at one or both of its poles. (*Bacillus* has flagella along its entire outer periphery). Both organisms use these flagella for locomotion. Species in this genus are generally Gram negative.

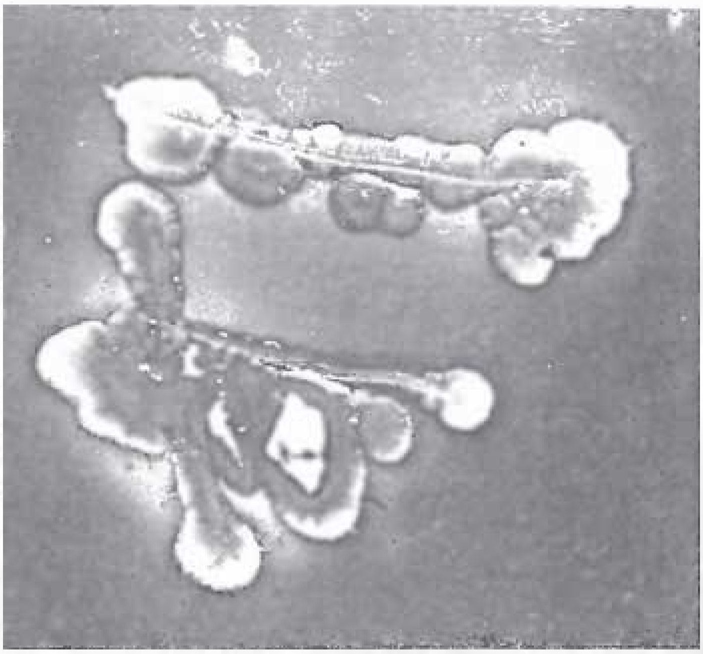

Figure 184 - *Pseudomonas putida*, a beneficial bacterium stimulatory to formation of fruitbodies in some mushroom species, growing on malt agar.

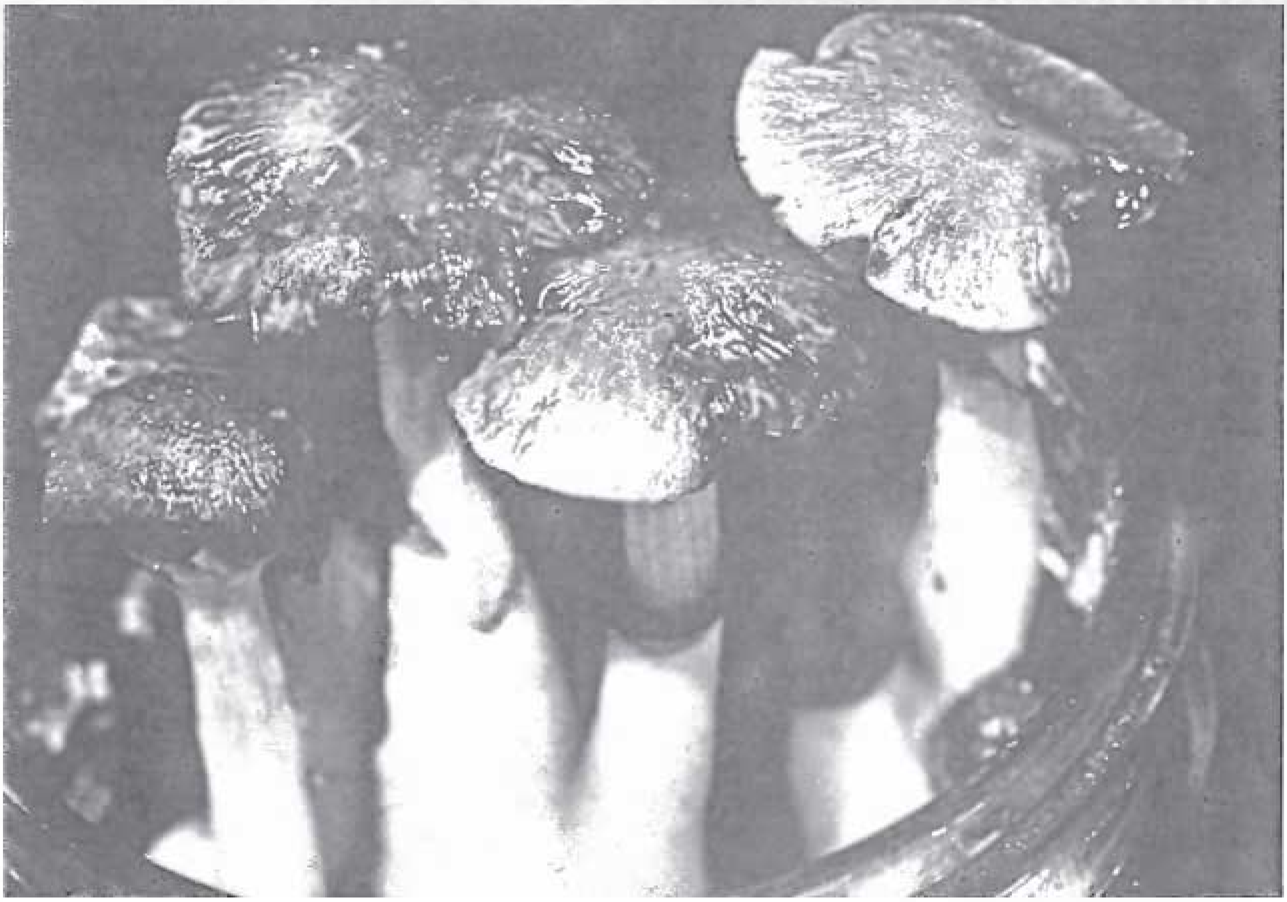
Figure 185 - Bacterial pit on *Psilocybe cubensis* from a *Pseudomonas* species.



History, Use and/or Medical Implications: Some species pathogenic to humans. Of special note is *Pseudomonas aeruginosa* (also known as *Ps. pyocyanea*), a species that causes blindness and other diseases.

Pseudomonas putida is stimulatory to primordia formation in certain strains of *Agaricus brunnescens* (*bisporus*) and its use is of potential commercial value.

Comments: More than 140 species have been identified thus far; only a few have been identified as affecting mushrooms. *Pseudomonas* species are much more sensitive to heat sterilization than the endospore-forming bacilli. *Pseudomonas* bacteria proliferate in standing water or anywhere there is moisture.

Pseudomonas tolaasii is the cause of bacterial blotch that can devastate crops of *Agaricus* and *Psilocybe*. One biological remedy for controlling this species was proposed by Nair and Fahy (1972) who showed that introduction of *Pseudomonas fluorescens*, a natural antagonist to *Pseudomonas tolaasii*, markedly decreased the occurrence of blotch while not hindering *Agaricus brunnescens* yields. Others believe *Pseudomonas fluorescens* to be merely a variety of *Pseudomonas tolaasii*, and hesitate to recommend it.

In a characteristic manner, *Pseudomonas tolaasii* causes sunken grayish brown lesions on the mushroom cap in which a slimy fluid collects. Another *Pseudomonas* species, yet unidentified, has been implicated in the cause of a more severe form of blotch, Bacterial Pit.

Pseudomonas also contaminates agar and grain cultures, inhibiting mycelial growth. The use of antibiotics (gentamycin sulfate) or micron filters prevents outbreaks of this contaminant. A few species cause the mycelium to grow more rapidly and luxuriantly. Similarly, considerable attention has centered on the beneficial role of *Pseudomonas putida* and allies in the casing layer. This subject is discussed in detail in Appendix II.

See also *Bacillus*.

Streptomyces (Firefang)

Class: *Actinomyces*

Order: *Actinomycetales*

Family: *Streptomycetaceae*

Common Name: Firefang.

Greek Root: From "strepto" meaning twisted and "myces" or fungus, in reference to the twisting and branching filaments that give rise to spores.

Habitat & Frequency of Occurrence: Ubiquitous on straw, manures and soil. *Streptomyces* is a predominant microoganism in the compost pile, thriving between 115-135°F. and preferring aerobic zones.

Medium Through Which Contamination Is Spread: Primarily air; secondarily from materials used in composting. *Streptomyces* are naturally present in all soils.

Measures of Control: Generally no controls are necessary during compost preparation, nor desired. General hygienic practices prevent this bacterium from becoming a problem contaminant in the laboratory.

Macroscopic Appearance: Grayish to whitish specked colonies, readily apparent on composted straw. On grain, *Streptomyces* has a delicate whitish mycelium and is powdery in form.

Microscopic Characteristics: Composed of an extensive, fine hyphal network, often branching, coiled and twisted. The hyphae in *Streptomyces* do not fragment into spores as in *Actinomyces* but form a chain-like structure of aerial hyphae called a sporophore from which cells evolve terminally. The filamentous hyphae and spores measure only 1 micron in diameter. Within each cell, no well defined nucleus is discernible. *Streptomyces* lack differentiated spore-producing bodies. Its spores are smooth or spiny.

History, Use, and/or Medical Implications: *Streptomyces* represents 80% of all actinomycetes which inhabit mushroom compost and is selected for its beneficial properties during Phase II. (See Chapter V).

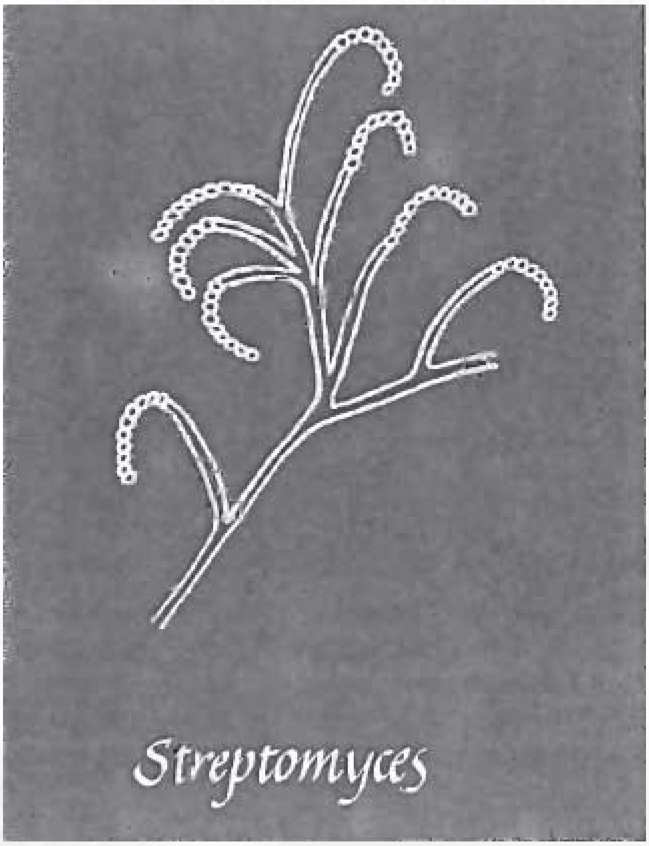


Figure 186 - Drawing of spore producing cells of *Streptomyces*.

Streptomyces griseus is the source of the antibiotic streptomycin, first discovered by Waksman in 1944. The autoclavable antibiotic gentamycin is derived from a genus closely allied to *Streptomyces*, the genus *Micromonospora*.

Comments: *Streptomyces* resemble both bacteria and fungi and are sometimes referred to as the "higher bacteria." *Streptomyces* differ from *Actinomyces* in that their spores are produced on an aerial chain-like structure and do not simply fragment from the hyphal network. Also, the filaments of *Streptomyces* frequently branch whereas those of *Actinomyces* do not. The hyphal filaments of *Streptomyces* are one fifth to one tenth as thick as that of true fungi.

Donoghue (1962) reported that a *Streptomyces* contaminant initiated fruitbodies in spawn of *Agaricus bisporus*, a species that does not normally form mushrooms on grain. Furthermore, he observed that mycelia associated with *Streptomyces* grew faster and more luxuriantly than those not infected with it. (For more information on the influence of bacteria on mycelial growth and fruiting, turn to Appendix II.)

See also *Actinomyces*.

For more information consult: Kurylowicz, W. *et al*., 1971 in "Atlas of Spores of Selected Genera and Species of *Streptomycetaceae*," University Park Press, Baltimore.

Alternaria (Black Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Dematiaceae*

Common Name: Black Mold; Gray Black Mold; Black Point.

Latin Root: From "alternus" which means alternating, in reference to the chains of alternating spores, which so characterize this genus.

Habitat & Frequency of Occurrence: Very common in nature, occasionally to frequently encountered in spawn production, and present in large numbers in household dust. *Alternaria* is infrequently seen on rye grain, and according to Bitner (1972), this contaminant is more prevalent on sorghum than on other grains. *Alternaria* is one of the major fungal saprophytes on grain, seeds, straw, leaves, rotting fruits and unsalted butter. In temperate climatic zones, it is more prevalent in the late summer and fall than at any other time.

Medium Through Which Contamination Is Spread: Air.

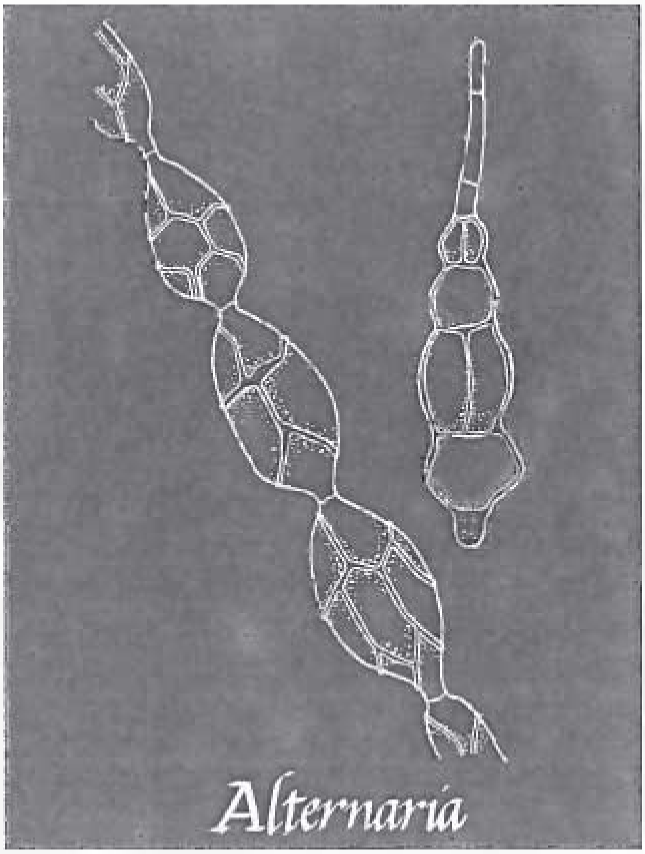

Figure 187 - Drawing of conidia typical of the genus *Alternaria*.

Measures of Control: Good hygienic habits; maintenance of a low dust level; and filtration of air through micron filters.

Macroscopic Appearance: A rapidly growing rich gray black to blackish mycelium. *Alternaria* first appears as scattered blackish spots in the spawn jars, soon spreading and overwhelming the mushroom mycelium. On agar, it resembles a black *Penicillium*-like mold.

Microscopic Characteristics: Vertically oriented lengths of cells (hyphae) emerging from a mat of mycelium that segregates into conidia, and which originated through pores at the apices of vertically oriented hyphae. Conidia (spores) are usually multicelled, sometimes two celled and large, measuring 20-100 x 6-30 microns.

History, Use and/or Medical Implications: Species in this genus causing allergies and other respiratory ailments in humans, particularly hay-fever. Because of their large size, *Alternaria* spores soon settle, falling at a rate of 3 millimeters/second in still **air**.

Comments: A black mold, occasional to common on enriched agar, easily separated from similarly colored molds by its unique conidia (spores). It has been claimed that *Alternaria* more frequently contaminates sorghum than rye although the authors can not corroborate this statement from their experiences.

See *Aspergillus* and *Cladosporium*.

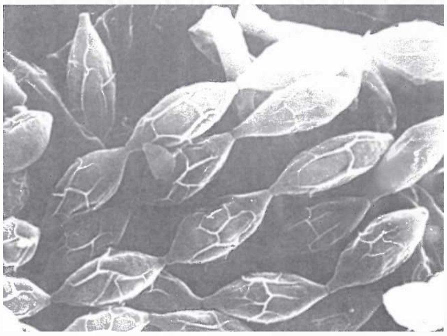

Figure 188 - Scanning electron micrograph of *Alternaria* conidia.

Aspergillus (Green Mold)

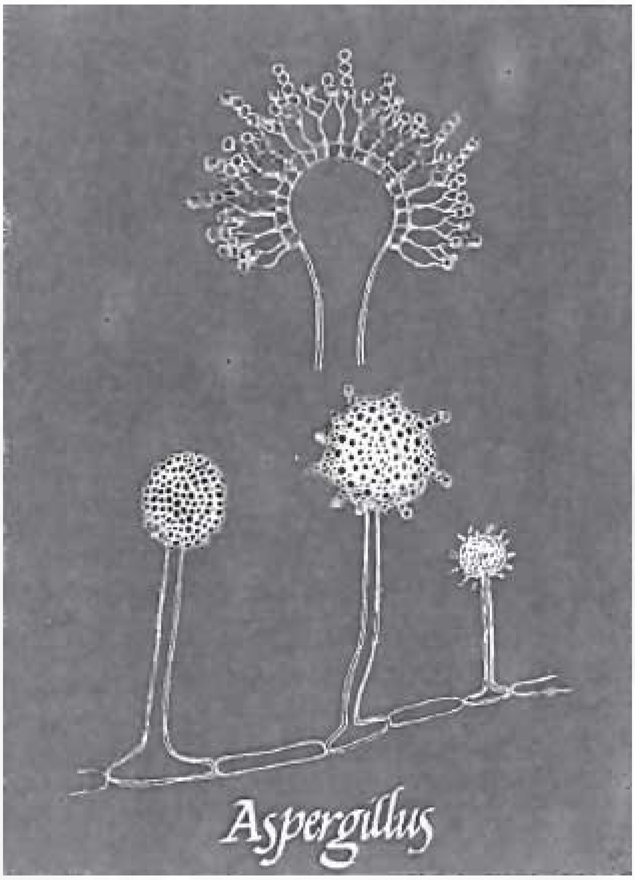

Figure 189 - Drawing of the characteristic sporulating structure of *Aspergillus*.

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Eurotiaceae*

Common Name: Green Mold; Yellow Mold; Black Mold.

Latin Root: From "aspergilliformis" which means brush-shaped in reference to the shape of the conidiophore.

Habitat & Frequency of Occurrence: Very common in agar and grain culture, and in compost making. Found on most any organic substrate, *Aspergillus* prefers a near neutral to slightly basic pH. Well used wooden trays and shelves for holding compost are frequent habitats for this contaminant in the growing house.

Medium Through Which Contamination Is Spread: Air.

Measures of Control: Good hygienic practices; removing supportive substrates, especially food residues and spent compost; and filtration of air through micron filters.

Macroscopic Appearance: Species range in color from yellow to green to black. Most frequently, *Aspergillus* species are greenish and similar to *Penicillium*. *Aspergillus niger*, as its name implies, is black; *Aspergillus flavus* is yellow; *Aspergillus clavatus* is blue-green; *Aspergillus fumigatus* is grayish green; and *Aspergillus veriscolor* exhibits a variety of colors (greenish to pinkish to yellowish). These molds, like many others, change in color and appearance according to the medium on which they occur. Several species are thermophilic.

Microscopic Characteristics: Sporulating structure tall, unbranched, stalk-like, supporting at its apex a spherical head to which linearly arranged chains of single celled spores (conidia), measuring 3-5 microns, are attached.

History, Use and/or Medical Implications: Some species toxic. *Aspergillus flavus*, a yellow to yellowish green species, produces the deadly aflatoxins. *A. flavus* attacks cottonseed meals, peanuts and other seeds high in oil that have been stored in hot, damp environments. Of all the biologically produced toxins, the alfatoxins are the most potent hepatacarcinogens yet found. The toxicity of this species was largely unknown until, in 1960, 100,000 turkeys mysteriously died from an outbreak of this disease in Great Britain.

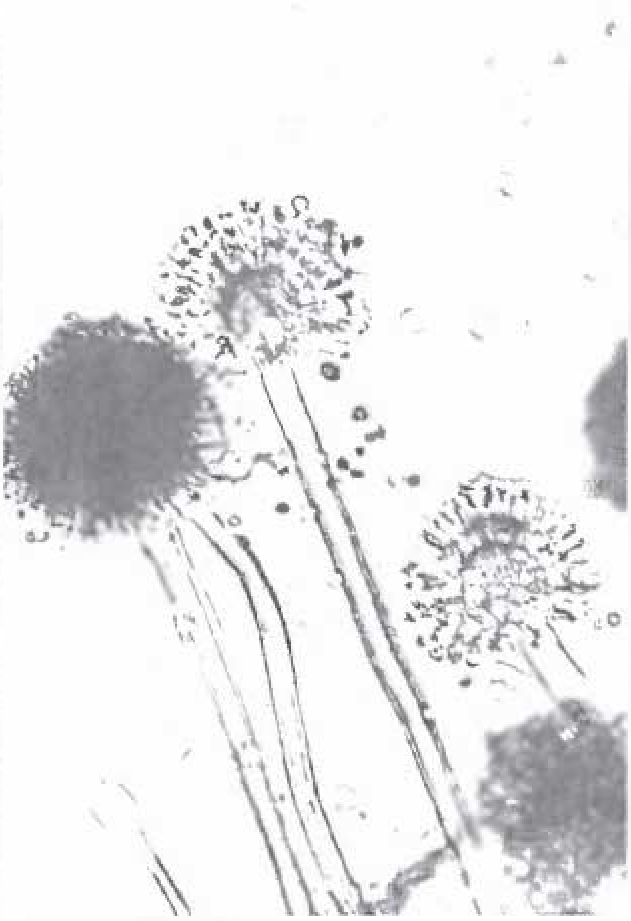

Figure 190 - *Aspergillus* species as seen through a light microscope.

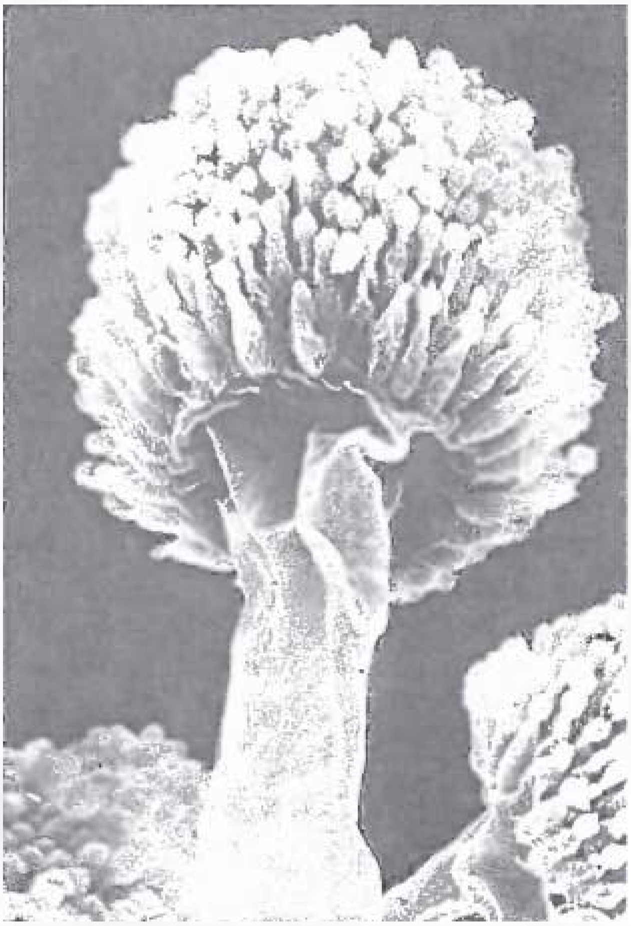

Figure 191 - Scanning electron micrograph of sporulating *Aspergillus*.

Since *A. flavus* grows on practically all types of grain, this species is of serious concern to mushroom spawn producers. Careful handling of any molds, particulary those of the genus *Aspergillus*, should be a primary responsibility of all managers and workers in mushroom farms. Aflatoxins are not, however, taken up in the fruitbodies when contaminated spawn or cottonseed meal is used to supplement a compost.

Aspergillus fumigatus and *Aspergillus niger*, two thermotolerant mesophiles, are also pathogenic to humans in concentrated quantities. The affliction is called aspergilliosis or "Mushroom Worker's Lung Disease". Spent compost is the most frequent source of *Aspergillus fumigatus*.

Aspergillus niger, the common black mold, has been cultured commercially for its ability to synthesize citric acid and gluconic acid from a simple sucrose enriched solution. In the past, citric acid was extracted from lemon juice; now it is made more profitably from this fungus.

Comments: This is a dangerous genus. Since one can encounters *Aspergillus flavus*, *A. niger*, *A. fumigatus* in the course of mushroom culture, precautionary steps should be undertaken to minimize exposure to these toxic contaminants.

Aspergillus candidus is a cream colored mold whose colonization of the grain results in a sharp escalation of the spawn temperature.

See also *Penicillium*. For further information consult "The Genus *Aspergillus*" by Raper and Fennel, a monograph in which 132 species were recognized. Presently, more than 200 species are known.

See Color Photograph 21.

Botrytis (Brown Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Name: Brown Mold.

Latin Root: From "botry" meaning bunch, as in a bunch of grapes, which the clusters of spores resemble.

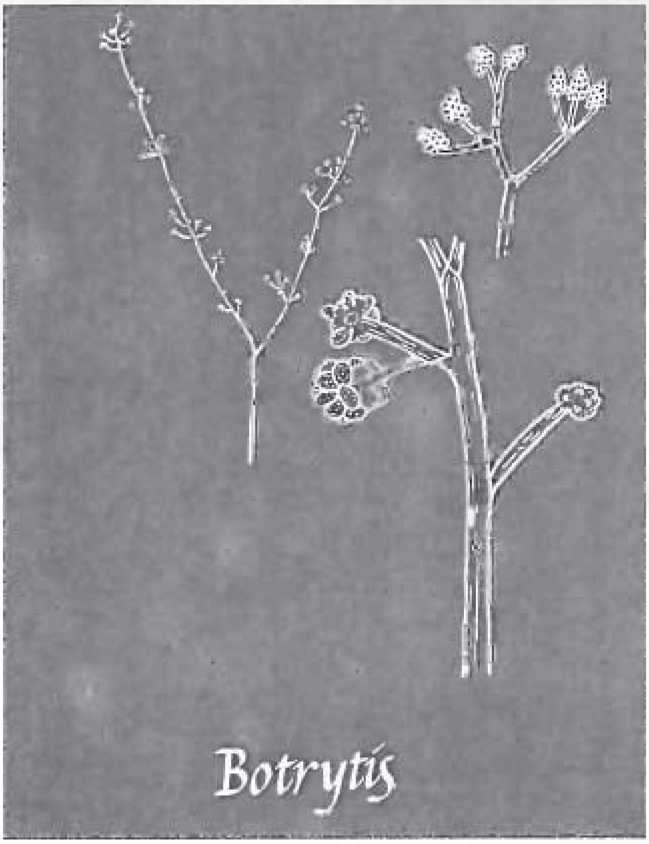

Figure 192 - Drawing of sporulating structure and spores (conidia) characteristic of *Botrytis*.

Habitat & Frequency of Occurrence: Common, most frequently seen on the casing soil where it prefers a mixture high in woody tissue; thriving in an environment of high humidity and moderate temperature. *Botrytis* often occurs on woodwork where moisture has condensed. It is less frequently seen on compost.

Medium Through Which Contamination Is Spread: Air; soil; and damp wood.

Measures of Control: Use of clean casing soils; removal and isolation of contaminated trays which are then thoroughly steam cleaned; positive pressurization of the growing room; and adherence to a strict schedule of hygiene to prevent this mold from spreading.

Macroscopic Appearance: White at first, especially along the margins, soon gray, fast growing, aerial, then dull golden brown to cinnamon brown as spores mature, spreading from casing soil to woodwork and vice versa. Spores become easily airborne by the slightest drafts. Outbreaks last two weeks at most, and sometimes develop into the sexual stage indicated by the formation of cup-like fruitbodies.

Microscopic Characteristics: Conidiophores long, measuring 10-20 x 5-15 microns, simply but irregularly branched at the apex but not enlarged, and not *Verticilium*-like. Spores (conidia) are one celled, oval to oblong, clear to grayish, some more brightly colored.

History, Use and/or Medical Implications: Apparently inocuous; no toxic species known. *Botrytis cinerea* is a species highly valued for its timely attack on ripening grapes. This species decreases the grapes' acidify while increasing their sugar content. It gives the grapes a most desirable odor and flavor, making infected crops ideal for sauterne table wines. Consequently, winemakers have been experimenting with the deliberate inoculation of their vineyards with *B. cinerea* for more than a century.

Comments: If the compost overheats during spawn run or casing colonization, *Botrytis* flourishes. It is generally not considered to be a "problem" contaminant but looked upon as an "indicator" mold by mushroom growers. *Botrytis* is usually overwhelmed or contained by the mushroom mycelium, although severe outbreaks, if not checked in their growth, can be detrimental to yields. *Botrytis crystallina* or *Botrytis gemella* are probably the species most commonly encountered.

The taxonomy of the *Botrytis* species seen in mushroom culture is unresolved, and therefore placing these molds in the *Botrytis* complex avoids nomenclatural problems. *Botrytis* has a perfect stage as *Peziza ostracoderma*, one of the common cup fungi. Some authors consider the imperfect form to more properly be classified in the genus *Chromelosporium* (belonging to the species *C. fulva*). By whatever name, this frequently encountered brown mold is not regarded as a virulent competitor.

Papulospora byssina, the Brown Plaster Mold, is similar but can be distinguished from *Botrytis* by the powdery granules evident using a hand lens, and by the shape of the conidiophore as viewed through a microscope.

See Color Photograph 23.

Chaetomium (Olive Green Mold)

Class: *Ascomycetes*

Order: *Sphaeriales*

Family: *Chaetomiaceae*

Common Name: The Olive Green Mold.

Greek Root: Having the same root as the suffix "-chaeta" which means long hair.

Habitat & Frequency of Occurrence: Common on fresh manure; especially on compost that has been anaerobically pasteurized; refuse materials; straw; "leaf mold"; soils; plant debris; paper products; and cloth fabric. *Chaetomium* is a rare contaminant of grain and is infrequently seen in agar culture. A white species occurs on the casing layer.

Medium Through Which Contamination Is Spread: Air; soil; compost; and grain.

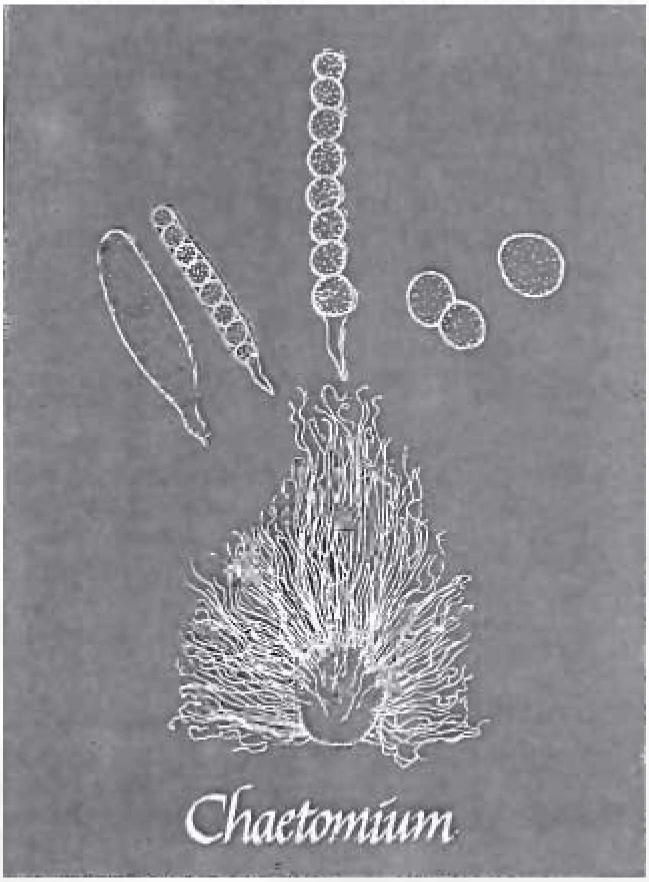

Figure 193 - Drawing of *Chaetomium* perithecium, asci and spores.

Measures of Control: General hygienic practices; aerobic pasteurization and Phase II. See Comments.

Macroscopic Appearance: Mycelia inconspicuous at first, grayish and in some species whitish, cottony, dense and aerial (as in "White Chaetomium"). Some forms become light brown, yellowish or with orangish hues when well developed. At maturity these molds can become dark green to olive green colored, and form scattered "burrs" which in fact are perithecia containing spores.

Microscopic Characteristics: Mycelium forming a thin walled envelope (a perithecium) from which unbranched hairs extend. A slit in the perithecium exposes sacs (asci) containing spores which are then liberated into the air. Spores are unicellular, darkly pigmented and can be ovoid, lemon-shaped or ellipsoid.

History, Use and/or Medical Implications: Secreting a compound called "chaetomin" that is toxic to Gram-positive bacteria and to mushrooms and other fungi.

Comments: *Chaetomium* inhibits mycelial growth through the toxins it produces as well as by competing with the mushroom mycelium for base nutrients.

Several true thermophiles are present in this genus. *C. thermophile* and its many varieties thrive in temperature zones from 82-136°F. Its spores are especially heat resistant. *Chaetomium* spores are killed at 140°F. for 6-16 hours or at 130°F. for 24-48 hours. *Chaetomium olivaceum* infests compost that has been exposed to high temperature, anaerobic conditions during Phase II. Compost prepared according to the Phase II program outlined in Chapter V practically eliminates the manifestation of *Chaetomium*. *Chaetomium globosum*, the most common species in this genus, attacks straw, compost and paper products and forms small burr-like colonies. Spores of this species are less resilient than those of its thermotolerant allies.

C. globosum is an occasional contaminant of agar and grain culture, and like *C. olivaceum* it is common on immature composts. White *Chaetomium* grows on the casing layer as a dense whitish mold. In general, *Chaetomium* is olive green while *Penicillium* and *Trichoderma* are generally blue green or forest green in color.

Chrysosporium (Yellow Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Aleuriosporae*

Common Names: The Yellow Mat Disease; Yellow Mold; Confetti Disease.

Latin Root: From "chryso-" meaning golden and "sporium" or spore.

Habitat & Frequency of Occurrence: Saprophytic, a common mold in soils, and endemic to composts prepared in direct contact with the ground. Although *Chrysosporium* species naturally inhabit the dung of most pastured animals and of chickens, today they are rarely seen in finished mushroom composts with the development of modern composting methods.

Medium Through Which Contamination Is Spread: Air; soil; and dung.

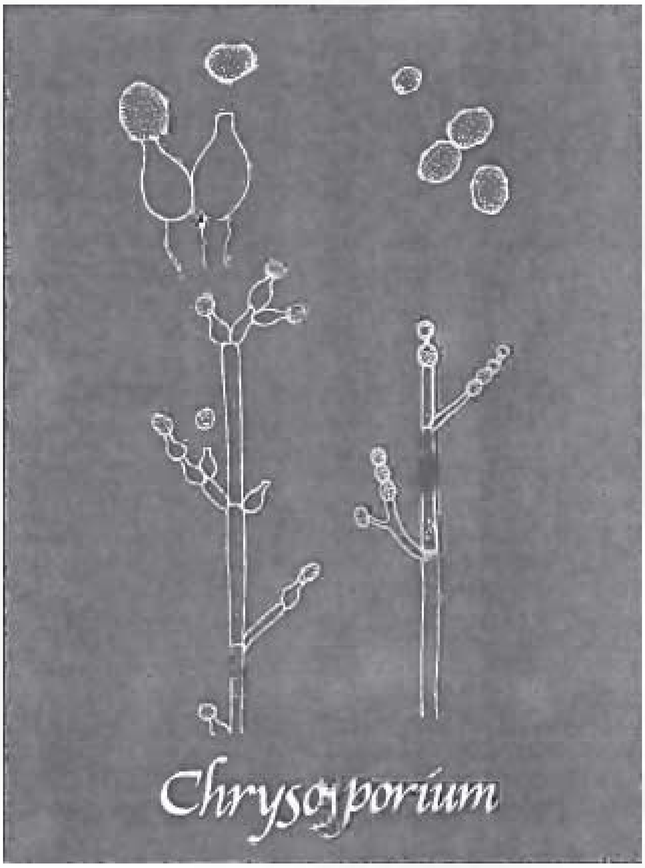

Figure 194 - Drawing of the sporulating structure typical of *Chrysosporium luteum*, the cause of Yellow Mat Disease.

Measures of Control: Concrete surface used for composting; isolation of mushroom compost from areas where untreated soils and raw dung are being stored; and filtration of air during Phase II. If *Chrysosporium* occurs before or at the time of casing, salt or a similar alkaline buffer can be applied to limit the spread of infection.

Macroscopic Appearance: Whitish at first, soon yellowish towards the center and maybe yellowish overall in color, forming a "corky" layer of tissue between the infected compost and the casing soil, and inhibiting fruitbody formation.

Microscopic Characteristics: Conidiophores poorly developed, relatively undifferentiated, irregularly branched, vertically oriented, for the most part resembling and associated with the vegetative mycelium. Clear, unicellular and often ornamented spores (conidia) develop terminally, either in short chains or singularly, and measure 3-5 x 4-7 microns.

History, Use and/or Medical Implications: The genus in general does not host many pathogenic species. One species of special concern is *Chrysosporium dermatidis* and allies, a mold causing a skin disease in humans.

Comments: *Chrysosporium* is an indicator mold whose presence can be traced to compost prepared on soil. Yellow mat disease is caused by *Chrysosporium luteum*, a synonym of *Myceliopthora lutea*. Another species, *Chrysosporium sulphureum*, is known as Confetti, and is at first whitish, then yellowish towards the center. These molds were fairly common in *Agaricus* culture previous to 1940, when composts were prepared directly on soil. With the advent of concrete composting wharfs, they have all but disappeared. According to Atkins (1974), this contaminant is more frequent in cave culture because of the use of ridge beds made directly on the floor of the cave. *Chrysosporium* is usually not detected until the first break and retards subsequent flushes. Moderate to severe outbreaks of either species can adversely affect yields.

Both raw and prepared composts can become infected with this mold. It is thought that the spores are introduced with the fresh air during the cool down period of the Phase II or from thermotolerant spores from within the compost itself. Species in this genus can be found on media of poor nutritional quality. They are generally not seen in spawn culture.

Chrysosporium can be grown for study on a hay infusion agar supplemented with sugar. Many Chrysosporia have sexual forms in the Gymnoascaceae, an ascomycetous family.

For further information see:
Carmichael, J.W., 1962 "*Chrysosporium* and some other Aleuriosporic Hyphomycetes".
van Oorshot, C.A.N., 1980 "A Revision of *Chrysosporium* and Allied Genera". Studies in Mycology No. 20. CBS Publication, Baarn, Nederland.

Cladosporium (Dark Green Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Dematicaeae*

Common Name: The Dark Green Mold.

Greek Root: From "klados" which means branched and "sporium" or spore. The name is in reference to the two celled spores produced on branches from the main body of the conidiophore.

Habitat & Frequency of Occurrence: *Cladosporium* is the most predominant genus of all the airborne contaminants. Its species can be both saprophytic and parasitic. At least three species infect grain spawn although they are not as common as the Aspergilli and Penicillia. Most species grow poorly on malt agar media. Many decompose paper products (several of the black molds on old books are Cladosporia), plant debris, vegetables and other higher plants.

Medium Through Which Contamination Is Spread: Air.

Measures of Control: Good hygienic practices; removal of supportive substrates; and filtration of air through micron filters.

Macroscopic Appearance: Species of *Cladosporium* causing problems in spawn production are typically dark green in color, often becoming blackish with age, and resemble the powdery *Penicillium* type molds.

Microscopic Characteristics: Conidia (spores) and conidiophores distinctly septate; darkly pigmented;

conidiophores vertically oriented and variously diverging; tall; forked into several terminal shoots at the apex from which the conidia arise in a chain-like fashion with the basal conidium being the oldest and the apical one being the youngest. Conidia are one or two celled, developing from the swollen ends of the conidiophores, and variously shaped (measuring from as small as 3-6 x 2-3.5 microns to as large as 15-20 x 6-8 microns). Some conidia are ovoid, lemon shaped and cylindrical, or are simply irregular in form and have peg-like markings ("scars") where adjacent spores have been attached.

History, Use and/or Medical Implications: Some species toxic. *Cladosporium carrionii* causes a severe skin infection that is usually associated with workers who suffer punctures from thorns or splinters.

Comments: In one study (Kramer, 1959) where agar plates were exposed daily to the outside air over a period of two years, *Cladosporium* spores were found to be the most numerically common of all airborne fungi, representing 45% of the totals tallied. Of these species, *C. cladosporioides* was the most frequently encountered. In contrast, *Penicillium* is the most common fungus indoors, undoubtedly due to the food habits of humans.

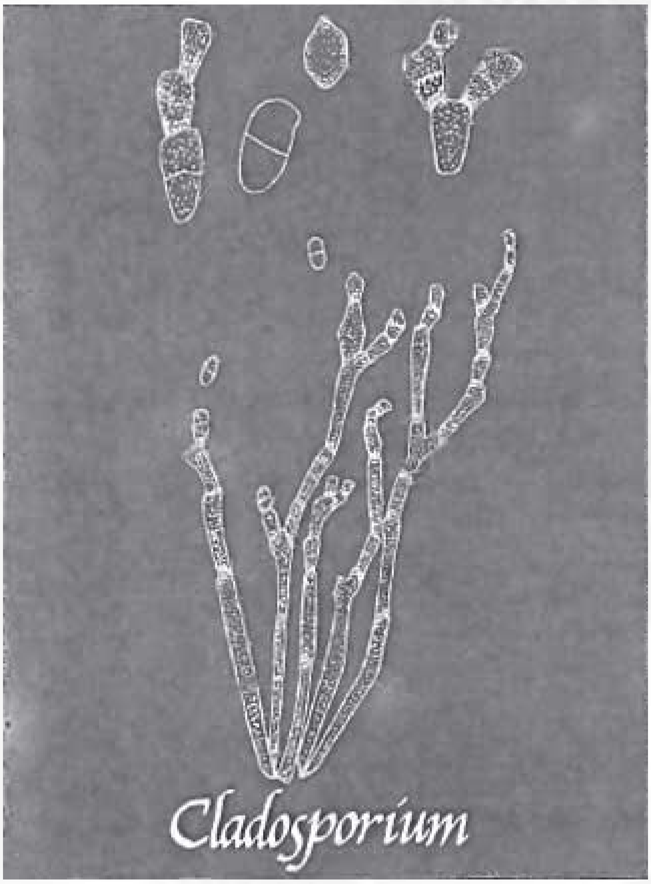

Figure 195 - Drawing of *Cladosporium*. Note the two celled conidia.

The dark conidiophore and the two celled conidia (spores) are the most distinguishing features of this genus. Over 160 species have been described. The perfect stage of a variety of *C. herbarum* Link ex Fr. is *Mycosphaerella tulasnei* Janz. *C. herbarum* has been isolated from timber, logs and wood pulp. *Cladosporium resinae* lives on creosote and other petroleum products, including the petroleum jelly used to "grease" the seals of pressure cookers. *C. fulvum* Cke. attacks tomato leaves, appearing as brown to violet colonies. Other molds similar in appearance are *Penicillium* and *Aspergillus*.

For more information see "*Contribution to the Knowledge of the Genus Cladosporium Link. ex Fr.*" by De Fries, 1952.

See Color Photograph 20.

Coprinus (Inky Cap)

Class: *Basidiomycetes*

Order: *Agaricales*

Family: *Coprinaceae*

Common Name: Inky Cap.

Habitat and Frequency of Occurrence: Frequent to common on compost and/or decomposing straw.

Medium Through Which Contamination Is Spread: Primarily air; secondarily through materials used in compost preparation.

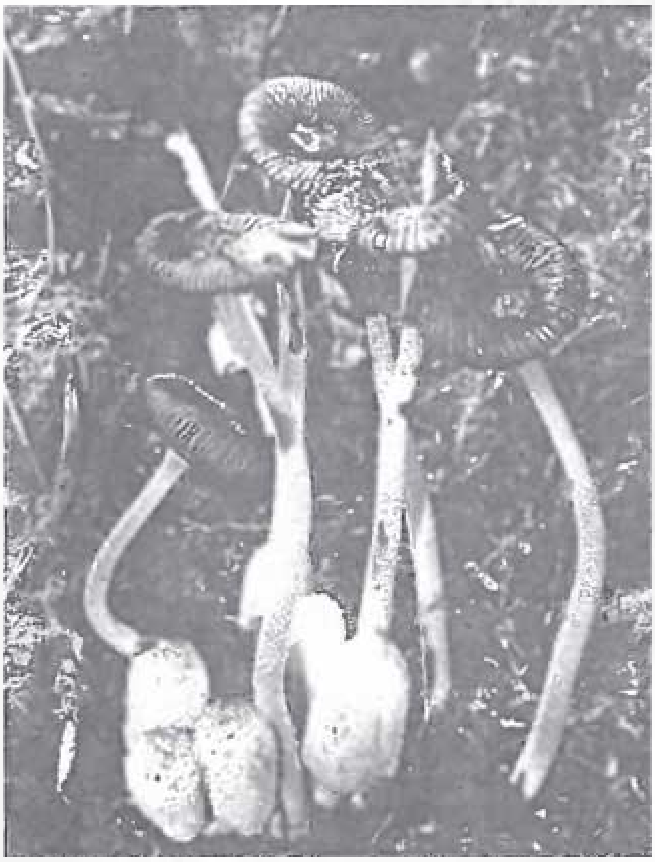

Figure 196 - *Coprinus*, the Inky Cap, on horse manure.

Measures of Control: Proper Phase I and Phase II management, especially full term pasteurization; reduction of ammonia and water in finished compost; and homogenous consistency of compost structure (avoidance of densely compacted zones).

Macroscopic Appearance: Appearing as a fast growing whitish mycelium, typically fine and lacking rhizomorphs, soon knotting into small ovoid primordia that quickly enlarge into a whitish mushroom with a long fragile stem and oblong cap. The cap soon disintegrates into a black inky liquid with spore maturity.

Microscopic Characteristics: Smooth, elliptical spores produced on club-shaped cells called basidia. Hyphae often have clamp connections joining adjacent cells.

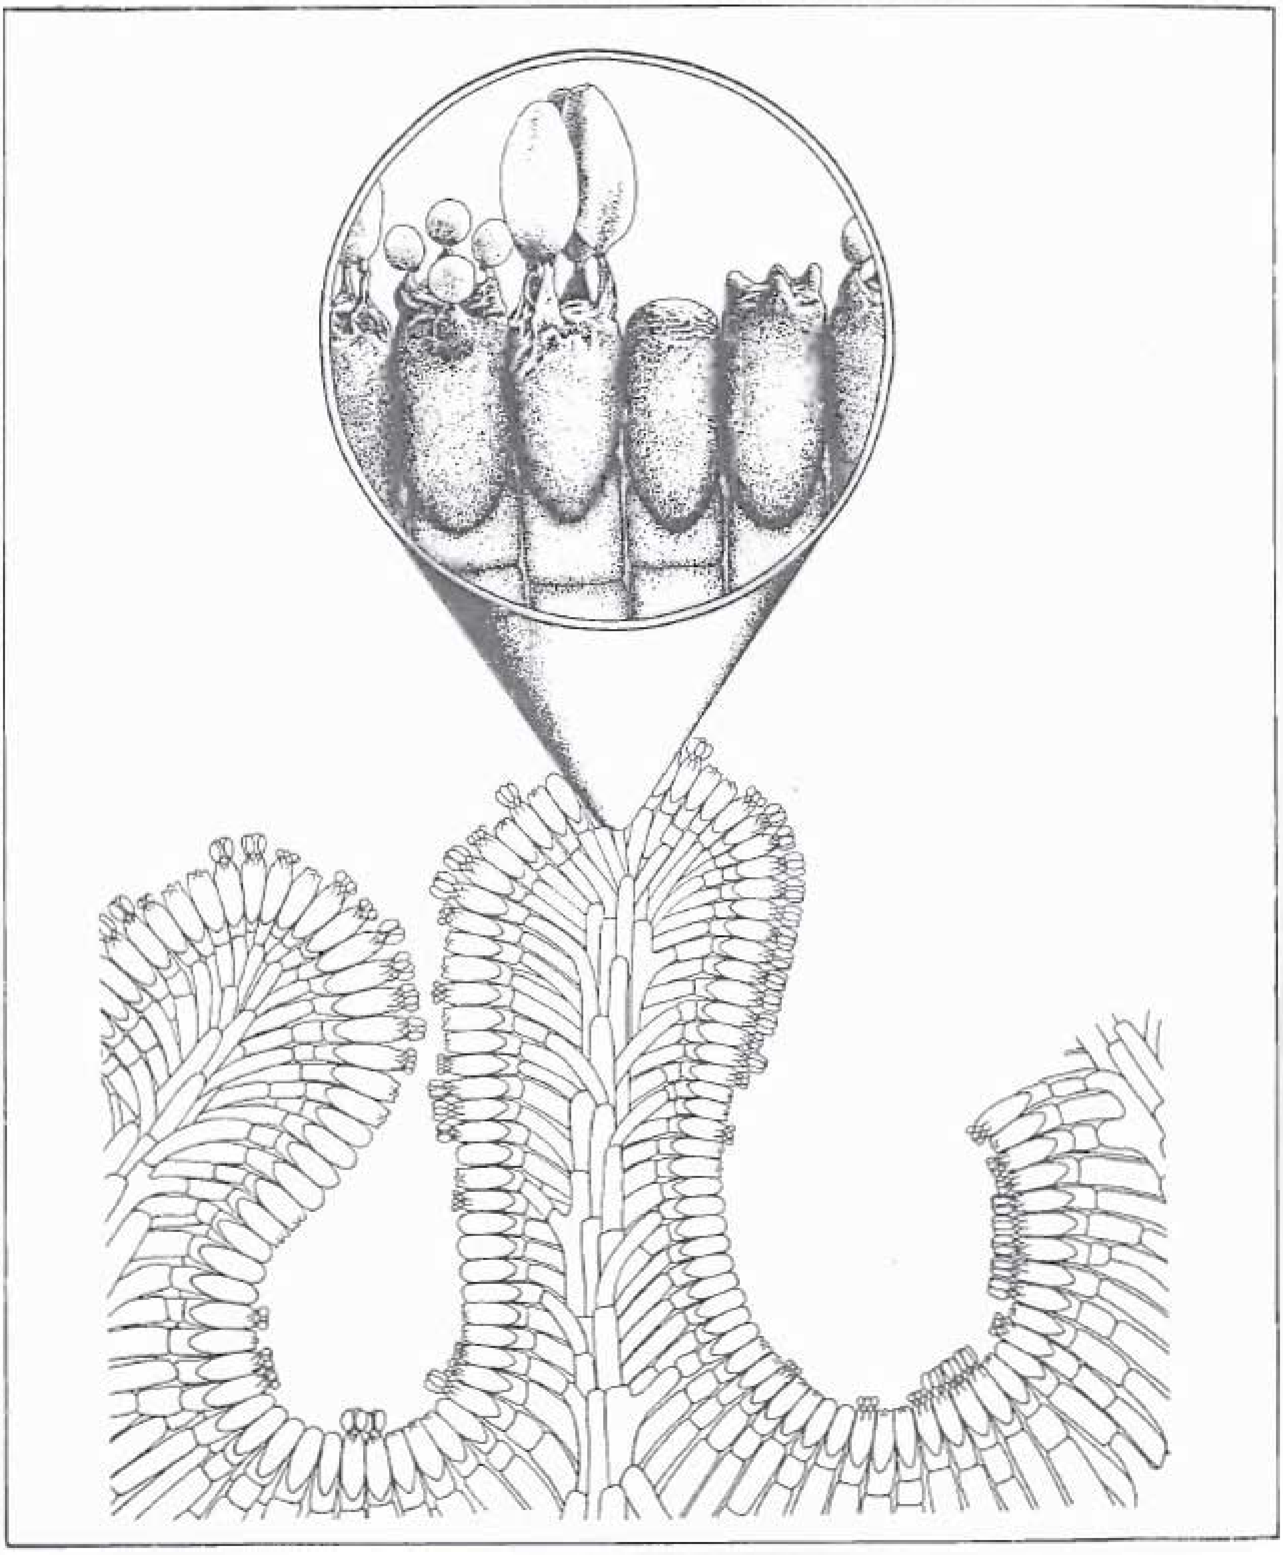

Figure 197 - Drawing of gill cross section with basidia and spores of *Coprinus*.

History, Use and/or Medical Implications: *Coprinus* species are noted for both their edibility and toxicity. *Coprinus comatus*, the Shaggy Mane, is a popular edible and choice species that is cultivated. (See the growing parameter outline for that species). *Coprinus atrementarius* has been reported by Atkins (1973) to be a competitor to the commercial cultivation of *Agaricus*, occurring in under-composted straw/manure. This species also causes severe nausea and other unpleasant symptoms if alcohol is consumed within twenty fours of ingestion. Jonsson *et al*. (1979) reported marked reduction in sperm counts in rats treated with coprine, the same compound responsible for the above described symptoms.

Comments: *Coprinus* spores are noted for their heat resistance and often survive the composting process. Although not considered a dangerous competitor, species in this genus are common in the piles of beginning compost makers. If this species occurs during spawn run or at cropping, it is an indication of residual ammonia in the compost. Composts that have excessive ammonia concentrations, composts that have been over-watered or those that are not homogenous in their structure encourage *Coprinus* infestation.

The species known to contaminate manure/straw composts are: *Coprinus fimetarius*; *Coprinus atramentarius*; and *Coprinus niveus*. According to Kurtzman (1978), *Coprinus fimetarius* has potential value as a commercially cultivated mushroom. All the above mentioned species are ones seen in poorly prepared composts. Bitner (1972) noted that *Coprinus* is a contaminant of grain spawn, although rarely seen and present in only one of every hundred or so contaminated spawn jars.

Cryptococcus (Cream Colored Yeast)

Class: *Fungi Imperfecti*

Order: *Cryptococcales*

Family: *Cryptococcaceae*

Common Names: The Yellowish Brown Yeast; The Carcinogenic Yeast.

Greek Root: From "kryptos" meaning hidden and "kokkus" or berry, for the form of the conidia.

Habitat & Frequency of Occurrence: Ubiquitous and common. *Cryptococcus* species are mostly saprophytic on plant debris, in soils, cereal grains and on bird (pigeon or chicken) droppings.

Medium Through Which Contamination Is Spread: Air and pigeon and/or chicken wastes.

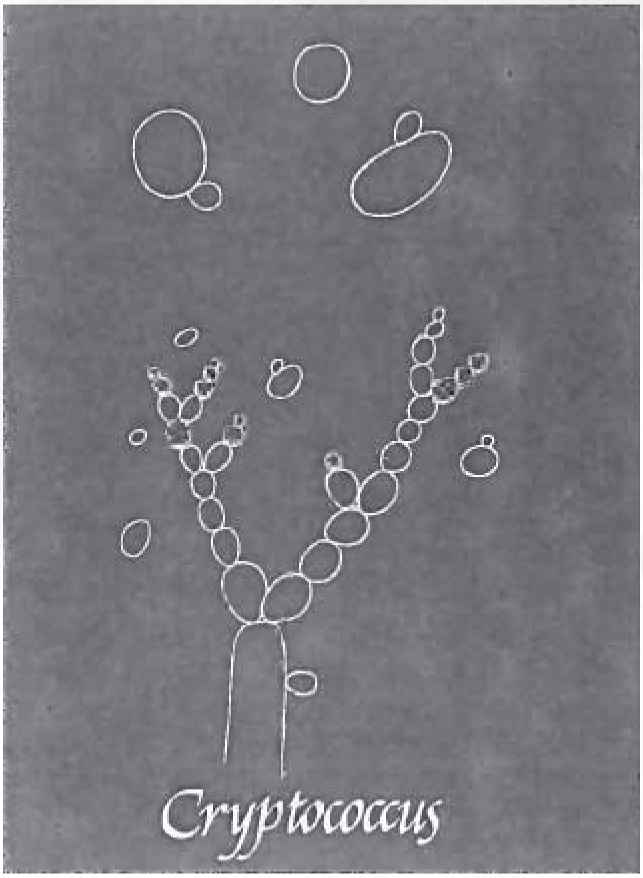

Figure 198 - Drawing of spore formation typical of *Cryptococcus* and many yeasts.

Measures of Control: Good hygienic practices; elimination of high humidity pockets; removal of supportive substrates; and filtration of air through micron filters.

Macroscopic Appearance: A spherical yeast not forming a pseudomycelium, encapsulated by a cream to brown colored mucus.

Microscopic Characteristics: Conidia (spores) vary in size, 4-20 microns in diameter; ovoid; reproducing through simple budding; not forming a true mycelium; and lacking a specialized spore-forming structure. In some species there can be a simple ascus (a "sack") enclosing a single spore. *Cryptococcus* species are Gram-positive.

History, Use and/or Medical Implications: A non-fermenting yeast with alliances to the Ascomycetes, *Cryptococcus neoformans* (Sanf.) Vuill. causes a deadly disease in animals and humans called cryptococcosis, otherwise known as "Torula meningitis" or "yeast meningitis". This yeast attacks and reproduces in the central nervous system, particularly in the brain and spinal fluid. Symptoms begin with a stiff neck and headache and end in total or partial blindness, paralysis, coma and respiratory failure. Less severe symptoms occur in other parts of the body, for which there is a better chance of recovery. It is believed that airborne spores are inhaled, entering the body via the lungs. This yeast thrives in droppings of pigeons and chickens.

Comments: *Cryptococcus* is a non-fermenting yeast with alliances to some Ascomycetes: *Torula* (Black Yeast), *Rhodotorula* (Red Yeast) and *Candida*.

In 1979 one of the containment buildings at the Tennessee Clinch River Breeder Reactor project had to be quarantined because of a massive outbreak of *Cryptococcus neoformans*.

Dactylium (Cobweb Mold)

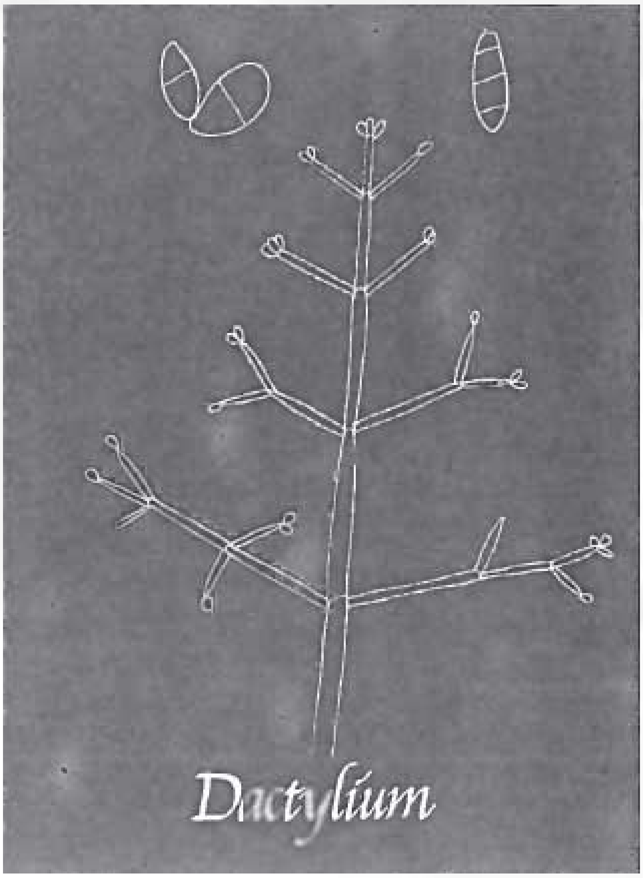

Figure 199 - Drawing of sporulating structure of *Dactylium*. Note multicelled conidia.

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Name: Cobweb Mold; Downy Mildew; Soft Mildew.

Greek Root: From "daktylos" meaning finger, in reference to the forking of the conidiophore.

Habitat & Frequency of Occurrence: Commonly seen on the casing soil or parasitizing the mushroom fruitbody.

Medium Through Which Contamination Is Spread: Air; casing soil; water and insects.

Measures of Control: Immediate isolation of parasitized fruitbodies from the growing environment; lowering of the relative humidity; and/or increasing air circulation. Carefully examine casing soil components for hygienic quality. Pasteurization of casing soil generally prevents its occurrence. Growth can be stopped by covering the cobweb mold with salt, baking soda or any highly alkaline compound.

Macroscopic Appearance: *Dactylium dendroides* Fr. is cobweb-like in appearance, first appearing as small scattered patches rapidly running over the surface of the casing soil, then overwhelming any and all mushrooms in its path. Afflicted mushrooms are covered with a fluffy down of delicate mycelium. This mold is initially grayish, sometimes whitish and can become pinkish tinged with age. When cut open, infected mushrooms are composed of rotting flesh and young buttons are reduced to formless masses of soft tissue.

Microscopic Characteristics: Conidia multicelled, usually composed of three or more connected cells. Conidia can occur singly or clustered, terminally positioned on the ends of branches which often fork in a *Verticillium*-like fashion and which originate from a major vertical shoot. Conidia are clear or slightly yellowish in color and measure 20 x 5 microns.

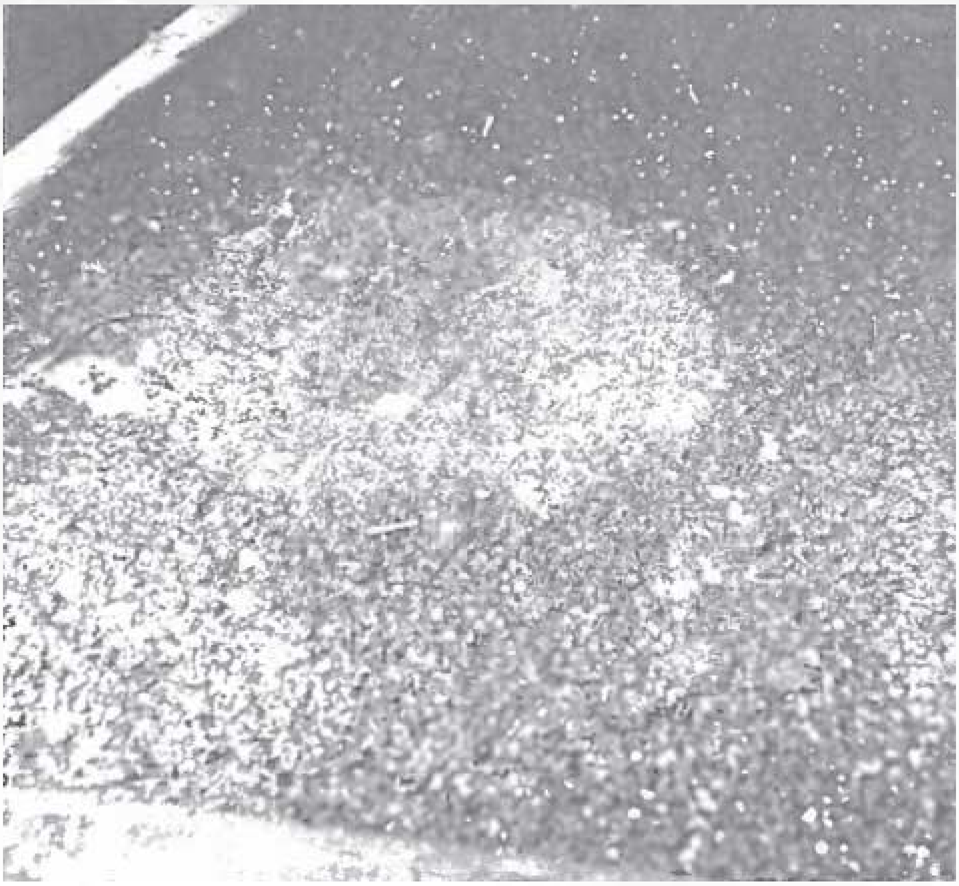

Figure 200 - Photograph of *Dactylium* running through casing layer.

History, Use and/or Medical Implications: None noted.

Comments: The Cobweb Mold is a fast growing, tenacious casing layer contaminant. Spores germinate upon contact with a mushroom, and soon envelope it with a soft mildewy mycelium.

Spores of *Dactylium dendroides* are killed when exposed to 115-122°F. for only ½ hour. (See Anderson, 1956). The genus *Dactylaria* is synonymous with *Dactylium*. Several species are known for their specialization in trapping nematodes by arranging their hyphae into loose coils. When one enters a loop, the hypha contract and traps the nematode.

Dactylium is the conidial form of *Hypomyces*, some species of which attack wild mushrooms, particularly *Lactarius*, *Russula*, *Agaricus*, *Amanita* and others. *Dactylium dendroides* is the asexual form of *Hypomyces rosellus*.

For more information consult: Lentz, P.L. 1966 "*Dactylaria in Relation to the Conservation of Dactylium*." Mycologia 58: 965-966.

Doratormyces (Black Whisker Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Stilbellaceae*

Common Names: The Black Whisker Mold; The Smoky Grey Mold.

Habitat and Frequency of Occurrence: A saprophyte, occasionally to frequently seen on the straws of an inadequately pasteurized compost; on wooden trays; rarely spreading to the casing soil; sometimes contaminating grain cultures; and seldom seen on agar. In nature *Doratomyces* is a major constituent of a soil's microflora.

Medium Through Which Contamination Is Spread: Primarily an airborne contaminant; secondarily transmitted through spent compost and left over debris.

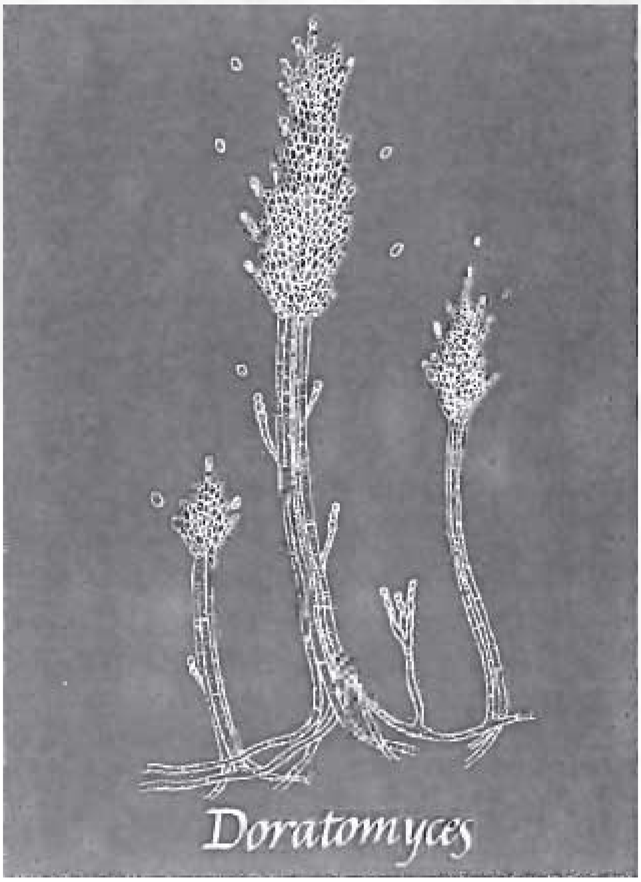

Figure 201 - Drawing of the sporulating structure of *Doratomyces* (*Stysanus*), the Black Whisker Mold.

Methods of Control: Air filtration; correct preparation and pasteurization of compost; and adherence to a strict schedule of hygiene in the laboratory and growing room. Whenever a room becomes contaminated with this fungus, a thorough cleaning is in order, particularly any trays that harbored this rapidly growing contaminant. The most common source of this fungus is spent compost or newly turned soils.

Macroscopic Appearance: A heavily sporulating grayish to blackish mold, permeating throughout the compost and when disrupted, emitting clouds of grayish spores. Contaminated regions of compost are more darkly colored and seem damper than uncontaminated regions. Its common name, the Black Whisker Mold, well describes the macroscopic appearance.

Microscopic Characteristics: Hyphae, conidiophores and conidia darkly pigmented. Conidiophores are single or aligned as compacted vertical assemblages of hyphae that variously diverge near the apex into short chains of dry, ovoid, unicellular spores in a *Penicillium*-like fashion.

History, Use and/or Medical Implications: Some species toxic. *Doratomyces* causes an asthma-like respiratory response (coughing, soreness of throat, nose bleeds) in those who are exposed to concentrations of its spores. Workers emptying spent compost from growing houses are the most likely to be inflicted with this illness.

Comments: *Doratomyces* is synonymous with *Stysanus*. *Doratomyces microsporus* (=*Stysanus microsporus*), the Smoky Grey Mold and *Doratomyces stemonitis* (=*Stysanus stemonitis*), the Black Whisker Mold, both contaminate the compost and emit huge quantities of spores when disturbed. A moderately strong competitor of mushroom mycelium, this mold grows well in undercomposted, poorly pasteurized and/or wet composts - composts poorly suited for good mushroom crops. If the compost bed heats up during spawn running and kills the grain inoculum, the grain kernels are soon attacked by this fungus which then resporulates and infects the compost. *Doratomyces* is an indicator mold, whose presence suggests poor composting, pasteurization or spawn running practices.

Epicoccum (Yellow Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Tuberculariaceae*

Common Name: Yellow Mold.

Habitat and Frequency of Occurrence: An occasional contaminant of grain culture. Species in this genus are decomposers of wood, leaves and stems of plants, playing an important role in the soil community.

Medium Through Which Contamination Is Spread: Air; soil; and grain.

Methods of Control: Isolation of contaminated cultures; careful screening of grain used for inoculum; and sufficient steam permeation of grain during sterilization.

Macroscopic Appearance: Species in this genus are variously pigmented. In grain culture, *Epicoccum* is distinguished by its bright yellowish orange to pinkish orange color and is often associated with a yellowish fluid which it apparently exudes. Its mycelium appears as dense zones within which blackish spores are formed. On most agar media, *Epicoccum* is slow growing and whitish. Outside the laboratory, *Epicoccum* can be found on leaves and twigs, forming small black dot colonies.

Microscopic Characteristics: Conidiophores compact, short and radiating from cushion shaped cells called "sporodochia" and from which dark, one celled, round spores (conidia) arise or with which they are associated. The conidia are typically reticulated or ornamented with small spine-like projections, measuring (5) 15-25 (50) microns. These reticulated conidia appear to be composed of several tightly interconnected cells.

History, Use and/or Medical Implications: None noted.

Comments: Not strongly inhibitory to mushroom mycelium. This mold can, however, spoil spawn. In grain culture, fruitings still develop in containers that are partially contaminated with this mold.

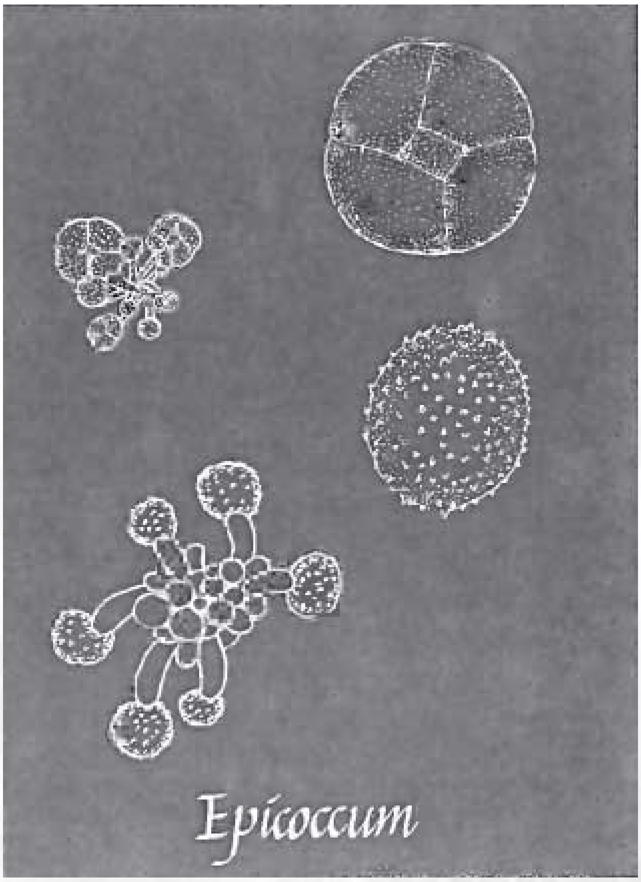

Figure 202 - Drawing of cushion shaped sporulating structure typical of *Epicoccum*, a yellow mold.

Epicoccum oryzae attacks rice, causing lesions that are pinkish to reddish in coloration. Another *Epicoccum* species was reported by Bitner (1972) to be the most common mold attacking sorghum spawn, comprising nearly 30% of all contaminated cultures. On the other hand, it represented only 5% of the contaminants on rye. The frequency with which this contaminant occurs varies substantially.

For more information: M.B. Schol-Schwartz (1957), "*The Genus Epicoccum (Link.)*."

Fusarium

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Tubericulariaceae*

Common Names: The Brightly Colored Contaminant; Damping Off Disease; or Yellow Rain Mold.

Greek Root: Having the same root as "fusiform", meaning to be swollen in the center and narrowing towards the ends, in reference to the distinctive shape of the conidia.

Habitat & Frequency of Occurrence: Commonly encountered in spawn production and in agar culture. A natural inhabitant of grains (rye, wheat, barley, rice), *Fusaria* also are found in soils, on living and decaying plants and on decomposing textiles and paper.

Medium Through Which Contamination Is Spread: Air; grain; and casing soil.

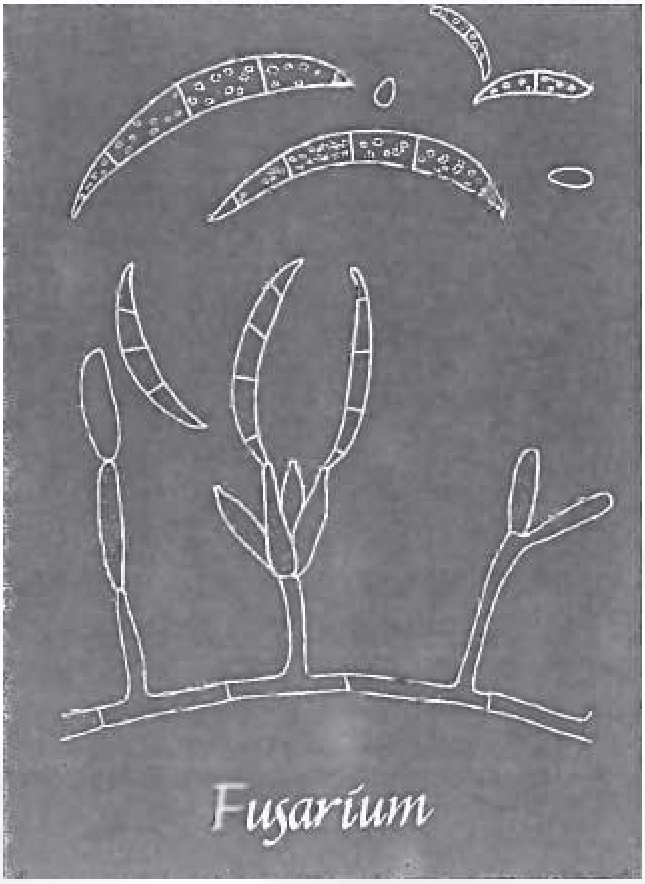

Figure 203 - Drawing of simple sporulating structure typical of the genus *Fusarium*.

Measures of Control: Sufficient sterilization of grain; isolation and proper disposal of contaminated cultures. General hygienic practices and air filtration prevent this contaminant. Increasing ventilation while simultaneously decreasing humidify hinders the proliferation of this potentially dangerous contaminant.

Macroscopic Appearance: Appearing as an extensive, fast growing, and whitish cottony mycelium which can remain whitish or, as in most cases, becomes brightly pigmented. *Fusarium* species most frequently seen on grain are shades of pink, purple or yellow.

Microscopic Characteristics: Conidia generally sickle shaped; multicelled; septate (segmented); and developing from short, simple and irregularly branched conidiophores that arise from a cottony mycelial mat. Conidia are canoe, crescent or sickle shaped, with the basal end notched or niched. Some pear shaped, single celled microconidia are also produced.

History, Use and/or Medical Implications: Some *Fusarium* species are highly toxic. Throughout history *Fusarium* molds have been responsible for diseases of major proportions. Usually the cause has been bread made from poorly wintered grain. In regions of the Ukraine, Eastern Siberia and central Asia, the disease caused by this fungus was called "Staggering Sickness" for its symptoms of vertigo, bleeding, headaches, chills and nausea. In a Soviet province during World War II, a single outbreak caused the deaths of nearly 30,000 people.

Given their past, it is not surprising to learn these fungi have attracted the interest of the military. In 1980 and 1981, the United States government accused the Soviet Union of embarking on a new variation of biochemical warfare when leaf and twig specimens allegedly brought from the war zones of Cambodia and Afghanistan were found laden with high concentrations of toxins from these species. The most prominent species producing these toxins (the trichothecenes) are *Fusarium sporothrichiodes* and *Fusarium poae*, although other *Fusaria* are also virulent. *Fusarium poae* is a violet colored contaminant occasionally encountered in mushroom spawn production. See Comments below.

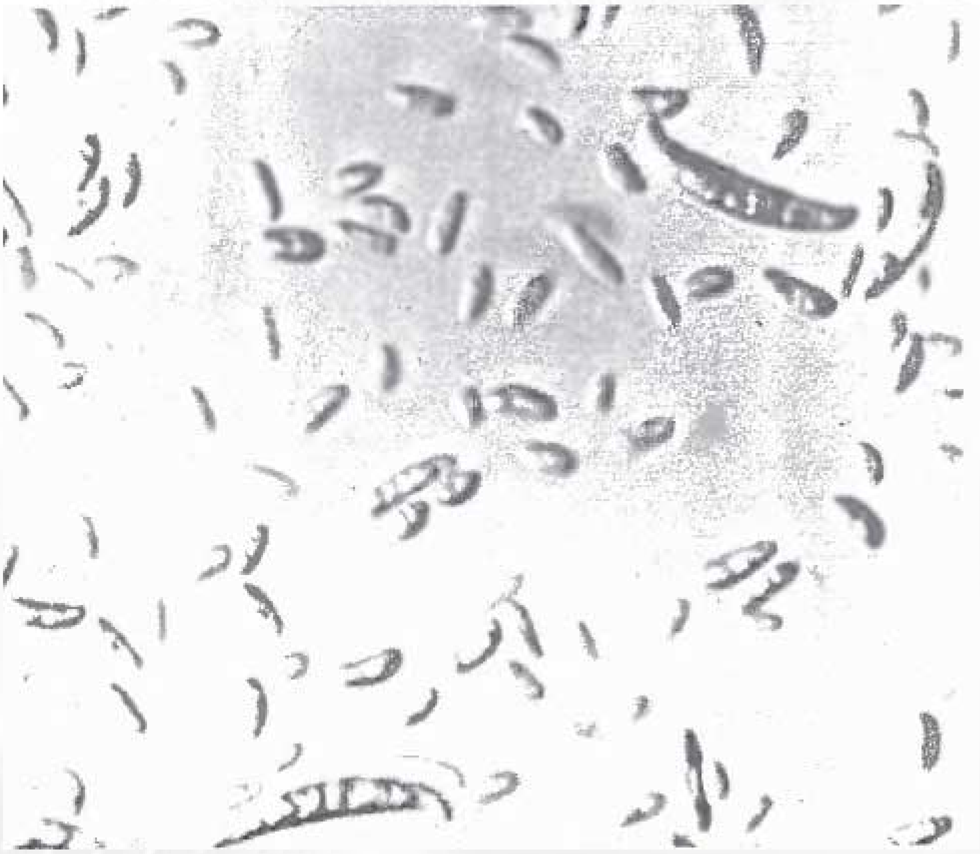

Figure 204 - Light micrograph of *Fusarium* conidia. Note multicelled macroconidia and single celled microconidia.

Because there are many toxic species in the genus, one should treat all *Fusarium* contaminants with due caution.

Comments: *Fusarium* may be a cause of mushroom "aborts". In one study, English researchers correlated high levels of *Fusarium* to this phenomenon. Even a moderate infestation by this contaminant inhibits mushroom growth. Mushrooms afflicted with this disease remain small and often have disproportionately small caps and stems whose interiors are brownish. Wolfe (1937) was able to induce Damping Off Disease by first isolating *Fusaria* and then physically introducing it into the casing layer of a healthy bed.

Although not as commonly encountered as *Penicillium* or *Trichoderma*, *Fusarium* can wreak havoc in a sterile lab if not soon contained. Grain is the main source of *Fusarium* contamination in mushroom culture. Twenty-eight *Fusaria* have been identified from cereal grains, five of which have been isolated from contaminated mushroom spawn jars (see Pepper & Keisling, 1963). These are:

F. lateritium, a pinkish species.
F. avenaceum, a reddish species.
F. culmorum, a vivid yellowish red species.
F. poae, a violet colored species.
F. oxysporum, a red violet species.
F. sp., a fast growing whitish species.

Fusaria can cause severe mycosis and these molds must be treated with extreme caution. Grain contaminated with *Fusarium* should be sterilized before handling.

There are, undoubtedly, more toxic species than the literature presently indicates.
One of the first patents ever to be awarded to a living organism was given for *F. gramineraum*.

Seagrave, 5., 1981 "*Yellow Rain: A Test of Terror*" Seattle Post Intelligencer, September 27, B2.

Geotrichum (Lipstick Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Name: Lipstick Mold.

Latin Root: From "geo" meaning earth, and "trichum" meaning hairy, in reference to the character of the mycelial mat.

Habitat & Frequency of Occurrence: Generally a saprophyte although some forms act as parasites. *Geotrichum* species are extremely common in nature but infrequently encountered in mushroom compost - unless it has been prepared directly on soil. *Geotrichum* dwells in soils, cow dung, old straw, compost piles and rots some fruits and vegetables. In general, species of this genus are mesophilic thermophiles and are therefore sensitive to pasteurization temperatures.

Medium Through Which Contamination Is Spread: Air; soil; and from old straw and spent composts.

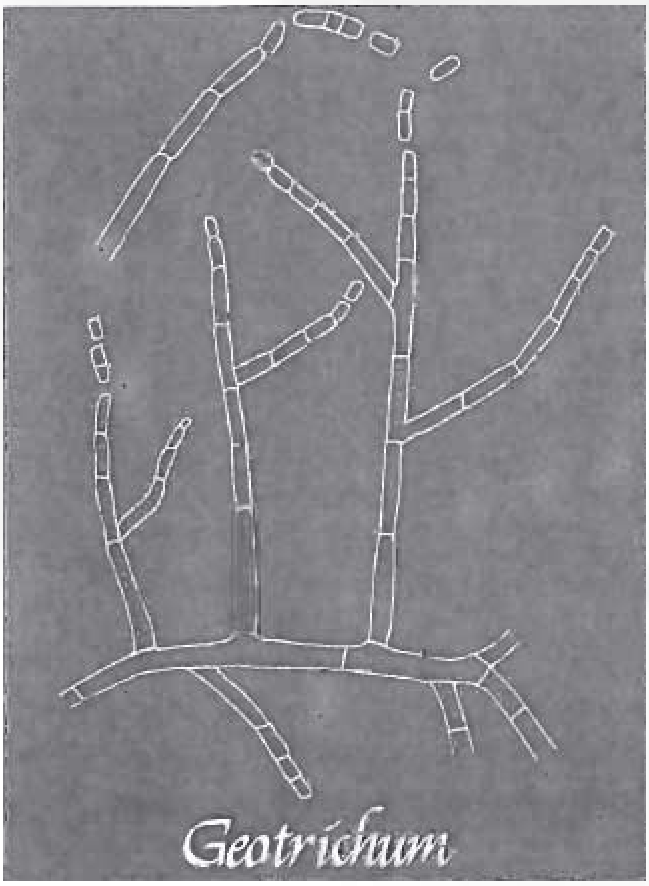

Figure 205 - Drawing of sporulating structure of *Geotrichum*, the Lipstick Mold, and its characteristically shaped conidia.

Measures of Control: Composting on a concrete surface; thorough pasteurization of compost and straw; and use of clean casing materials.

Macroscopic Appearance: Mycelium whitish at first, often faking on a "frosty" appearance and then forming whitish balls of mycelium. With age, the mycelium becomes pinkish and then reddish due to the maturation of spores. Older colonies of this fungus fade to a dull orange.

Microscopic Characteristics: Hyphae septate, in the form of extensive but random chains of cells, from which cylindrical conidial spores segment, measuring 5-10 x 3-6 microns. Conidiophores are simple and often indistinguishable from the mycelial network.

History, Use and/or Medical Implications: Few species toxic. *Geotrichum candidum* causes an oral, bronchial, pulmonary and/or intestinal disease known as geotrichosis that infects humans and other mammals.

Comments: Commonly encountered in agar plates made from a soil infusion; otherwise rarely encountered in sterile culture. An occasional contaminant of mushroom beds (compost), Lipstick Mold inhibits primordia formation and development. With the advent of concrete composting surfaces and peat based casings, this contaminant has been virtually eliminated from modern mushroom farms.

This fungus is closely allied to, if not synonymous with *Sporendonema purpurescens*.

For more information see:
Sinden, J.W., 1971 "*Ecological Control of Pathogens and Weed Molds in Mushroom Culture*" Annual Review of Phytopathology 9.
Carmichael, J.W., 1957 "*Geotrichum candidum*" Mycologia 49. pp. 820-830.

Humicola (Gray Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Series: *Aleuriosporae*

Common Name: Gray Mold.

Latin Root: From "humus" meaning soil and the suffix "cola" meaning dweller, inhabitant.

Habitat & Frequency of Occurrence: A rare contaminant of sterile culture. Thermophilic species are frequently seen in the second phase of composting, thriving in the 115-125 degree F. range. Naturally occurring on grains, straw, wood, soils and other organic matter high in cellulose.

Medium Through Which Contamination Is Spread: Air; soil; and grain.

Measures of Control: Thorough sterilization of grain and incubation of spawn at moderate temperatures. *Humicola* is a thermophile and thrives in elevated temperature zones. Since the presence of *Humicola* is considered beneficial to compost, no countermeasures are necessary if it occurs in that substrate.

Macroscopic Appearance: Mycelium on agar a fine to thick grayish to colorless mat, varying according to the media employed. On grain its mycelium is typically thick, colorless at first, soon gray and eventually dark gray with spore production. On compost, *Humicola* is an aerial, fluffy, whitish mycelium that is soon grayish with spore maturity. It is frequently seen at or near the surface where temperatures are 115-125°F.

Microscopic Characteristics: Conidia one celled, typically globose, brownish colored and often sculptured. Conidiophores are also darkly pigmented, simple, undeveloped and similar to the mycelium or at times having short lateral branches at whose swollen apices a single conidium is borne. Alternately, short chains of microconidia formed by flask shaped cells (phialides) can occur.

History, Use and/or Medical Implications: Selected for use in compost nutrient conversion during Phase II of composting.

Comments: *Humicola* plays an important role in the conversion of the nitrogen in ammonia into protein rich compounds that the mushroom mycelia can digest. In this regard *Humicola* is an ally to the compost preparation process. Compost makers have long believed that *Humicola nigrescens* should be encouraged to grow during Phase II because a compost colonized with it resulted in higher yields. *Humicola* prospers in the 115-125 (130)°F. range. When the finished compost has been brought down to spawning temperature, these fungi are rendered inactive, and are then consumed by the mushroom mycelium.

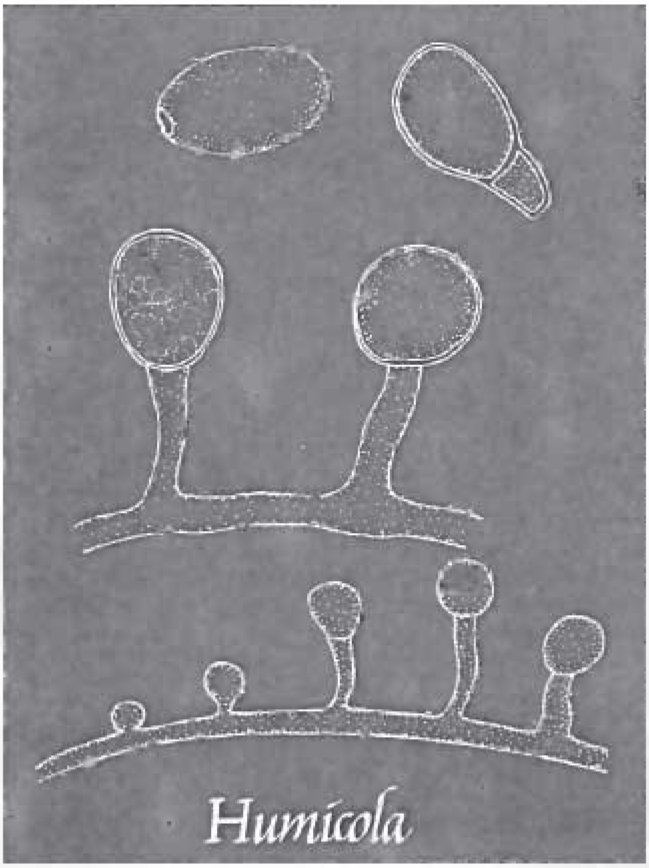

Figure 206 - Drawing of sporulating structure and spores (conidia) of *Humicola*.

On grain *Humicola grisea* is most frequently seen; on horse manure/straw composts *Humicola nigrescens* is most commonly encountered. *Humicola* that occurs during cropping does not seem to pose a serious threat to the overall crop.

Most species are mesophilic; some are thermophilic; and all are saprophytic. *Humicola* is not a problem contaminant.

See *Torula*, another thermophilic fungus beneficial to composting.

For more information consult: Bels-Koning, H.C., Gerrits, J.P.G., and Vaandrager, M.H. 1962. "*Some Fungi Appearing Towards the End of Composting*," Mushroom Science V.

Monilia (White Flour Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Names: White Mold; White Flour Mold; or Pink Mold

Latin Root: From "monile" or necklace for the chain-like arrangement of the mycelium and spore producing cells.

Habitat & Frequency of Occurrence: Relatively common on agar; grain; compost and casing soil.

Medium Through Which Contamination Is Spread: Primarily air; soil; and grain.

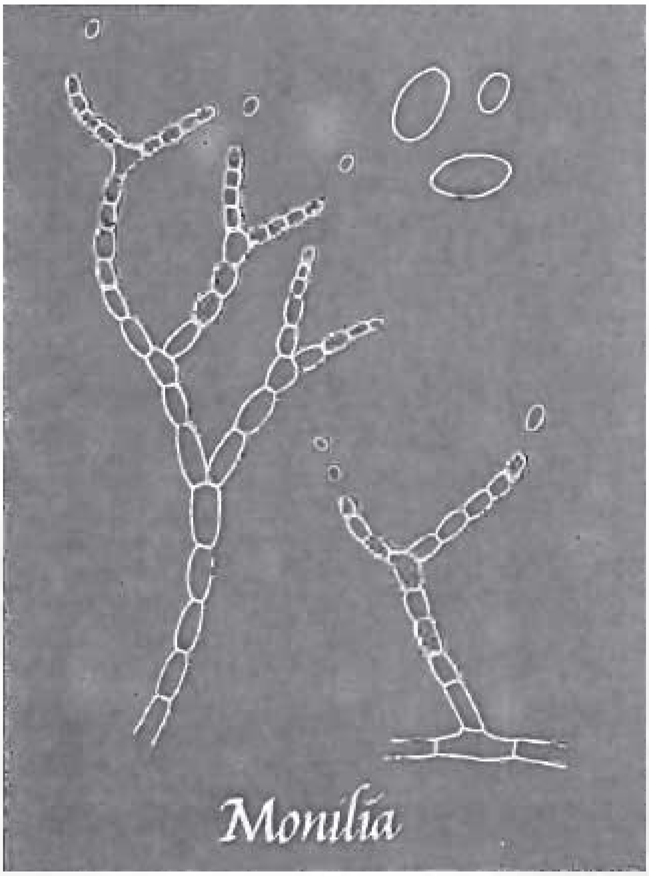

Figure 207 - Drawing of chain-like structure by which *Monilia* produces conidia (spores).

Measures of Control: Air filtration; maintenance of good hygiene in laboratory and growing room, especially in the isolation and removal of contaminated cultures and debris from previous croppings. Thorough sterilization of grain and pasteurization of casing reduces the possibility of contamination arising from within. This contaminant is believed to be externally introduced through airborne spores. High efficiency filters prevent *Monilia* spores from contaminating spawn and lessen the risk of contamination in the growing room.

Macroscopic Appearance: Represented by two mutable forms: the imperfect form *Monilia* is generally a fine powdery whitish mold; and the perfect form *Neurospora* is a rapid growing tenacious aerial mold that is pinkish with spore maturity. In grain both the whitish and the pinkish *Neurospora* are encountered. White *Monilia* has a remarkable resemblance to finely ground perlite and can easily be mistaken for it. On casing soil, the pink form is more common. Both are very rapid growing.

Microscopic Characteristics: Conidia unicellular; oval to lemon shaped; produced in large quantities on yeast-like chains with the terminal cells being the youngest and originating from a simple, septate mycelial network. Less frequently, conidial spores are produced singly. Conidiophores are extremely simple and similar to mycelium or absent altogether. Its mycelium is hyaline, white or gray colored while the conidia are tan, gray or most commonly pink in color.

History, Use and/or Medical Implications: Not known to be pathogenic. A disease known as moniliasis in medicine is actually caused by a related yeast-like fungus, *Candida*, and is more correctly termed candidiasis. *Candida* has been incorrectly called *Monilia* in medical mycology texts. Several genera share the same overall microscopic features and can be easily confused with *Monilia*. Indeed, *Monilia* is a pivotal genus amongst a constellation of genera. For the purposes of the home cultivator, all these forms might be more usefully called a "complex of genera".

Comments: *Monilia*'s perfect form is represented by *Neurospora* (see that genus) and either phenotype is largely determined by nutritional factors, particularly pH. *Monilia* can vary substantially in color on grain spawn: from a thick whitish mycelial mat to a powdery white, gray or pink colored mycelium. Perhaps the most devastating form is the whitish one for its resemblance to mushroom mycelium. Also seen in agar culture, the pink form is noted for its high aerial mycelium. It climbs the sides of Petri dishes. If not treated, this contaminant can be very difficult to eradicate. Complete cleaning of the laboratory is the only recourse. After a *Monilia* outbreak careful attention must be directed at reestablishing spawn integrity.

Monilia and *Neurospora* attack the mushroom beds and casing layers with rapid growing grayish mycelia that soon develop pinkish tones with spore maturity. Contamination by this fungus is usually traced to unclean casing or infected spawn.

Consult the genus *Neurospora*.

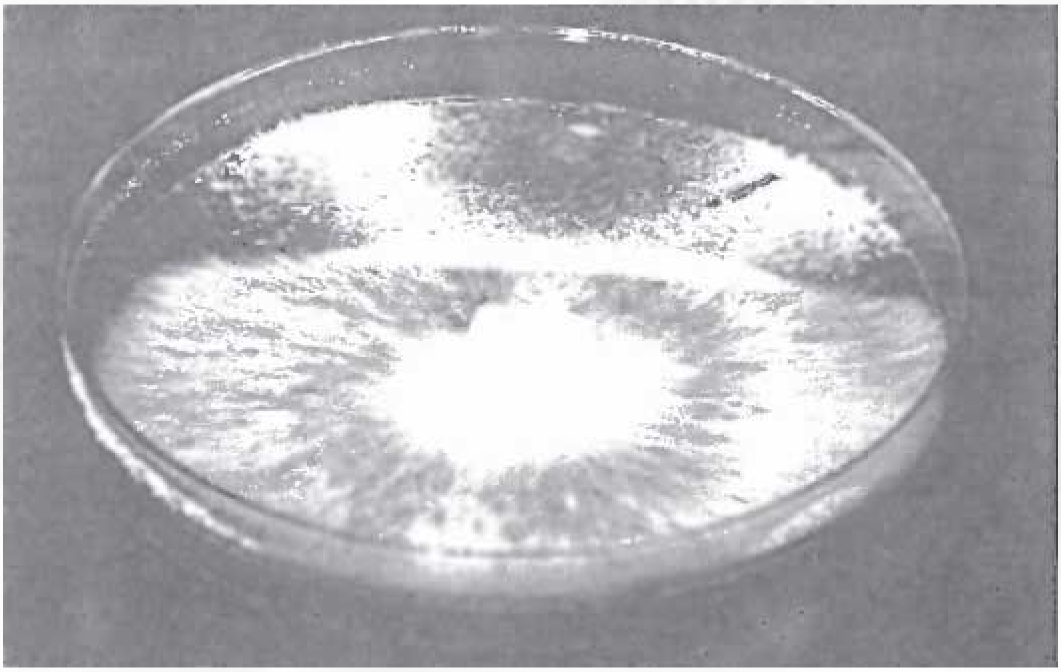

Figure 208 - *Monilia*-like mold on agar media with mushroom mycelium.

Mucor (Black Pin Mold)

Class: *Zygomycetes*

Order: *Mucorales*

Family: *Mucoraceae*

Common Names: the Black Pin Mold; the Black Bread Mold

Habitat & Frequency of Occurrence: A common saprophyte of stored grains; horse dung; old straw; mushroom composts; peat; soil; and plant debris. *Mucor* also rots textiles.

Medium Through Which Contamination Is Spread: Primarily air; secondarily grain and contaminated compost.

Measures of Control: Air filtration; sufficient sterilization of grain; and immediate removal and isolation of contaminated regions, 'spent' compost, aged mushrooms or cropping debris. Exercising general hygienic practices usually prevents this contaminant from becoming a problem.

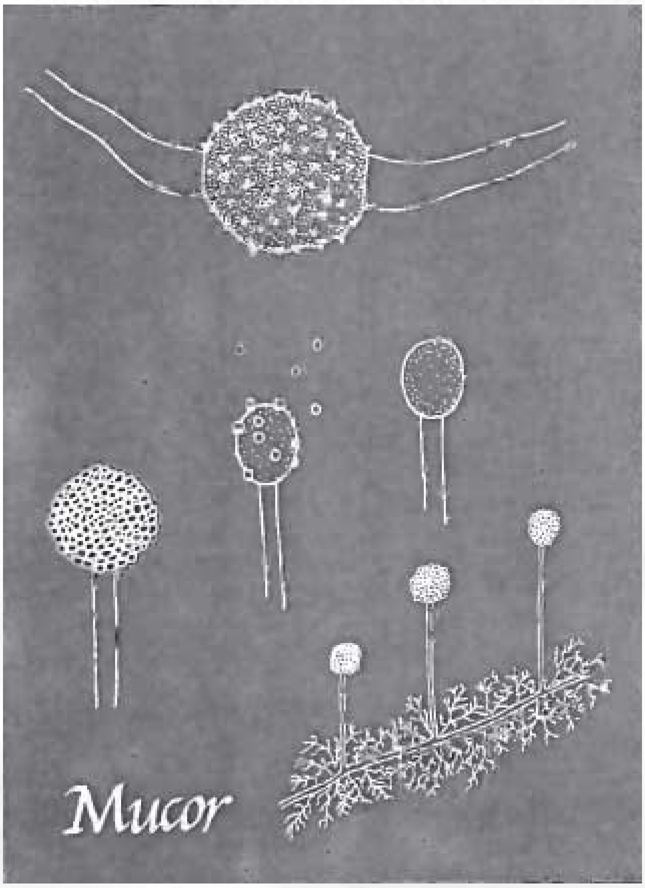

Figure 209 - Drawing of sporulating structure (sporangiophore) of *Mucor*.

Macroscopic Appearance: A fast growing fungus forming an interwoven dense mycelial mat, whitish at first, producing a stalk-like sporangiophore which is not swollen at the apex but is enveloped by spherical spore producing body. Soon becoming grayish and then blackish overall with spore production. When *Mucor* sporulates, it appears like a "forest of black headed pins". On malt agar, sporangiophores often do not form, making identification difficult.

Microscopic Characteristics: Tall sporangiophores arising singly from the mycelial mat, adorned with a spherical sporangium composed of many spores. Hyphae are non-septate (lacking distinct cell walls).

History, Use and/or Medical Implications: Some species toxic. *Mucor pusillus* and other mucuraceous fungi are the cause of a rare but deadly disease known as mucormycosis or phycomycosis. Although *Mucor* attacks open wounds, the outer ear and the lungs, it is not a primary parasite but one that takes advantage of poor health caused from other diseases. This disease and ones related to it are more prevalent in tropical and semitropical zones than in temperate regions. For more information on the pathogenic aspects of fungi in this group refer to the reference below.

Comments: A vigorous contaminant and seen at various times in spawn production, inhibiting and overwhelming the mushroom mycelium. On malt agar media *Mucor* is a fast growing, non-sporulating, cottony and whitish mycelial network competing with or overwhelming mushroom mycelium. *Mucor* mycelium is non-rhizomorphic and lacks the clamp connections that is characteristic of many mushroom mycelia.

If in doubt whether a whitish mycelium is *Mucor* or not, inoculate some bread with some mycelium covered kernels and incubate at a warm temperature. If the mold is *Mucor*, it will sporulate in a few days and be easy to identify.

The most frequently seen species of this genus are *Mucor racemosus* and *Mucor plumbeus*. *Mucor pusillus*, a true thermophile, thrives in the 68-131°F. (20-55°C.) range and is a major constituent in the microflora of compost piles. *Mucor* infected spawn, when inadvertently inoculated onto the mushroom compost, can result in the total contamination of the bed within a few days. Consult *Sepedonium*, a contaminant whose vegetative mycelia resembles the non-sporulating mycelium of *Mucor*. See also *Rhizopus*, a genus that differs from *Mucor* by its having a smaller sporangium receding from the "head" of the sporangiophore.

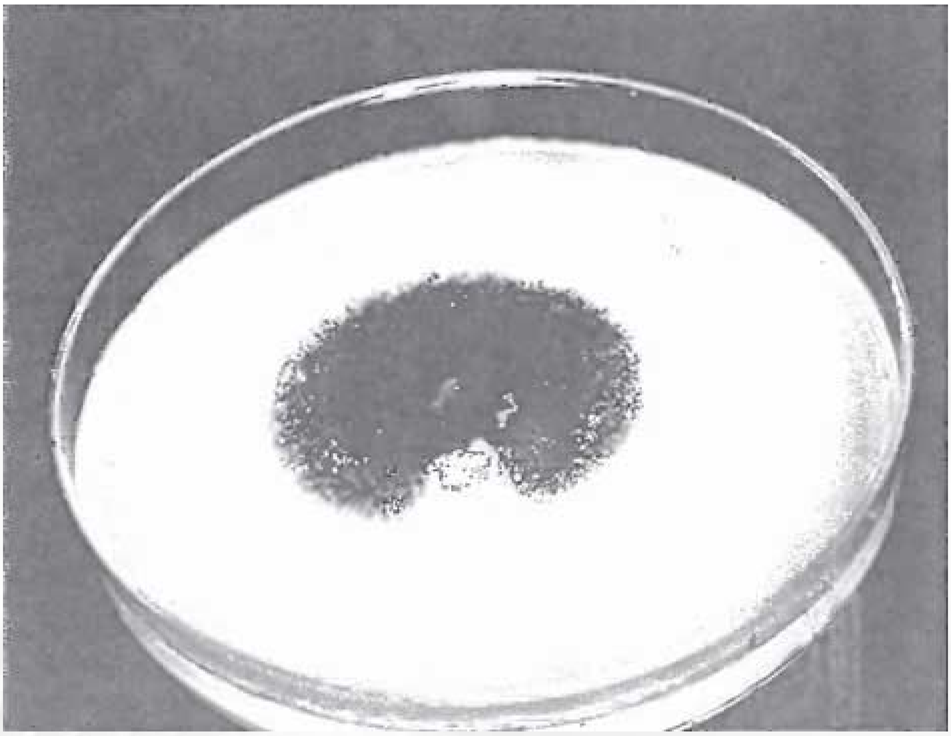

Figure 210 - *Mucor*, the Black Pin Mold, on malt agar.

For more information consult: Emmans, C.W., C.H. Binford, and J.P. Utz 1963, "*Medical Mycology*" Lea and Febiger, Philadelphia.

Mycelia Sterilia (White Mold)

Class: *Fungi Imperfecti*

Order: *Mycelia Sterilia*

Common Name: White Mold.

Habitat and Frequency of Occurrence: Contaminants fitting into this order occasionally encountered in sterile culture.

Medium Through Which Contamination Is Spread: Hyphal fragments airborne.

Measures of Control: General hygienic procedures, including the filtration of air through high efficiency particulate air (HEPA) filters, recommended.

Macroscopic Appearance: Typically appearing as a fast growing whitish mycelium, fine and or cottony in its growth. Species of *Mycelia Sterilia* closely resemble mushroom mycelium and may be mistaken for it. Sometimes they form whitish to blackish aggregates of hyphae that are sclerotia-like.

Microscopic Characteristics: Having a well developed hyphal network, with or without clamp connections. Only a vegetative mycelial stage is known. Since sporulating structures are absent, fungi in this group reproduce through random fragmentation of hyphae.

History, Use and/or Medical Implications: The genus *Sclerotium* noted for two species that parasitize a variety of green plants. Otherwise, the Order is unremarkable.

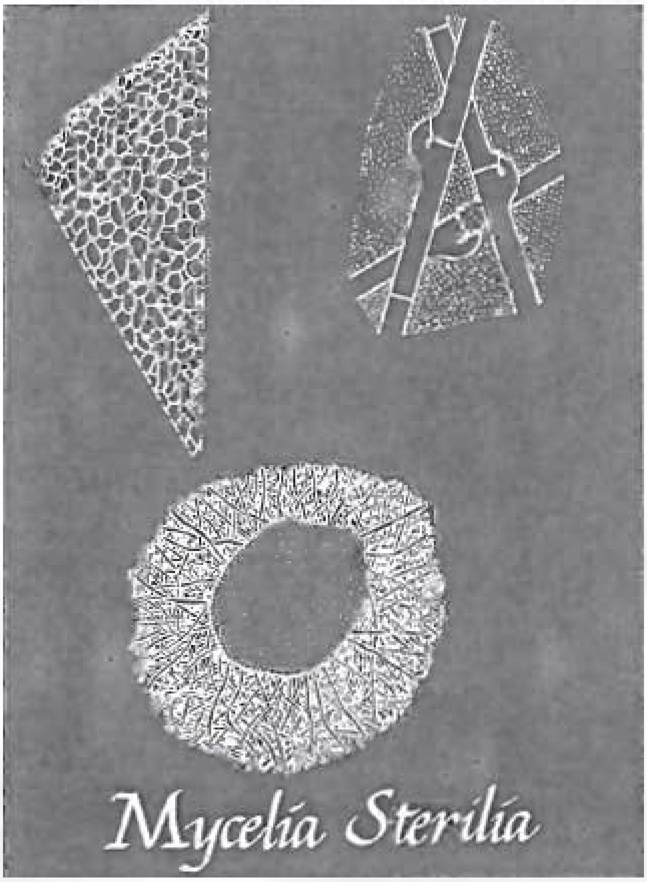

Figure 211 - Drawing of mycelial network showing hyphae with clamp connections and sclerotia-like bodies characteristic of species in the Order *Mycelia Sterilia*.

Comments: *Mycelia Sterilia* is often called a "garbage order" for non-sporulating mycelium of molds that can not be otherwise identified. Either a fungus has lost the ability to produce spores and can exist only in a vegetative state, or it will only produce spores on media of narrow nutritional specifications. In both cases, it is extremely difficult, if not impossible, to identify a fungus that has no visible conidial (sporulating) stage.

There is a white mold that occasionally contaminates agar media and, by default, qualifies for placement into the Order *Mycelia Sterilia*. Beginning cultivators have been known to propagate these sterile fungi in large quantities thinking them to be mushroom mycelia. This group of contaminants can be very competitive and should not be underestimated.

See also *Mucor*, a mold that has a vigorously growing whitish mycelium on agar media and one that often does not sporulate until it is transferred to grain.

Mycogone (Wet Bubble)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Hyphomyceteae*

Common Names: Bubble; Wet Bubble; White Mushroom Mold; and La Mole.

Greek Root: From "myco" or fungal and the suffix "gone" meaning reproductive body. This mold is named in reference to this mold's tendency to parasitize the mushroom fruitbody.

Habitat & Frequency of Occurrence: Very common, infecting the mushroom itself and causing significant losses to crops. *Mycogone* naturally occurs in soils from which this aggressive contaminant attacks the mushroom fruitbody. It does not grow well at temperatures lower than 60°F.

Medium Through Which Contamination Is Spread: Mostly through soils; debris (stem butts, etc.); and spent compost. Workers, especially harvesters, are one of the primary vehicles for spore dispersal. Watering infected areas further spreads this contaminant.

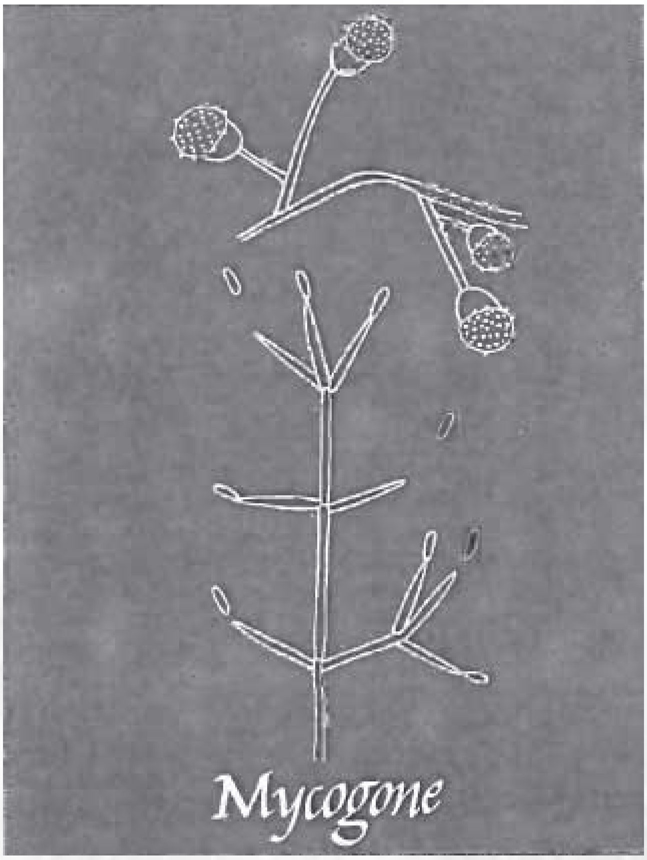

Figure 212 - Drawing of sporulating structure characteristic of *Mycogone*.

Measures of Control: Use of clean casing materials; moderation of temperature and adhering to a strict regimen of hygiene, especially between cropping cycles. Without touching the casing, infected mushrooms should be removed from the bed. The localized area is then sprinkled with salt, baking soda or a similar alkalinic substance. Do not water until the infected area is treated.

Macroscopic Appearance: Appearing as a whitish mold attacking primordia and turning them into a soft whitish ball of mycelia. From the brown and rotting interior of these "bubbles", amber fluid containing spores and bacteria ooze. More mature mushrooms that are afflicted with this disease have a felt-like covering of mycelium and a disproportionately small cap relative to the size of the stem.

Microscopic Characteristics: Conidiophores short; generally hyaline; relatively undeveloped; lateral; and altogether similar to the mycelia. Two types of conidia, terminally produced, can occur. The first and most distinctive type of chlamydospore is dark, round and two celled with one being large and rough walled, often adorned with short spine-like projections, and which is attached to a smaller cup shaped smooth cell. The second conidial type is smaller, ellipsoid, unicellular and develops apically from the ends of *Verticillium*-like conidiophores.

History, Use and/or Medical Implications: Not known to be pathogenic to man or animals.

Comments: *Mycogone perniciosa* Magnus is the species in the genus responsible for attacking the mushroom crop. Its mycelia intergrows with mushroom mycelia, according Kneebone (1961). This is a vigorous and resilient contaminant. Its spores are killed at 120°F. when exposed to moist heat (pasteurization) for 24 hours. Isolation of contaminated mushrooms, increasing ventilation, lowering temperature and proper bed cleaning techniques all limit the spread of *Mycogone*. Kneebone recommends the use of chlorinated water (150 ppm) during normal crop watering to impede the germination of its spores.

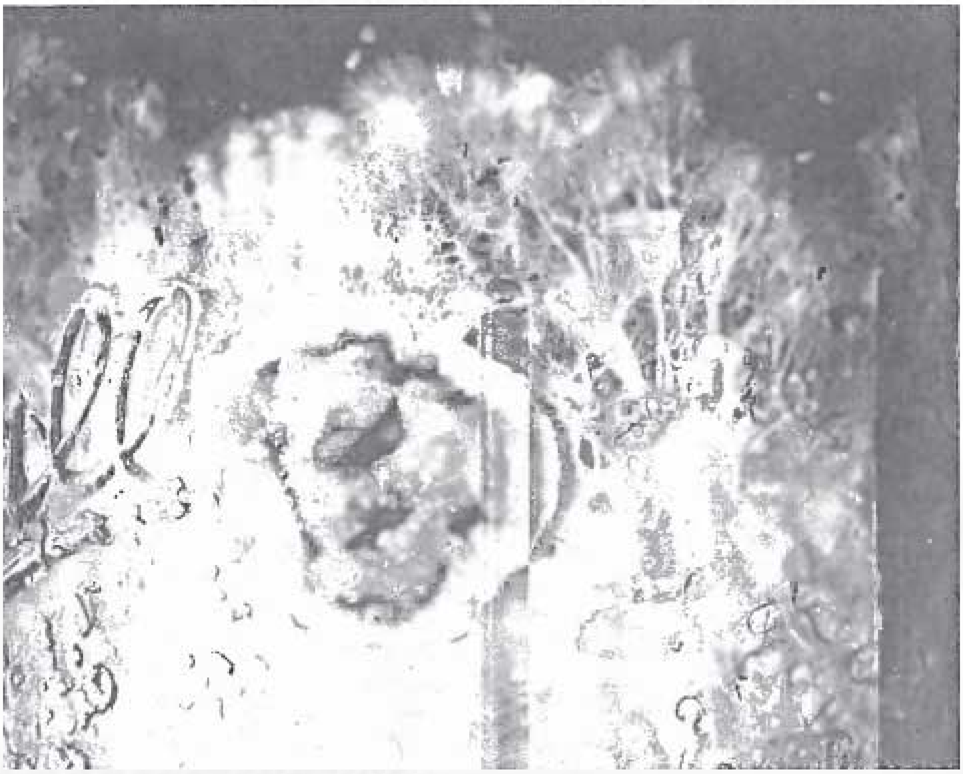

Figure 213 - *Mycogone*, Wet Bubble, on cased rye grain spawn.

Harvey *et al*. 1982, noted that if *Mycogone* appears during the first flush, then its spores were probably introduced via the casing - either at the time of its application or during spawn run through it, a period of about two weeks. Later infestations are more probably spread by flies, workers, air currents or other means.

Mycogone is believed by some mycologists to be an imperfect form of *Hypomyces*, an ascomycetous fungus that parasitizes wild mushrooms, especially *Russula* and *Lactarius*.

See also *Verticillium* and *Dactylium*.

Neurospora (Pink Mold)

Class: *Ascomycetes*

Order: *Xylariales*

Family: *Sordariaceae*

Common Names: Pink Mold; Red Bread Mold

Latin Root: From "neuro" meaning nerve and "spora" or spore, in reference to the longitudinal nerve-like ridges running along the axis of the spore.

Habitat & Frequency of Occurrence: Commonly to occasionally seen on agar and grain. *Neurospora* is fast growing, sometimes taking only 24 four hours to totally colonize a media filled Petri dish. It is ubiquitous in nature, occurring on dung, in soils and on decaying plant matter.

Medium Through Which Contamination Is Spread: Primarily air; secondarily soils; dung and grains.

Measures of Control: Air filtration; incubation of cultures in a sterile environment; thorough sterilization of grain; isolation and destruction of contaminated cultures; and otherwise maintaining the standard regimen of hygiene.

Macroscopic Appearance: A fast growing, creeping aerial mycelia that becomes bright pinkish in color with spore maturity.

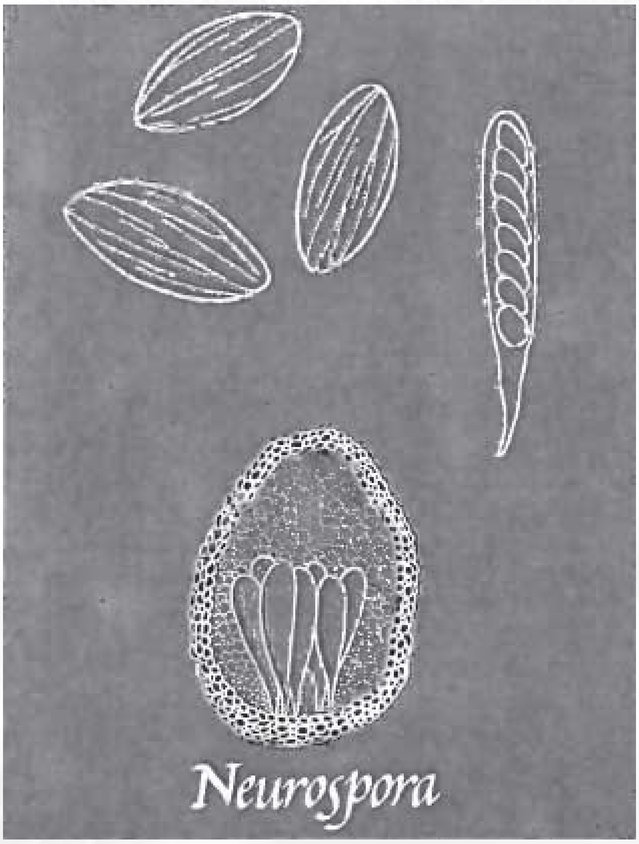

Figure 214 - Drawing of sporulating structure and distinctive spores of *Neurospora*, a pink mold.

Microscopic Characteristics: Spores distinctively longitudinally ribbed with nerve-like ridges, produced eight at a time (rarely four) in a sac-like organ called an ascus which is in turn enclosed within a ball-like perithecium that can be dark brown to black to pink in color. Its mycelium is usually pigmented, a feature influenced by the type of habitat. Its imperfect form, *Monilia*, consists of a simple mycelia network which branches. *Monilia* segments at the tips from which ellipsoid, oval or globose spores are formed in short chains from the terminal ends. *Monilia* spores are frequently pinkish.

History, Use and/or Medical Implications: Not known to be pathogenic to man or animals. *Neurospora crassa* has become a standard species for studying fungal genetics in culture.

Comments: *Neurospora* has an imperfect form represented by the genus *Monilia* which forms spores not in a sac-like envelope but in simple chains at the end of hyphae. (See that genus). *Neurospora* and/or *Monilia* are some of the fastest growing contaminants on grain and agar. The color of this contaminant, in either form, varies substantially. The ability of this organism to mutate into both an asexually reproducing fungus (*Monilia*) and a sexual one (*Neurospora*) is a factor largely determined by nutrition and pH - low pH levels encourage the expression of *Monilia* while higher pH media favor *Neurospora*.

The characteristic pinkish tone and unique spore structure make *Neurospora* an easy contaminant to identify. Since this fungus grows through cotton stoppers or filter discs, a single contaminated jar, though sealed, can spread spores to adjacent spawn jars within the laboratory. This condition is more likely if the filter discs or cotton plugs are the least bit damp; or if the external humidity is high. Furthermore, *Neurospora* spores germinate more readily at elevated temperatures.

The red bread mold belongs to the *Neurospora crassa* complex. The pink mold seen in mushroom culture is most frequently *Neurospora sitophila*, a pernicious contaminant that is difficult to eliminate.

All infected cultures should be removed as soon as possible from the laboratory and destroyed. A thorough cleaning of the laboratory is absolutely necessary. If contamination persists, remove all spawn and start anew. Since *Neurospora* spores are spread via the air, high efficiency particulate air (HEPA) filters readily eliminate this contaminant.

Refer to the genus *Monilia*, an imperfect form of *Neurospora*.

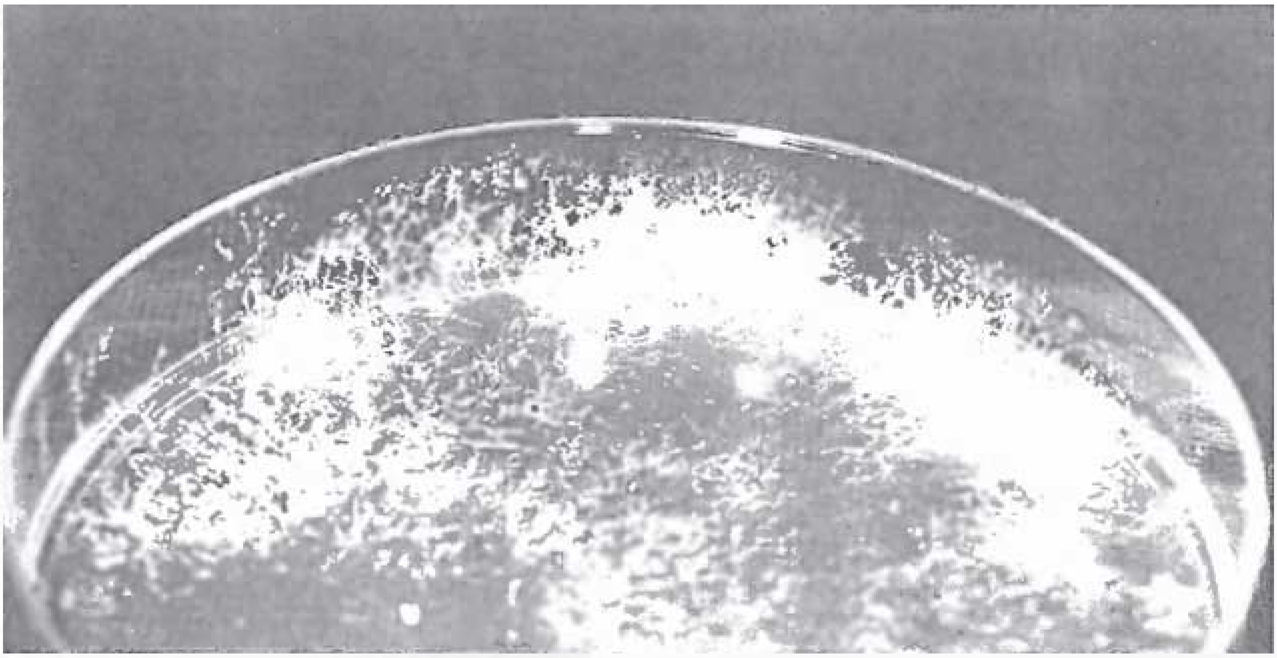

Figure 215 - *Neurospora* contaminating PDA media. Note creeping aerial mycelium.

Papulospora (Brown Plaster Mold)

Class: *Fungi Imperfecti*

Order: *Mycelia Sterilia*

Common Name: Brown Plaster Mold.

Latin Root: From "papulosus" meaning pimple-like and "spora" or spore. Named in reference to the rounded groups of cells that resemble sclerotia and are characteristic of this genus.

Habitat & Frequency of Occurrence: A saprophyte, common on overly mature composts or on compost with excessive moisture. Some species grow directly on the wood used in the construction of the trays and then spread to the beds.

Medium Through Which Contamination Is Spread: Primarily air; from spent compost; or from untreated trays that once harbored this contaminant.

Measures of Control: Avoidance of over-composting; proper balancing of moisture in the compost; expeditious removal of old or contaminated compost; steam cleaning of trays; and maintaining good hygiene between crops.

Macroscopic Appearance: Dense whitish mycelium, resembling *Scopulariopsis fimicola* (the White Plaster Mold) in the early stages, soon becoming cinnamon brown from small bead-like or "powdery" sclerotia-like balls of cells. The balls of cells are easily seen with a hand lens and are darkly pigmented. Often there is a whitish rim of new growth along the outer periphery of the mycelium.

Microscopic Characteristics: True conidia absent, propagating through simple fragmentation of mycelia or through dense spherical sclerotia-like masses of dark cells.

History, Use and/or Medical implications: None known.

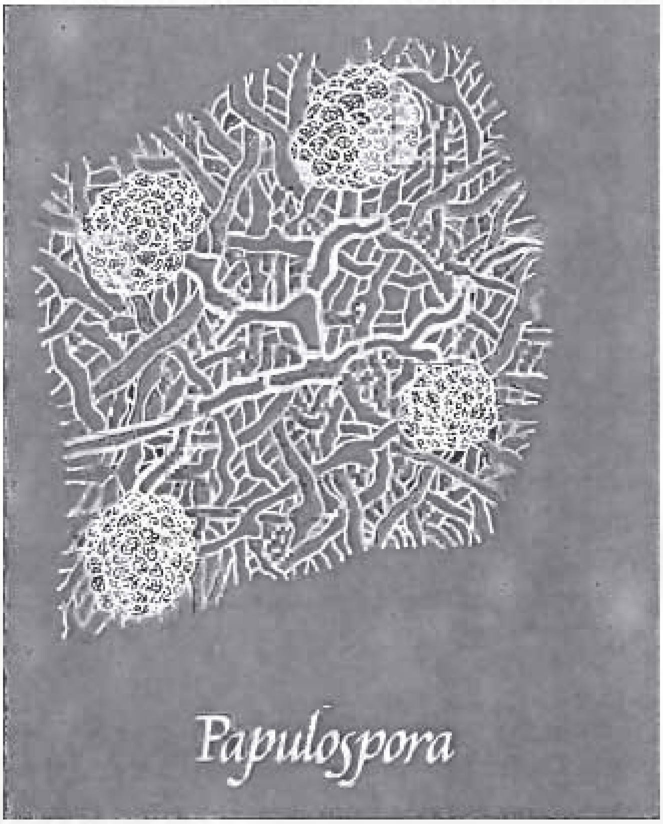

Figure 216 - Drawing of non-sporulating sclerotia-like mycelial mass that is typical of the Brown Plaster Mold, *Papulospora byssina*.

Comments: *Papulospora* is competitive to mushroom mycelium and can therefore postpone or inhibit fruiting. *Papulospora byssina* Hotson is the brown plaster mold commonly encountered in mushroom cultivation. Colonies of this contaminant can grow up to several feet in diameter if corrective countermeasures are not taken. It frequently grows on wooden trays or shelves. The Brown Plaster Mold is detrimental to mushroom crops only in the sense that *Papulospora* usurps valuable nutrients that would otherwise be available to the mushroom mycelium. According to Atkins (1974), wet, compact and overly mature compost is likely to favor these contaminants.

Because no conidial (spore producing) phase is known, it has been placed in the "garbage" order of little understood fungi, the *Mycelia Sterilia*.

See also Botrytis and *Scopulariopsis*.

Penicillium (Bluish Green Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Eurotiaceae*

Common Name: The Bluish Green Mold.

Latin Root: From "penicillum" meaning a brush-like tuft of hairs, so named in reference to the shape of the sporulating body.

Habitat & Frequency of Occurrence: An extremely common contaminant. Although not as prevalent in nature as *Cladosporium*, *Penicillium* is the most prevalent of indoor contaminants, a fact that is undoubtedly related to human eating habits. *Penicillium* species abound on foodstuffs such as fruits, cheeses and stored grains. Many species prefer habitats with an acid pH. Penicillia are occasional to frequent on under-developed mushroom compost, casing soil and on discarded mushroom debris.

Medium Through Which Contamination Is Spread: Primarily through the air, although stored grain and other foodstuffs, as well as humans are the most frequent carriers of this mold.

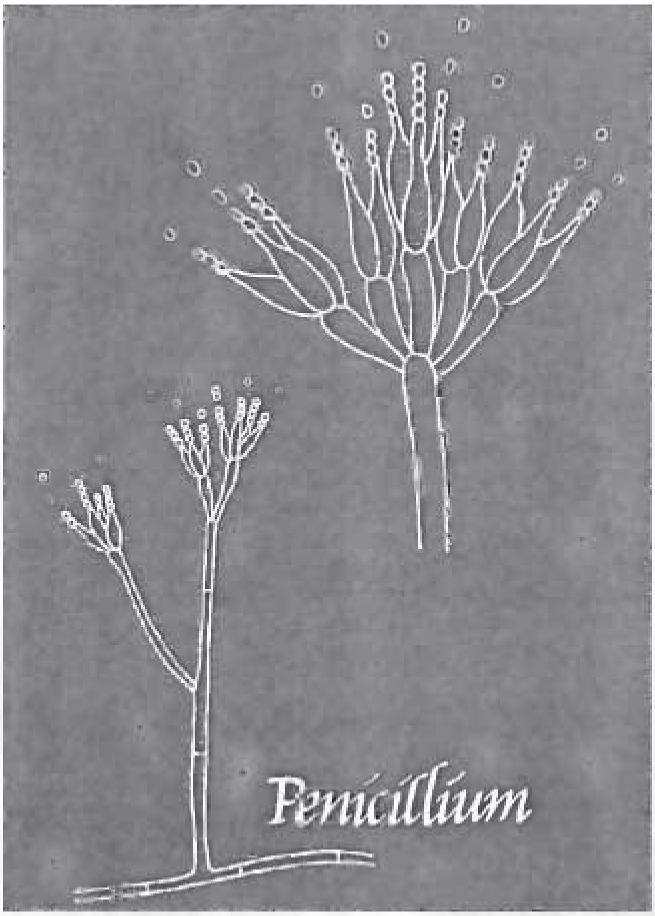

Figure 217 - Drawing of sporulating structure characteristic of *Penicillium* molds.

Measures of Control: Air filtration; removal of waste products; isolation of contaminated cultures; and maintenance of a high level of hygiene.

Macroscopic Appearance: Appearing as a granular or powdery bluish green mold, often with a broad whitish rim of new growth. Some species, less frequently encountered, are whitish, yellowish or even reddish in color. Many species exude droplets of fluid from their surfaces having antibiotic properties.

Microscopic Characteristics: Conidiophores arising singly, long, and branching near the apex into short chains of globose, green, dry conidia. Compared to mushroom spores, the conidia of Penicillia are minute, measuring only 2-4 microns in diameter.

History, Use and/or Medical Implications: In 1928-1929 while Dr. Alexander Fleming was studying *Staphylococcus aureus*, he noticed that a green mold contaminant inhibited his cultured bacteria when the two grew in close proximity. A fluid that was being exuded from the fungus caught his curiosity. Upon reporting his finding, colleagues later found the fluid contained a powerful new antibiotic which was named penicillin. He had, in fact, cultured *Penicillium notatum* Westl. Currently penicillin is commercially produced by high yielding strains of *Penicillium chrysogenum* Thom. Through its use, millions of people have been cured of illnesses that were previously untreatable. From the widespread use and abuse of this drug, however, new, more virulent and penicillin resistant strains of bacteria have evolved.

From the production of steroids to the making of roquefort cheese (by *Penicillium roquefortii*), this genus is resplendent with species of proven value to man. Few, if any, are pathogenic.

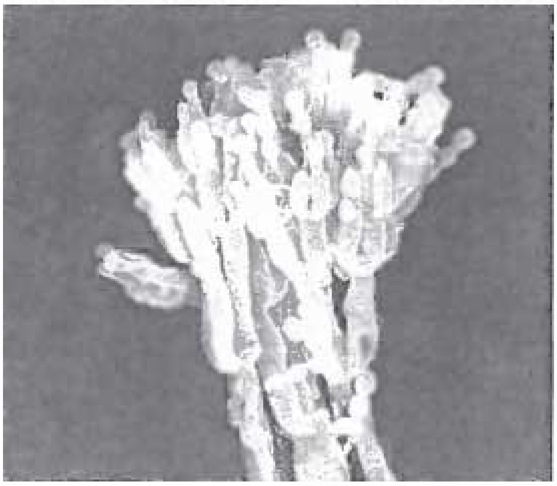

Figure 218 - Scanning electron micrograph of *Penicillium*.

Comments: Since the high count of *Penicillium* spores indoors is directly traceable to decomposing foodstuffs, one can reduce the prevalence of this contaminant by simply following good hygienic practices. *Penicillium*, a prolific spore producer, is an ubiquitous fungus. It is probably the most common contaminant seen in the laboratory. Although *Penicillium* can attack compost, casing soil and mushroom debris, it is not as prevalent as *Trichoderma* in these habitats. Other green molds, similar in appearance, are *Cladosporium* and *Aspergillus*.

Penicillium sometimes contaminates poorly prepared compost or spawned compost that has undergone secondary heating. Here, grain kernels formerly colonized by mushroom mycelium become susceptible to weed molds such as *Penicillium* and *Doratomyces* and then spread onto the compost and/or casing soil.

Differing from *Aspergillus* and *Trichoderma* in the shape of the conidiophore.

For further information: "*The Penicillia*" by Raper and Thom (1949) who recognized 138 species at the time of publication.

See Color Photograph 20.

Rhizopus (Black Pin Mold)

Class: *Zygomycetes*

Order: *Mucorales*

Family: *Mucoraceae*

Common Names: Bread Mold; The Pin Mold.

Latin Root: From the prefix "rhizo", pertaining to roots, and the suffix "pus" or foot, in reference to the rhizoids at the base of the sporangiophore that is characteristic of some species in this genus.

Habitat & Frequency of Occurrence: A saprophyte, commonly seen in both agar and grain culture. *Rhizopus* naturally inhabits dung and soils and is a decomposer of dead plant and animal matter. Within the home, this contaminant is most often seen on old bread or on poorly stored grain and fruits.

Medium Through Which Contamination Is Spread: Primarily air.

Measures of Control: Air filtration; strict adherence to general hygienic practices; and steam sterilization of grain and agar media.

Macroscopic Appearance: Similar to *Mucor*. When sporulating, *Rhizopus* appears as a dense mat of tall, aerial, vertically oriented hyphae upon which sit dark grey to grey black heads. It resembles a forest of pins.

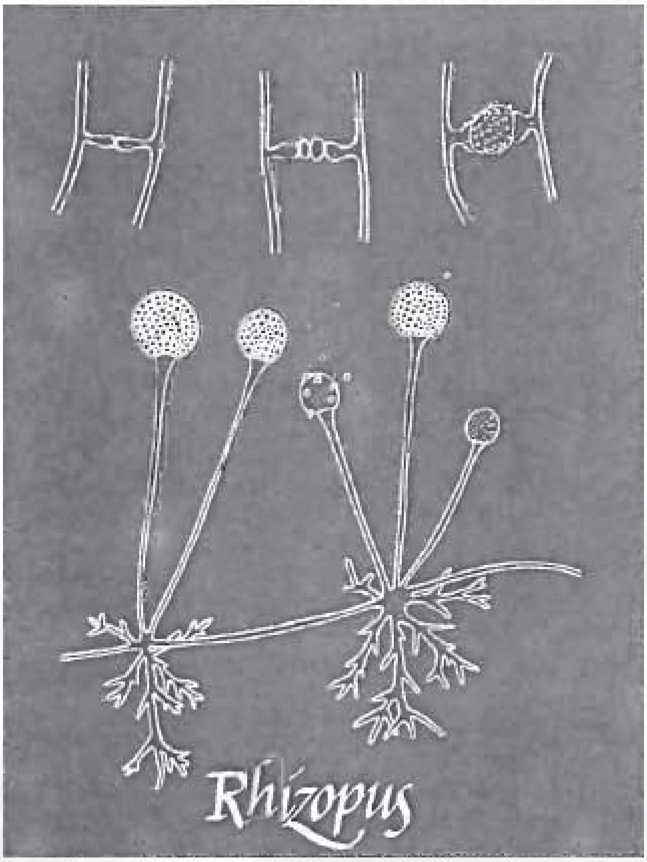

Figure 219 - Drawing of asexual sporangiophore and sexual zygosporium of *Rhizopus*.

Microscopic Characteristics: A creeping hyphal network that gives rise to individual, vertically oriented stalks that are unbranched and at whose base distinct rhizoids can be attached. The apex is swelled into a vesicle upon which a dark spherical body (sporangium) rests. This sporangium does not fully envelope the sporangiophore. Hence, the sporangiophore swells before contacting the sporangium. The sporangium is a mass of spores within a thin envelope of tissue that soon disintegrates and frees the asexual spores. Joining these individual sporangiophores are long interconnecting mycelial veins called stolons. Mating can also occur between two sexually complementary hyphae and results in the formation of a globose reproductive body, a zygosporium. (See Fig. 219). Its mycelia lacks distinct cell walls.

See also *Mucor*, a mold that is closely related to *Rhizopus*, but whose sporangium completely covers the apex of the sporagiophore.

History, Use and/or Medical Implications: In itself, not a pathogen to man. Reports in the medical literature have in the past blamed *Rhizopus* for zygomycosis when in fact other related genera - *Absidia* and *Mucor* - were responsible.

Rhizopus stolonifer, the black bread mold, is also utilized in the commercial production of fumaric acid and cortisone. Other species in the genus secrete assorted alcohols and acids as metabolic waste products.

Comments: Along with *Aspergillus* and *Penicillium*, species of this genus are the primary contaminants of grain spawn. *Rhizopus* is very rapid growing, and is called the Pin Mold for the shape of the spore producing body. *Rhizopus stolonifer* (=*Rhizopus nigracans*) is called the Black Pin Mold and can elevate the substrate temperature from room temperature to the 95-104°F. range. At this level, the populations of the true thermophiles increase dramatically, further heating up the host substrate to temperatures lethal to the mushroom mycelium.

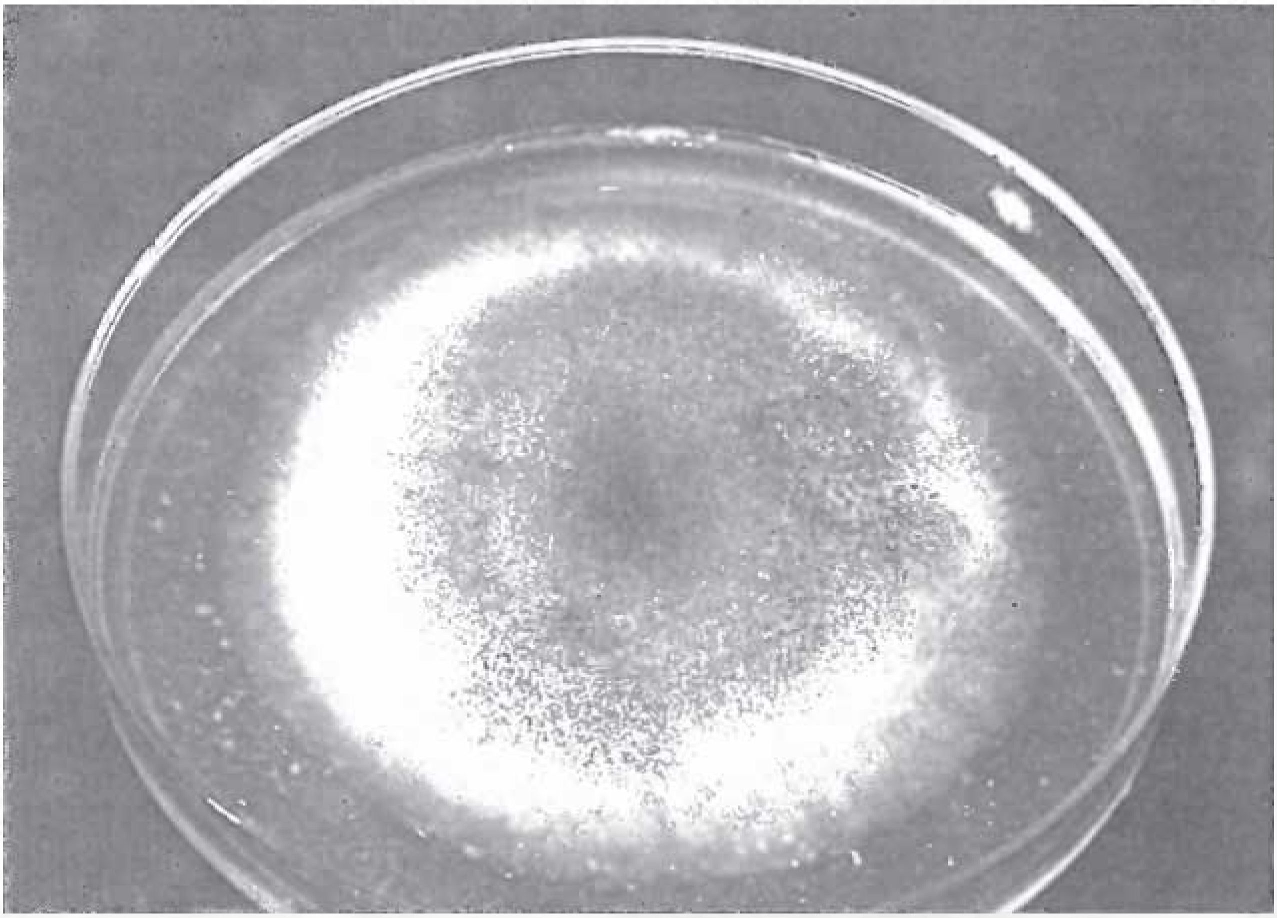

Figure 220 - *Rhizopus*, the Black Pin Mold, on malt agar.

Scopulariopsis (White Plaster Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Series: *Annelosporae*

Common Names: White Plaster Mold; Flour Mold.

Latin Root: From "scopulatus" meaning broom-like or brush shaped, in reference to the structure of the sporulating reproductive body.

Habitat & Frequency of Occurrence: A saprophyte, occasionally seen in composts that have been over-watered or are too high in nitrogen. *Scopulariopsis* also forms on the casing during the fruiting cycle. It naturally grows in soils, on hay, on rotting leaves and on other decaying plant material including grain. This group of molds generally prefer an alkaline pH.

Medium Through Which Contamination Is Spread: Primarily airborne spores, spent compost and insects; and from materials previously in contact with this contaminant that were not thoroughly cleaned before use.

Measures of Control: Proper preparation and sufficient air during Phase II composting discourages this fungus. Atkins (1974) reported that excessive moisture and subsequent anaerobic pasteurization were the two main factors contributing to the spread of the White Plaster Mold. Before filling, the addition of gypsum to an overly wet compost will bind loose water, a condition favourable to this mold.

Macroscopic Appearance: Circular colonies of densely matted, whitish mycelia; with age developing slight pinkish tones. This mold often appears as "splotches", mostly on the compost bed and to a lesser degree on the casing soil.

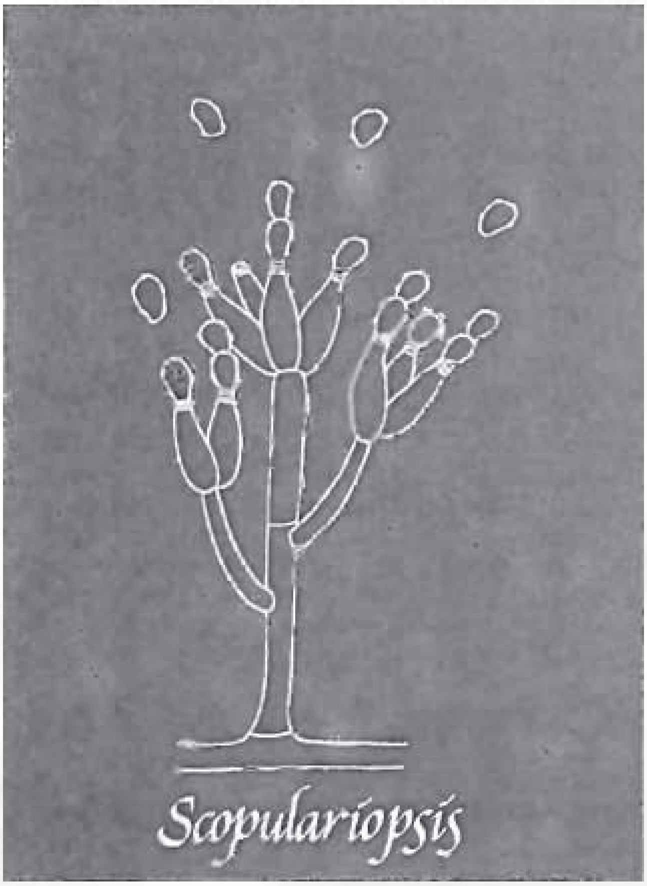

Figure 221 - Drawing of sporulating structure typical of *Scopulariopsis*.

Microscopic Characteristics: Conidiophores short, soon branching, delineating into several elongated cells which then give rise to short chains of globose, hyaline, finely warted, dry conidia that measure 5-8 x 5-7 microns. Annular zonations are present at the junction of the sporogenous cells and the first spore in the conidial chain. Terminal cells in the chain are the oldest and typically the largest. The conidiophores generally resemble that of *Penicillium* and thus are described as penicillate, or brush shaped.

History, Use and/or Medical Implications: One species toxic to humans: *Scopulariopsis brevicaulis* (Saccardo) Brainer. This species usually attacks tissue already diseased by other microorganisms. It is an improbable threat to the health of mushroom cultivators.

Comments: *Scopulariopsis fimicola* is the White Plaster Mold seen on compost beds. It is very detrimental to the growth of mushroom mycelia. Its presence is usually an indication of a short, wet and over-mature compost. This condition predisposes the compost to a difficult Phase II with dense anaerobic areas, ammonia-lock and consequently high pH levels. All these factors contribute to the growth and spread of *Scopulariopsis fimicola*, the species of White Plaster Mold most frequently seen in mushroom culture.

Contamination can also arise from within the mushroom house if there has been a prior history of problems with this contaminant and if strict contamination control procedures have not been instigated. Not surprisingly, one often finds *Scopulariopsis* with the Inky Cap (a *Coprinus* species) which is also associated with residual ammonia in composts.

See also *Papulospora* (*P. byssina* Hots.), a genus containing the Brown Plaster Mold whose early stages of growth resemble the White Plaster Mold.

Sepedonium (White or Yellow Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Series: *Aleurisporae*

Common Names: Yellow Mold; White Mold.

Habitat and Frequency of Occurrence: Occasionally to frequently encountered on agar; more common on compost; and parasitic on wild mushrooms (both Basidiomycetes and Ascomycetes).

Medium Through Which Contamination Is Spread: Primarily through the air, but also from spent compost.

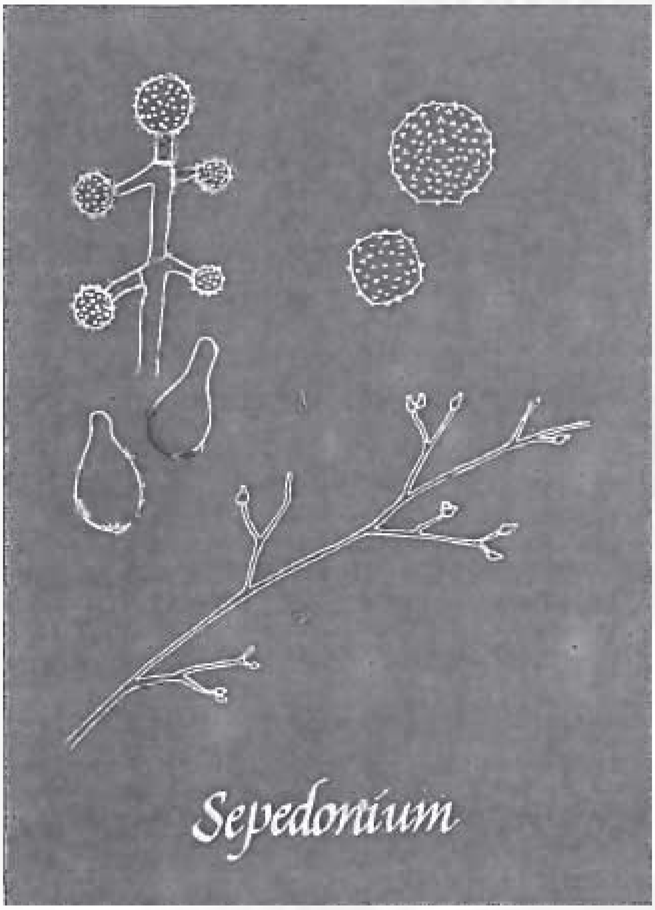

Figure 222 - Drawing of sporulating structure and flask shaped conidia.

Methods of Control: Air filtration; strict maintenance of hygiene in the laboratory and growing room; the expeditious removal of spent compost; and the thorough disinfection of wooden compost containers.

Macroscopic Appearance: On malt agar and on rye grain appearing as a fast growing whitish mold, very similar to cottony mushroom mycelia and frequently mistaken for it. On compost it is a fine white mold which with age becomes yellowish to golden yellow from spore production. It is not as prolific a spore producer as the powdery *Trichoderma*. If spores are not produced at all, the mycelia remains whitish. This mold attacks composts that otherwise have been properly prepared for mushroom growing.

Microscopic Characteristics: Two types of spores formed. The more obvious are large, globose chlamydospores ornamented with short spines and similar to those of *Mycogone*; except in this genus a hemispheric foot cell, shaped like a teacup is absent. Conidiophores are simple, relatively undeveloped, resembling mushroom mycelium and not easily distinguished from it except that they lack clamps. Globose to vase shaped conidia develop terminally at the end of these branches, either singly or in loose clusters.

History, Use and/or Medical Implications: Some species possibly toxic. It has been suggested that this mold secretes a sweet odor nauseous to some mushroom workers and possibly the cause of a little understood respiratory illness. Not much is known.

Comments: *Sepedonium* spores are noted for their heat resistance. It is a whitish mold until the yellow conidia are produced. On malt agar media, *Sepedonium* is fast running, and out-grows most mushroom mycelia. When the two fungi grow within close proximity to one another, a line of inhibition usually develops between the two. If conidiospores or chlamydospores are not produced, this mold is difficult to identify. The conidiophores are indistinct, very much resembling its own mycelium. From the authors' experience this contaminant is a vigorous competitor on agar media. Its appearance necessitates a thorough cleaning of the laboratory and spawn incubation environment. If this mold contaminates grain spawn and goes undetected, use of this spawn in subsequent inoculations would be disastrous.

The second site of contamination is horse manure/straw compost where it most frequently appears during spawn run. Only detrimental when large outbreaks occur, *Sepedonium*'s presence on compost can be traced to insufficient pasteurization or spent compost residues in the trays or shelves. Although not regarded as a serious competitor on mushroom compost, *Sepedonium* is another fungus believed to be a food source for mites (Kneebone, 1961).

Sepedonium, like *Mycogone*, is an imperfect state of *Hypomyces*, a common parasite on mushrooms. In the wild, *Sepedonium chrysosperma* parasitizes *Boletus* species (particularly *B. chrysenteron*) and causes them to abort. The chlamydospores of *Sepedonium* are generally similar to *Mycogone*.

See also *Mucor* and *Mycelia Sterilia*, two fast running whitish molds on agar media.

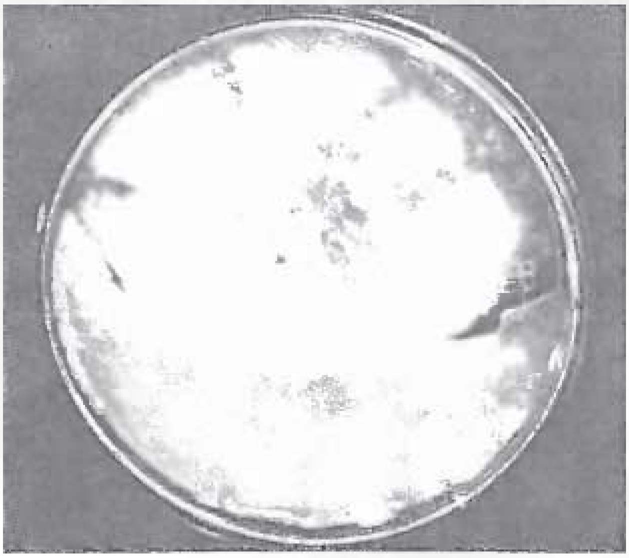

Figure 223 - *Sepedonium* mold competing with *Psilocybe cubensis* mycelia on malt agar media.

Torula (Black Yeast)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Dematiaceae*

Common Name: Black Yeast (*Torula nigra*).

Latin root: From the same root as the adjectival "torulosus", meaning cylindrical shaped with bulges and constrictions at regular intervals, chain-like.

Habitat and Frequency of Occurrence: Saprophytic, common. Many thermophilic species participate in the decomposition of straw and manure in the making of mushroom composts. Although *Torula* is rarely seen in agar culture, its cousin *Rhodotorula*, a red yeast, is frequently seen.

Medium Through Which Contamination Is Spread: Primarily an airborne contaminant; secondarily transmitted through compost.

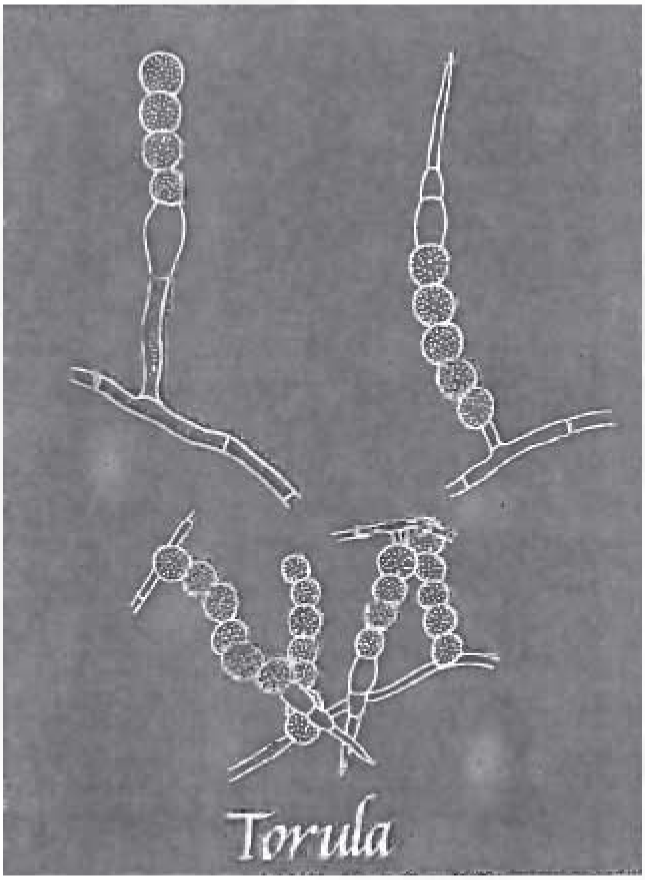

Figure 224 - Drawing of the sporulating structure of *Torula*, the Black Yeast.

Methods of Control: None generally needed or desired. *Torula* is a beneficial, thermophilic microorganism thriving in the 115-125°F. range.

Macroscopic Appearance: Whitish at first, then grayish, soon dark brown or jet black with spore production. As *Torula* matures, the mycelium becomes covered with a mass of spores that give it a soot-like appearance. On compost, this fungus appears similar to *Humicola*.

Microscopic Characteristics: Mycelium colorless or slightly pigmented. True conidiophores are lacking. Hyphae abruptly terminate into conidia which are ovoid, translucent, dark brown, smooth and produced in branched or unbranched chains by either of two methods. In one form, the more mature spores of a conidial chain develop apically, with the younger spores arising from the spore closest to the hyphal branch. (This is called basipetal development). In a second form, conidia can develop by simple budding from the tips of a hypha, in a yeast-like fashion. The budding hypha narrows towards the apex into immature spores and finally terminates with an attenuating tail. Freed are conidia found singly or attached several at a time.

History, Use and/or Medical Implications: Not thought to be pathogenic. Confusion with *Cryptococcus* has in the past given *Torula* an undeserved pathogenic reputation. Cryptococcosis in the medical literature is often though incorrectly termed torulosis.

Comments: *Torula*, like *Humicola*, is an ally to the mushroom compost maker, converting ammonic nitrogen into protein usable to the mushroom. *Torula thermophila* Cooney & Emerson is the species most frequently seen in composting straw and manure. Originally isolated from chicken droppings, this species is a true thermophile with a temperature range from 73-136°F., and an optimum of 104°F. The *Torula* genus is known for a number of thermophilic species that survive the pasteurization process and flourish at standard Phase II conditioning temperatures (118-125°F). When pasteurized compost is cooled down to room temperature, this fungus is rendered inactive and in turn becomes a food source for the mushroom mycelium.

Rhodotorula reproduces very similarly to *Torula*. It is known as the Red Yeast, commonly contaminating agar cultures. *Rhodotorula glutinis*, a common soil inhabitant, may play an important role in the reproductive cycle of the common Chantarelle mushroom, *Cantharellus cibarius*. Pure cultures of Chantarelles have been difficult to obtain from wild specimens. And, Chantarelle spores do not germinate using standard laboratory techniques. In 1979, a Swedish mycologist named Nils Fries discovered that, in the presence of *Rhodotorula glutinis* and activated charcoal, *C. cibarius* spores readily germinate. Pure cultures of Chantarelles, once nearly impossible to obtain, are now feasible. Other related yeasts may have a similar stimulatory effect on various mushrooms species currently not prone to cultivation.

Torula species, as with most yeasts, are separated from one another largely by chemical means.

Trichoderma (Forest Green Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Names: Forest Green Mold; Green Mold; and Trichoderma Blotch.

Greek Root: From "trichos" meaning hairy and "derma" or skin.

Habitat & Frequency of Occurrence: Very common on compost, casing soil and to a lesser degree on grain and agar. *Trichoderma* often parasitizes mushrooms under cultivation and can inhibit or reduce fruitings. Many species grow on wood or woody tissue and are abundant in peat. *Trichoderma* frequently grows on the wooden trays holding compost.

Medium Through Which Contamination Is Spread: Primarily an airborne contaminant when contaminating agar or grain cultures. On casing soils, it is introduced through the peat or humus. *Trichoderma* is often spread during harvesting, bed cleaning or watering. Species in this genus generally prefer an acid pH in the 4-5.5 (6) range.

Measures of Control: Careful picking; disposal of dead and diseased mushrooms; lowering of humidity levels; lowering carbon dioxide and increasing air circulation to eliminate dead air pockets. Use of clean casing materials lacking undecomposed woody tissue lessen the chance of *Trichoderma* contamination. Isolated outbreaks of *Trichoderma* can easily be contained by one of several methods. Since *Trichoderma* thrives in acid habitats, raising the pH of the surrounding soil inhibits further growth. Perhaps the simplest way to raise pH is to cover the infecting colony with salt, sodium hypochlorite or sodium bicarbonate (baking soda) or a solution thereof. Recognizing and treating this fungus in its earliest stages, before many spores are produced, greatly reduces the risk of satellite colonies spreading throughout the growing room. Mushrooms afflicted with *Trichoderma* should be carefully isolated. All items coming in contact with it (tools, workers, etc.) should be resanitized. Steam pasteurization at 160°F. for one hour effectively kills the spores of this fungus.

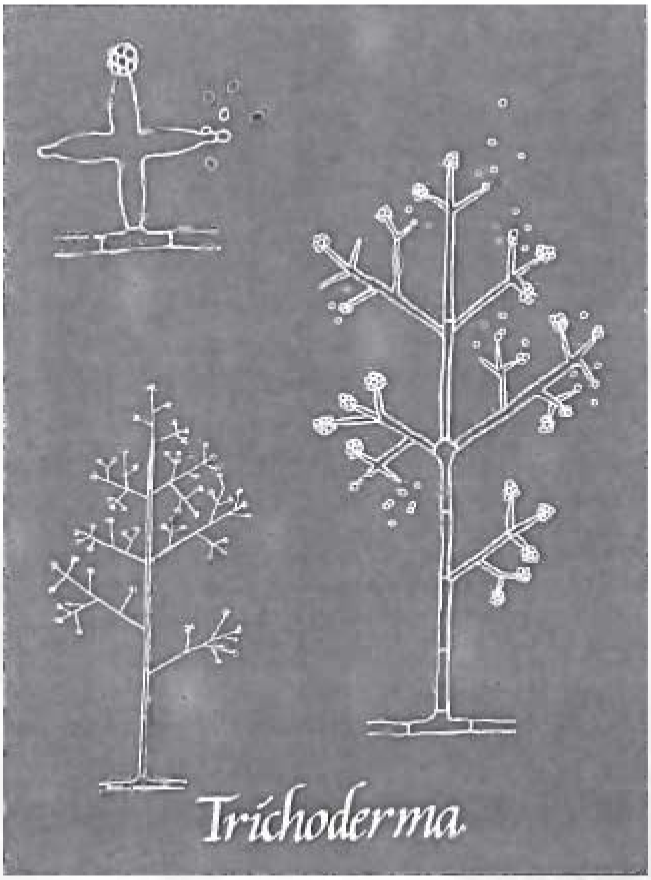

Figure 225 - Drawing of conidia and sporulating structure typical of *Trichoderma*.

Macroscopic Appearance: A cottony mold, growing in circular colonies on the casing soil or on compost; grayish and diffuse at first; rapidly growing; and soon forest green from spore production. On malt agar colonies of *Trichoderma* have an aerial, cottony and brilliant forest green mycelium whereas *Penicillium* has an appressed, granular and blue green mycelium. Some infrequently encountered species are whitish or yellowish, but the majority of those seen in mushroom culture are greenish shaded.

Parasitized mushrooms have dry brownish blotches or sunken lesions on the cap or stem. They are often enveloped by a fine downy mildew that may eventually become greenish from spore production, and are grossly misproportioned.

Microscopic Characteristics: Conidiophores clear, profusely branched upon whose ends small bunches of ovoid greenish pigmented, smooth spores are borne. In many species uniquely shaped sporogenous cells are present roughly resembling bowling pins and arranged as triads. After squashing a sample for viewing under the microscope, the conidiophores readily disassemble and are difficult to recognize. The freed conidia, however, are not arranged in linear chains as commonly seen in *Aspergillus* and *Penicillium*, but are in loose clusters or are scattered as individuals. A most distinctive feature is that the conidia are encased in a mucus-like substance, making the spores sticky. Spores measure 3-5 x 3-4 microns.

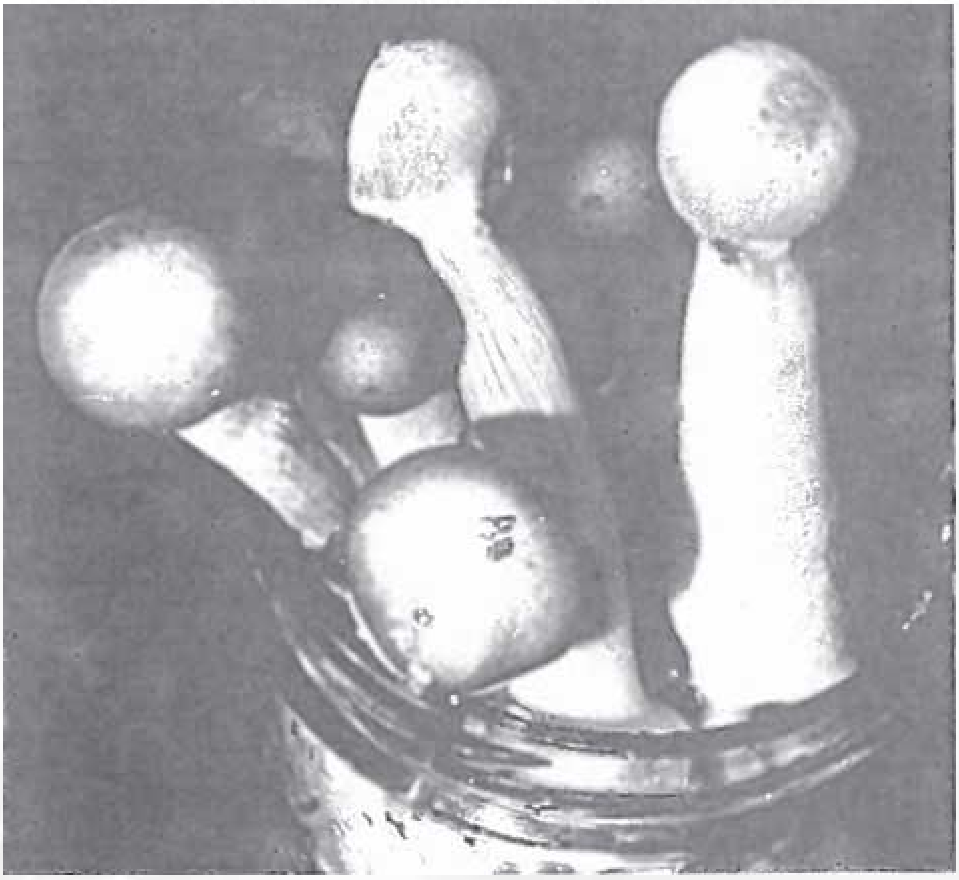

Figure 226 - *Trichoderma*-like mold parasitizing *Psilocybe cubensis*.

History, Use and/or Medical Implications: Not known to be pathogenic. One industrial application utilizes *Trichoderma*, *Penicillium* and *Cladosporium* to precipitate precious metals such as gold and platinum from solutions. The process is being patented.

Comments: In cased grain culture, *Trichoderma* is the most frequently encountered contaminant on the casing layer and usually originates there. Upon casing, spores harbored in the peat infect exposed grain kernels and sporulate. The contaminated kernels become a platform for further contamination. The mold then spreads through the casing layer until it breaks through to the surface of the casing layer. Also, *Trichoderma* is prone to casings with undecomposed woody tissue and those incorporating potting soils. *Trichoderma* is also caused by excessively wet casings applied to sterile grain spawn.

Trichoderma is an ubiquitous fungus that is encouraged by improperly adjusted environmental parameters. Conditions of excessively high and prolonged humidity in combination with stagnant air and high carbon dioxide levels tip the ecological balance of the casing soil's micro-ecology in favor of this contaminant. Once *Trichoderma* populations bloom, this mold quickly infects newly formed primordia and developing fruitbodies which become deformed. This pathogen also grows on discarded mushroom debris, particularly stem butts.

Afflicted mushrooms have brownish specks or lesions on the stem, especially near the base or apex. A fuzzy mycelium similar to *Verticillium* may be present on the cap. These lesions are dry, whereas the blotches caused by bacteria tend to be moist. The growth of the fruitbody is abruptly arrested by this mold. Under extreme conditions this mold sporulates directly on the mushroom, becoming green in color. Adjacent mushrooms, newly formed pinheads and subsequent crops need not be affected if air circulation is increased to proper levels and if humidity is decreased to within tolerable limits (3-5 exchanges of air per hour while maintaining 85-92% humidity). *Trichoderma* is alleged to secrete toxins that inhibit mushroom primordia formation and growth.

Another problem with *Trichoderma* is that its spores are utilized by red pigmy mites as food. *Trichoderma* spores are sticky and attach to anything coming in contact with them. In this way, mites further aid the spread of *Trichoderma* contamination. And, soon after an outbreak of *Trichoderma*, it is not unusual to see a population explosion of mites.

Most notable are *Trichoderma viride* (a synonym of *Trichoderma lignorum*), an early appearing mold with roughened spores and *Trichoderma koningii*, a smooth spored mold seen later in the cropping cycle. Both are mushroom pathogens.

See *Verticillium*, a mold with similar symptoms when attacking fruit bodies.

See Color Photograph 22.

Trichothecium (Pink Mold)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Name: Pink Mold.

Greek Root: From "trichos" meaning hairy and "theke" meaning sac or capsule.

Habitat and Frequency of Occurrence: For the most part, a saprophyte, rarely encountered in spawn making even though it is one of the many microflora associated with grain. *Trichothecium* is an occasional contaminant in agar culture and in poorly prepared or immature composts.

Medium Through Which Contamination Is Spread: Primarily an airborne contaminant.

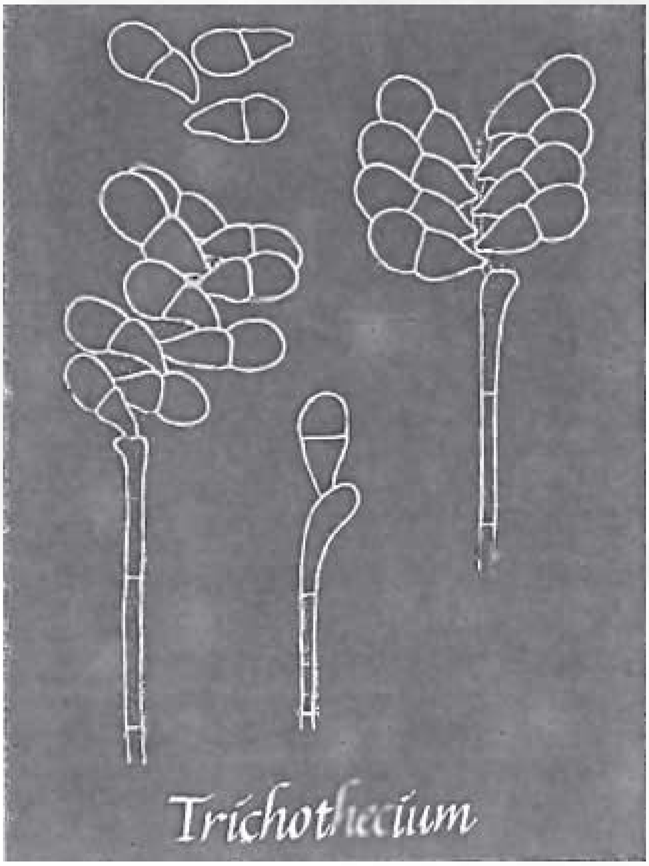

Figure 227 - Drawing of conidia and sporulating structure of *Trichothecium*.

Measures of Control: Air filtration and maintenance of good hygiene in the laboratory.

Macroscopic Appearance: Mycelium initially whitish; soon pinkish with spore production; and typically slow growing on malt agars. *Trichothecium* is a powdery *Penicillium* type mold.

Microscopic Characteristics: Conidia measuring 12-18 x 4-10 microns; colorless to brightly colored; two celled; pear shaped, ellipsoid or ovoid; borne in clusters with the basal cell being smaller than the terminal one; and positioned at the apex of tall, thin, unbranched, but septate conidiophores. Spore bunches are attached to one another either in a chain-like fashion or in loose groups but not lineally.

History, Use and/or Medical Implications: One mold notable. *Trichothecium roseum* Link ex Fr. secretes an antibiotic (trichothecin) that is toxic to bacteria, fungi and animals.

Comments: More frequently seen in the course of agar culture than on grain, this contaminant can become a formidable problem if not detected early, and if large spore populations are permitted to develop within the laboratory.

Also occurring on compost and occasionally on the casing soil, particularly where nitrogen enriched compounds have not been converted into protein usable to the mushroom mycelium. By itself it is not strongly inhibitory to mushroom mycelium, but thrives in habitats generally unsuited for good mushroom growth. Adhering to good compost practices and following standard hygienic procedures prevents this fungus from occurring.

See also *Fusarium*, a genus containing several pinkish colored contaminants and *Geotrichum*, a genus known for the Red Lipstick molds.

Verticillium (Dry Bubble)

Class: *Fungi Imperfecti*

Order: *Moniliales*

Family: *Moniliaceae*

Common Names: Dry Bubble; Brown Spot; and Verticillium Disease.

Latin Root: From "verticillus" meaning whorled or having branches on the same plane, in reference to the shape of the conidiophore.

Habitat & Frequency of Occurrence: A common parasite of the fruitbody. *Verticillium* is promoted during cropping under conditions of excessive humidity combined with inadequate air circulation. *Verticillium* grows within a broad temperature range although warmer temperatures (62°F. and above) are preferred. Singer (1961) reported an optimum of 72°F. *Verticillium* abounds in soils and is introduced into the growing environment via the materials composing the casing.

Medium Through Which Contamination Is Spread: Primarily transmitted from one infected region to another by mushroom harvesters, flies and insects. Watering infected mushrooms further spreads *Verticillium* spores.

Measures of Control: General hygiene maintenance; proper picking and cleaning practices; removal or isolation of infected cultures; increasing air circulation; lowering of humidity; and elimination of flies and mites. If *Verticillium* is evident before a crop is harvested, carefully pick the infected mushrooms, seal them in a plastic bag and leave the growing room with minimal contact with unaffected areas. *Verticillium* spores are highly viscous and are best transmitted by motile hosts, especially mites and other insects. Never water an infected bed until the diseased mushrooms have been removed and the infected zones have been salted with alkaline buffer (baking soda, sodium hypochlorite).

Macroscopic Appearance: Slightly infected mushrooms characterized by brown colored spots or streaks on the basal or upper regions of the stem and on the caps of developing primordia. These spots become grayish colored from spore production. Afflicted mushrooms often bend towards the side that is infected. If the mushrooms do develop at all, they are typically tilted to one side or the other. *Verticillium* attacks developing fruitbodies - the more severely infected are grossly malformed, especially young primordia which are turned into sclerotia-like balls of amorphous whitish mycelia. More mature but diseased mushrooms have a deformed pileus, sometimes with a "hair lip", and frequently with a downy grayish mycelium over the cap. The stem can be covered with a downy mycelium and often vertically splits, roughly resembling a peeled banana. The cap becomes disproportionately small relative to the fatter than normal stem. The overall texture of the mushroom is dry and leathery.

When this mold attacks *Psilocybe cubensis*, there are several additional characters worthy of note. Parasitized *P. cubensis* caps frequently become plane at an early stage. The stem becomes swollen and hollow, narrowing radically towards the apex. Only in an extremely humid environment does a downy mildew develop over the cap and stem surface. The "Verticillium spots" so commonly reported by growers of *Agaricus*, a white mushroom, are more accurately called "Verticillium streaks" on *P. cubensis*, a mushroom with a brownish cap and a whitish stem.

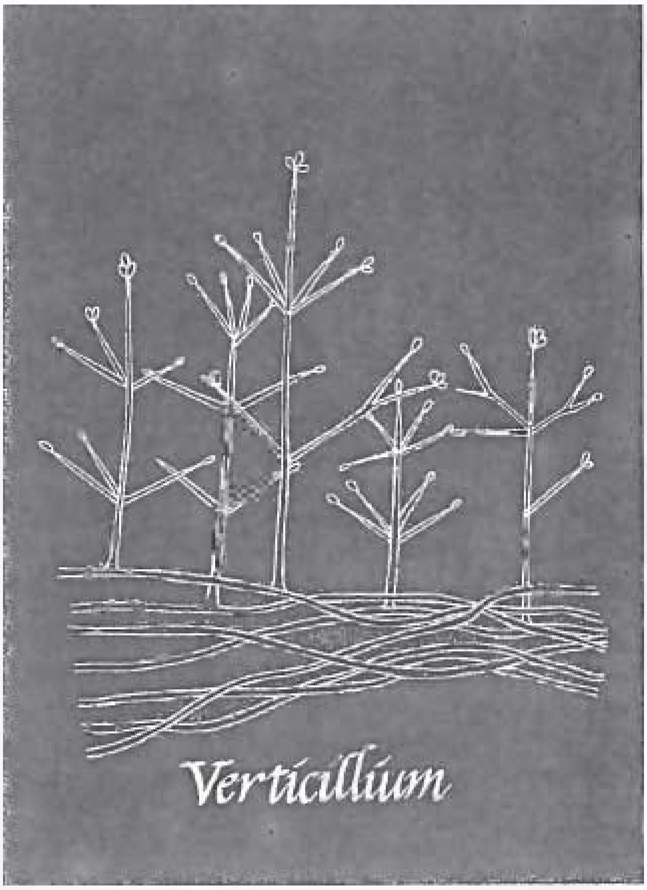

Figure 228 - Conidia and sporulating structure of *Verticillium*.

Microscopic Characteristics: Conidia hyaline; unicellular; ovoid to ellipsoid; minute, measuring 1-3 x 1-2 microns; borne singly or in small groups at the tips of narrow branches that whorl from a central trunk at regular intervals. Conidiophores are slender and relatively tall.

History, Use and/or Medical Implications: Apparently inocuous, no pathogenic species are known.

Comments: *Verticillium* is the most common fungal disease parasitizing the mushroom crop and the bane of both small and large scale growers. One misfortune of losing an early flush to *Verticillium* disease is the increased probability of other diseases appearing. Split stems open the mushroom up to attack by numerous insects and other pathogens. Not surprisingly, the sciarid fly is a vector for the spread of *Verticillium* spores from parasitized mushrooms to healthy ones. It becomes clear that if conditions are right for *Verticillium*, the conditions are right for other molds. The cultivator may soon have to deal with not one contaminant, but many.

Verticillium malthousei Ware is synonomous with *Verticillium fungicola*. Both are "brown spot" fungi that envelope the mushroom with a fine grayish mycelium and cause brownish lesions on their surfaces.

Verticillium albo-atrum is another species in mushroom culture, although not as frequently seen.

An easy method for the home cultivator to distinguish *Verticillium* infection from *Trichoderma* is to plate out the suspect mold on malt agar media. If the mold is *Trichoderma*, forest green colonies of mycelium will form. Other than green colonies of mycelium suggests the contaminant be *Dactylium* or *Verticillium*.

Usually one sees *Trichoderma* blotch simultaneous to or after the occurrence of green mold colonies on the casing layer. If there is no evidence of green mold on the casing layer and the mushrooms display these symptoms, then the mold is probably *Verticillium* or *Dactylium*. *Dactylium* can be distinguished from *Verticillium* by its locus and manner of infection. *Dactylium* is a grey, aerial mold, fast growing and obvious on the casing. *Verticillium* is primarily evident on the fruitbody and scarcely seen on the casing.

Steane (1979) reported that *Agaricus bitorquis* seemed especially resistant to *Verticillium* disease whereas *Agaricus brunnescens* was more susceptible to it. Furthermore, he noted that farms regularly suffering from this disease could greatly reduce the level of infection by intermittently growing *A. bitorquis* between *A. brunnescens* crops.

A saprophyte and parasite causing "wilt disease" of many plants, particularly garden vegetables, *Verticillium* is abundant in most soils. Some *Verticillium* species are endoparasitic to nematodes - their spores germinate in the mouth tubes of the nematode with the resulting mycelia quickly digesting the organism from within. Other pathogens that have similar symptoms to one or more of the various stages of *Verticillium* are: *Dactylium*; *Trichoderma*; *Mycogone*; and Virus.

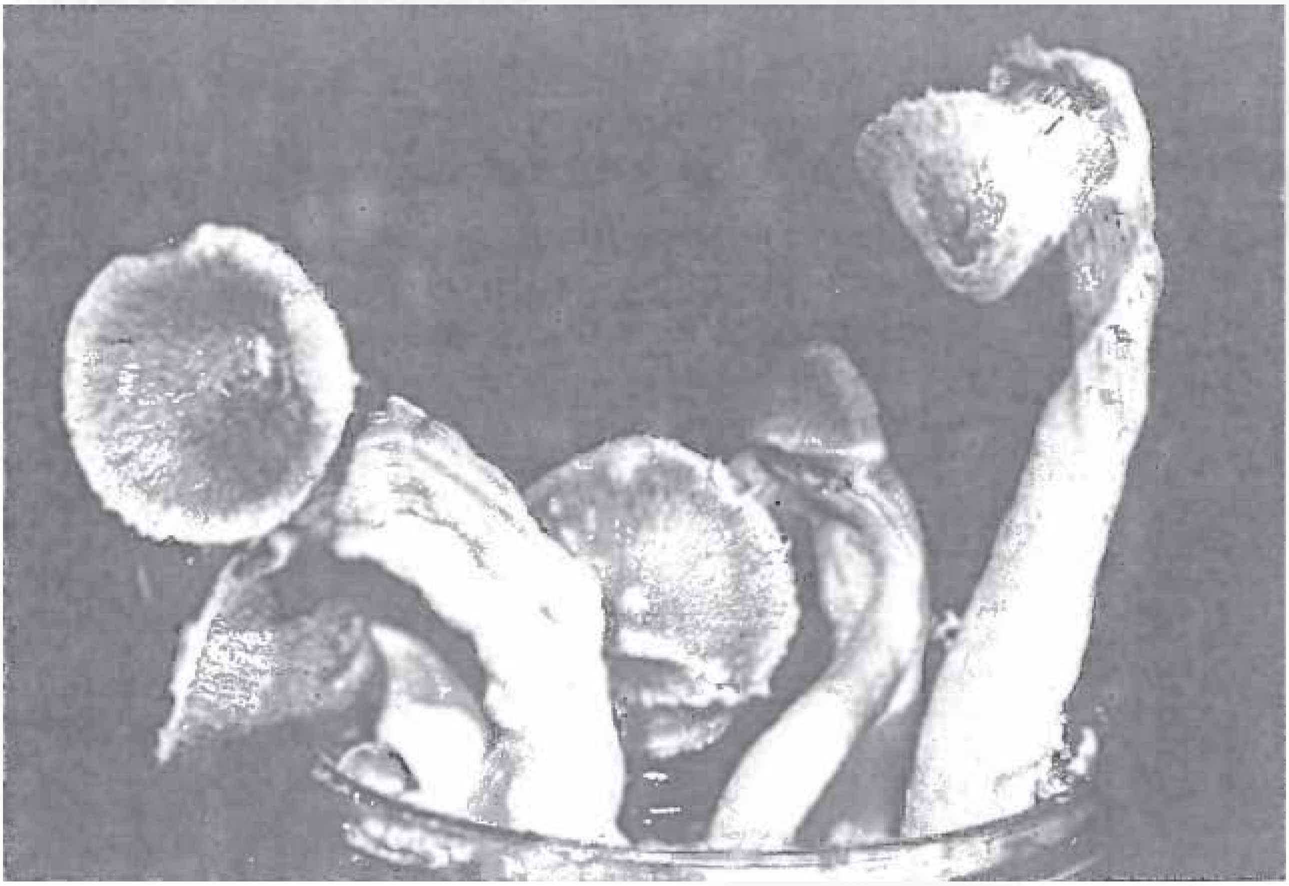

Figure 229 - *Verticillium* attacking *Psilocybe cubensis.*

XIV. THE PESTS OF MUSHROOM CULTURE

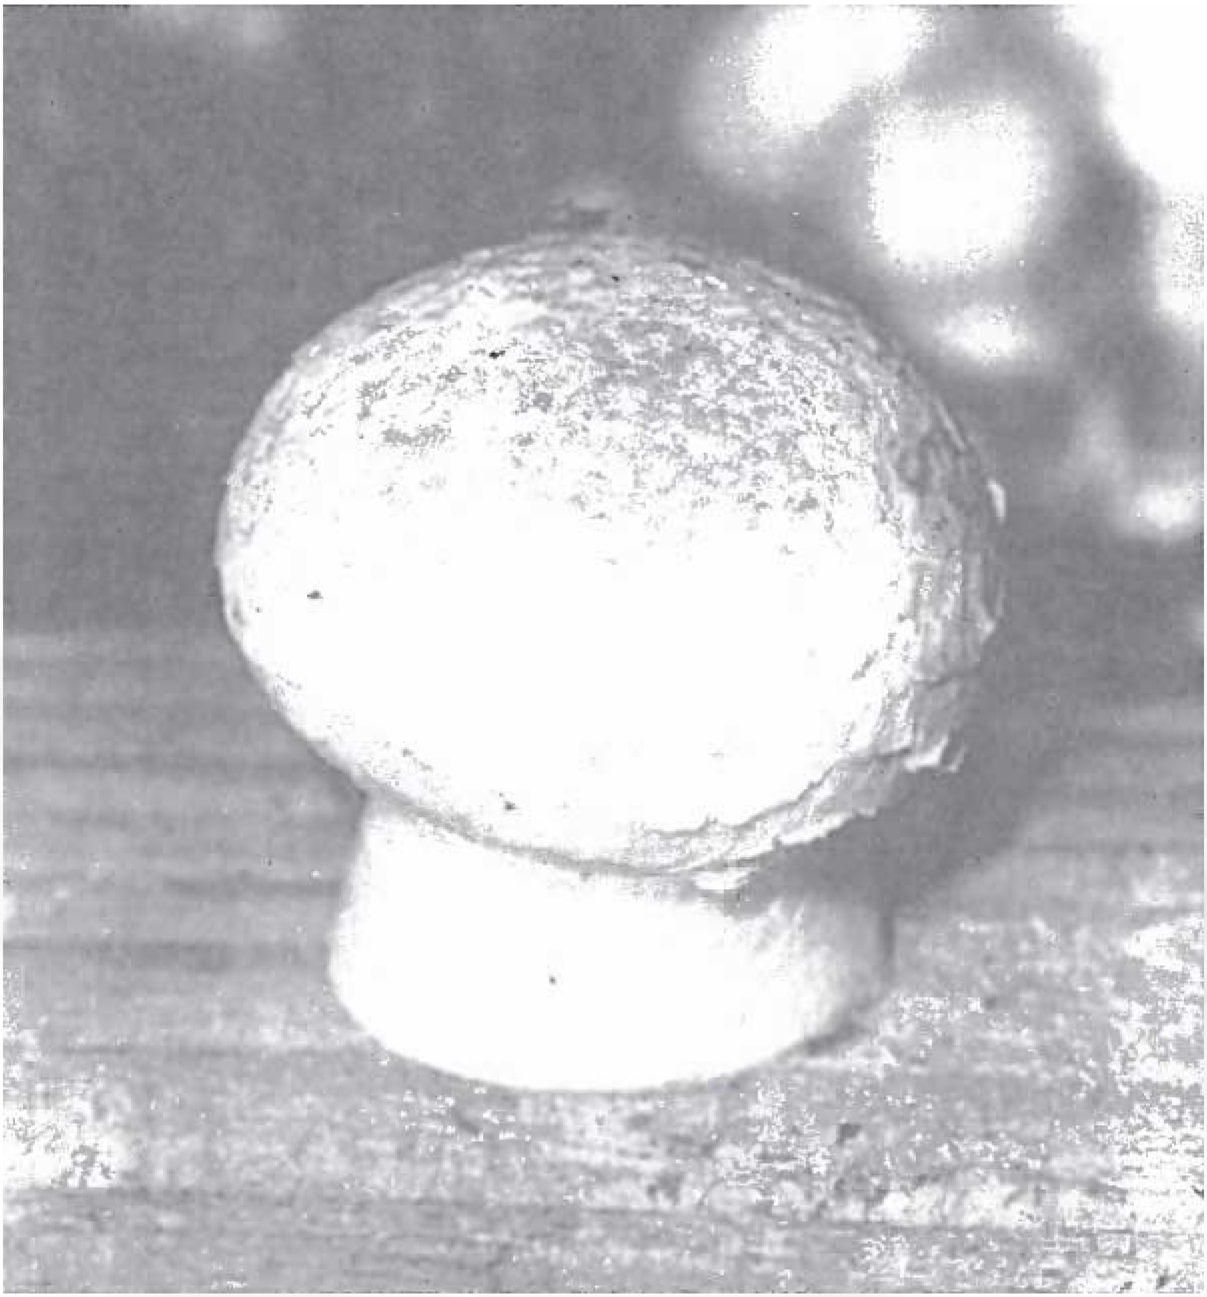

Figure 230 - Red Pepper Mites swarming on *Agaricus brunnescens*.

Mushroom Flies

Mushroom flies and midges are present in nature wherever fungi are found. Attracted by the odor of decomposing manure and vegetable matter, as well as the smell of growing mycelium, these insect pests zero in and lay their eggs on or near the mycelium and fruitbodies. Under proper conditions these eggs hatch. But it is the larvae that do the extensive damage to the mushroom plant, either by directly feeding on the mycelial cells or tunneling through the mushroom fruitbody. Because of the concentration of attractive odors, a commercial mushroom farm is always under siege by these pests. To insure insect free crops, certain measures are necessary. Unfortunately the bulk of these control measures involve insecticides, an approach not recommended by the authors. The use of insecticides is not only costly and hazardous to human health, but also represents a short term solution of a symptom rather than the solution of the problem itself. The answer to disease and pest control in mushroom growing is strict hygiene for which there can be no substitute.

Fly Control Measures

1. Pasteurization periods and temperatures must be sufficient to kill all stages of insect growth - 140°F. for 2 hours in composts or other bulk substrates.
2. All Phase II, spawning, spawn running and cropping rooms must be airtight. Physically excluding insects from these areas is the most positive control one can exercise. Even the smallest crack can serve as an entrance to the growing room. The spawn running rooms should be the most secure with access to these areas restricted. All doors should be weather-stripped and tight fitting. Positive pressure and air locks also help.
3. All tools and implements should be cleaned and disinfected before use on a new crop. A commonly used disinfectant is a 2% chlorine solution.
4. Breeding areas must be prevented by removing from the premises all excess or spent substrates, used grains, mushroom trimmings and other related by-products.
5. The growing room and all containers should be washed and disinfected between crops. Wood in particular harbors contaminants, including virus infected mushroom mycelium. Treatment of wood with cuprinol or copper sulfate is common. Petroleum based products should be avoided.
6. Fresh air intakes and exhaust vents must be screened with fine mosquito netting. Be sure there are no cracks around the filters and fan housing.
7. The room should be equipped with an insect monitor. The use of a monitor alerts the grower to fly emergence from within the growing room or to fly entry from the outside. The monitor can be as simple as a 12" x 12" plywood board to which a small black light (long wave UV) is centrally mounted. On either side of the light sticky paper is attached. There are also small pest lights commercially available. (See Resource section in the Appendix).

Sciarid Fly

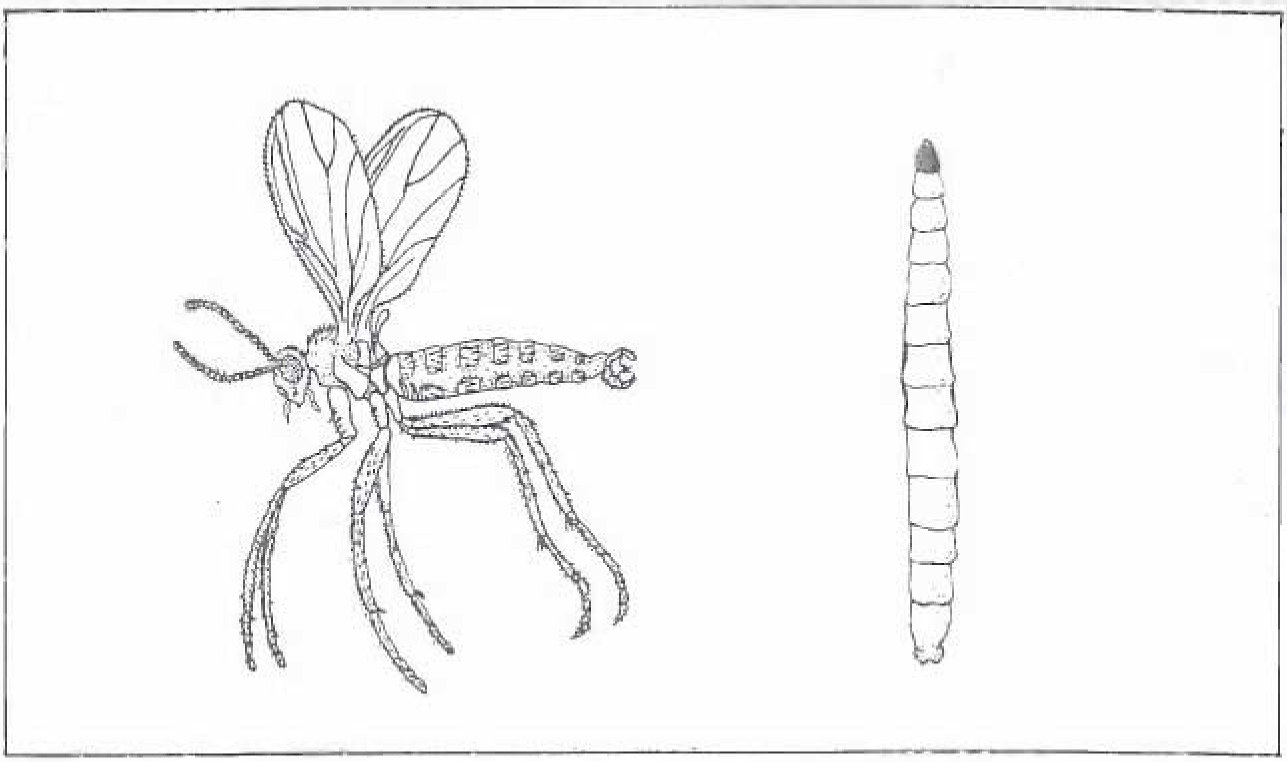

Figure 231 - Sciarid adult and its larva. (Adapted from P.R. VanderMeer; Penn. St. Univ. Coop. Ext. Ser.)

Order: *Diptera*

Family: *Lycoriidae* (Fungus Gnats)

Genus/Species: *Lycoriella solani, Lycoriella mali, Lycoriella auripila*

Common Names: Sciarid Fly, Big Fly

Natural Habitat: Predominantly saprophytes, living on wild mushrooms, rotting wood, leaf mold and manure piles. Maturing mushrooms are frequently infested with sciarid larvae, the so-called "worms" that commonly ruin choice wild edibles.

PHYSICAL CHARACTERISTICS:

Mature Stage: Sciarids are small gnat-like flies characterized by two long segmented antennae, large compound eyes, a black head and thorax and a yellow segmented abdomen. Females are about 3 mm. long and can be distinguished by the swollen abdomen which ends in an ovipositor. Males are about 2 mm. long and have a narrow abdomen ending in a distinct clasper.

Larval Stage: Larvae measure 6-12 mm. long with twelve abdominal sections and a distinct black shiny head. The long creamy white body has a semi-transparent cuticle with a visibly darkened alimentary canal. Larvae go through four development stages, or instars, before pupating.

Pupal Stage: Fully mature larvae spend two to three days spinning a cocoon of fine silky threads and compost fragments. These threads are sometimes detected as slime trails left behind in the substrate as the wandering larvae pupate. Once the cocoon is finished, the larva contracts into a pupal stage, thus beginning the transition to the adult stage. Pupae are 2-4 mm. long and change from white to almost black.

Life Cycle: Developmental period in days

Temperature	Egg	Larva	Pupa	Adult
At 75°F.	2	16	3	5-7
At 61°F.	7	23	8	(no data)

Sciarids thrive in the summer and fall with populations building to a peak in September and October. Sciarids then die with the onset of cold outside temperatures.

Comments: The sciarid fly is responsible for considerable damage to commercial *Agaricus* crops. Attracted by the smell of newly pasteurized compost, sciarids home in from miles away. A female can lay between 150-170 eggs at a time. Eggs laid in the compost just after Phase II composting hatch quickly into larvae during the spawn running period. These larvae then feed on the running mycelium as well as compost, which is broken down into a foul smelling, soggy mass, totally unsuitable for spawn growth. Massive infestations can cause total crop failure.

At lower infestation levels, larvae migrate into the casing layer and then emerge just as the first mushroom pins appear or as late as the first flush. These adults lay more eggs in the casing, and the newly hatched larvae attack both mycelia and mushrooms. Symptoms of this attack include:

1. Dead pinheads.
2. Pins or mushrooms that are loosely connected to the casing due to severed mycelial connections.
3. Brown or black spots on pinheads or on the stems of mushrooms.
4. "Salt shaker pins" perforated by larval tunnels.
5. Browning of the stem where cut.

Secondary damage to mushroom crops by sciarid flies comes from their role as carriers of mites and diseases, including the pathogens *Verticillium* and *Trichoderma*. A single sciarid fly can carry up to 20 mites!

Phorid Fly

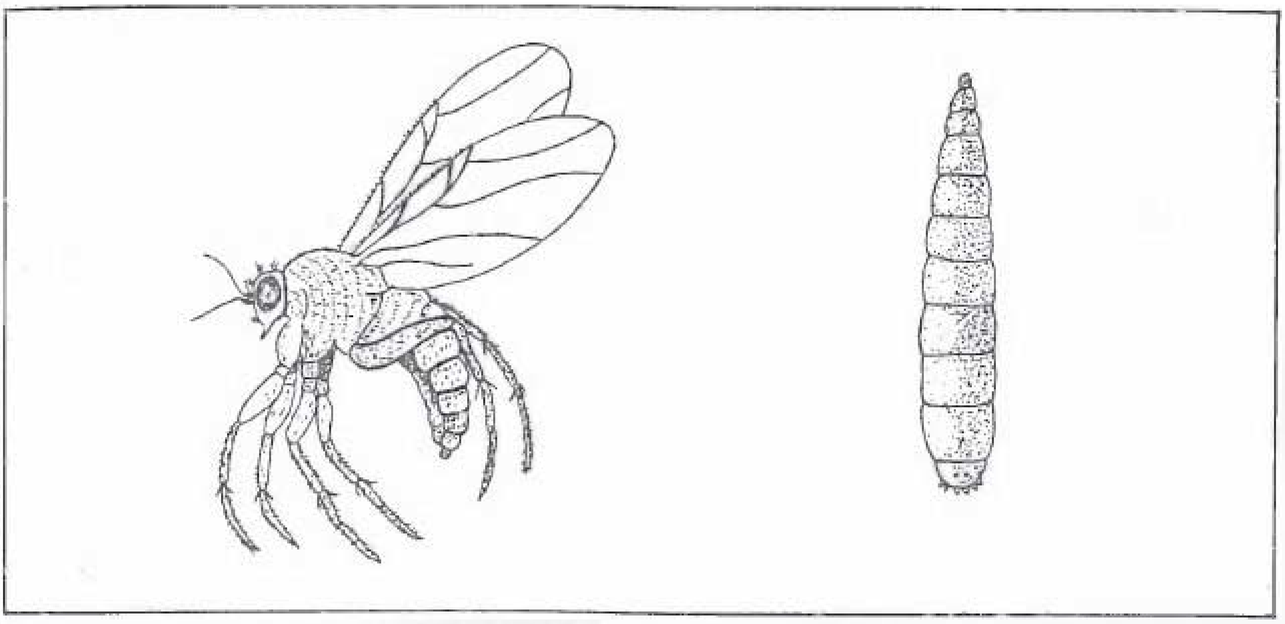

Figure 232 - Phorid fly and its larva. (Adapted from P.R. VanderMeer; Penn. St. Univ. Coop. Ext. Ser.)

Order: *Diptera*

Family: *Phoridae*

Genus/Species: *Megaselia nigra, Megaselia halterata*

Common Names: Phorid Fly, Dung Fly

Natural Habitat: Commonly inhabiting manure piles and rank, decaying vegetation; feeding on wild fungi and their mycelia. Phorid larvae are frequently seen tunneling through wild mushrooms.

PHYSICAL CHARACTERISTICS:

Mature Stage: Distinguishing features are a humped back, a rapid jerky run, a rounded third antennal segment and a yellowish to reddish brown back. Adults measure 2-5 mm. long. Females live 16 days and males live 10 days.

Larval Stage: Larvae are 6-10 mm. long, white and semi-transparent. The head is characterized by a pair of "mouth hooks" with seven teeth. The segmented body tapers from the head to the posterior end. Larvae pass through three instars.

Pupal Stage: Pupae are white at first then becoming pale yellow to brown. They can be distinguished by a pair of curved black respiratory horns.

Life Cycle: Developmental period in days			
Temperature	**Egg**	**Larva**	**Pupa**
At 75°F.	2	5	8
At 61°F.	4	14	28

Comments: Phorids can do extensive damage to the mushroom crop and are considered the principal mushroom pest in western Europe. Mated female phorids are drawn by the odor of mushroom mycelium. This attraction increases during the spawn running period and peaks at full colonization. Each female can lay up to 50 eggs which are placed in close proximity to the mycelium. In mature mushroom crops, females lay eggs on the gills, in the casing, and adjacent to young pinheads. Once hatched, the larvae feed on the mycelium, then tunnel into the mushrooms through the base of the stem. Arising from these tunnels are secondary bacterial infections causing further damage and brownish discolorations.

The fact that females will not lay eggs in total darkness gives the grower an effective method for preventing Phorid infestation during spawn running.

Cecid Fly

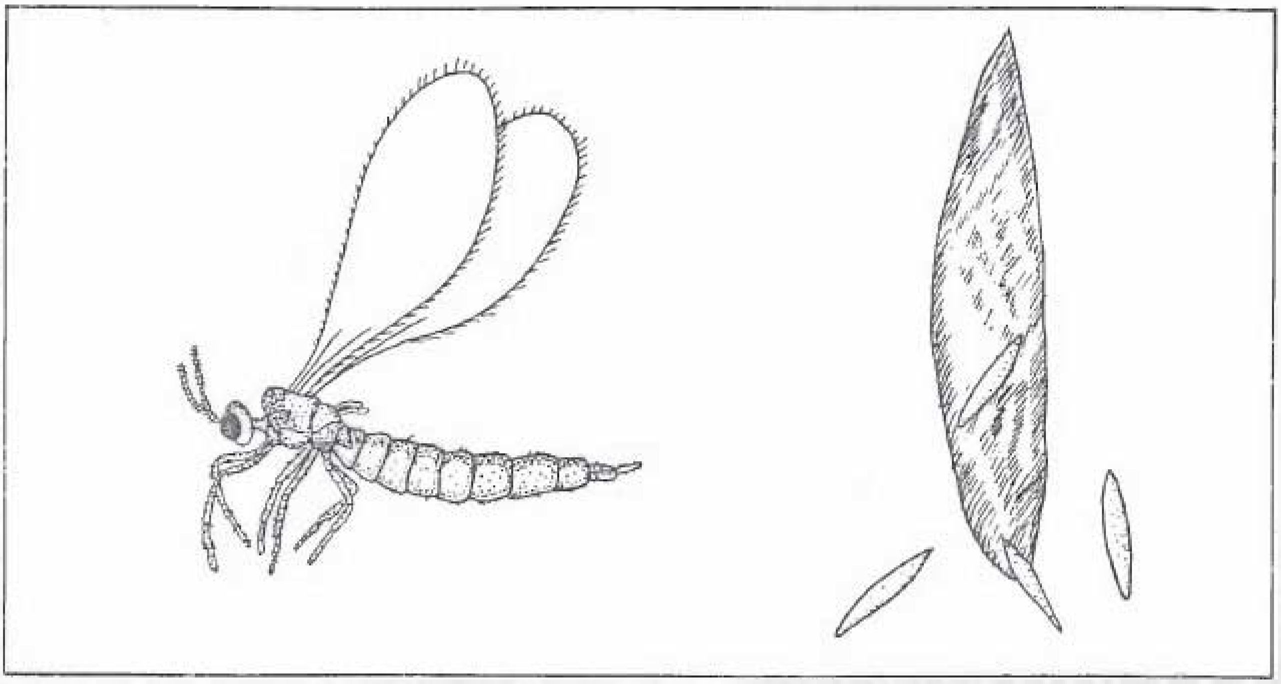

Figure 233 - Cecid fly and its mother larva. (Adapted from P.R. VanderMeer; Penn. St. Univ. Coop. Ext. Ser.)

Order: *Diptera*

Family: *Cecidomyiidae*

Genus/Species: *Heteropeza pigmaea, Mycophila speyeri*.

Common Names: Cecids, Gall Midges

Natural Habitat: Commonly inhabiting decaying wood, rotting vegetation and manure piles or wherever fungal mycelium occurs.

PHYSICAL CHARACTERISTICS:

Mature Stage: Adult cecids measure less than 1 mm. long making them almost invisible to the naked eye. *H. pigmaea* are orange with a long segmented abdomen and segmented antennae. Wing venation or structure is noticably absent except close to the thorax.

Larval Stage: Newly born larvae are 1 mm. long and 2-3 mm. when mature. *H. pigmaea* are white to cream; *M. speyeri* are bright orange. Larval movement is facilitated by free water, whereas in dry conditions this movement is by flexion, jumping as far as 2 cm. Larvae are photokinetic (moving to light) and can reproduce through paedogenesis, a process whereby mother larvae give birth to daughter larvae. Under optimal conditions mother larvae can produce 14-20 daughter larvae in six days. Thus, in a short period of time a population explosion can occur.

Pupal Stage: *H. pygmaea* larvae molt to a rigid "hemi-pupa" within which new daughter larva evolve. Conditions favorable to larval growth lead to a "resting mother larvae" stage which can remain alive up to 18 months. *M. speyeri* has neither of these particular attributes although it also performs paedogenesis. Larvae of both species can change to "imago" larvae, form only one instar, then molt to free pupae, emerging as adults five days later.

Life Cycle: Developmental period in days			
Egg	**Mother Larva**		**Daughter Larva**
2	5-6	(2)	5-6

Comments: Cecid larvae pierce or tear growing hyphae, sucking out the contents. The main loss suffered by commercial growers is contamination of the mushrooms by larvae. *H. pygmaea* can also carry a bacterium which produces longitudinal brown stripes on the stem. In the infected mushrooms, tiny black droplets of fluid form on the gills, which then become spotted or turn black.

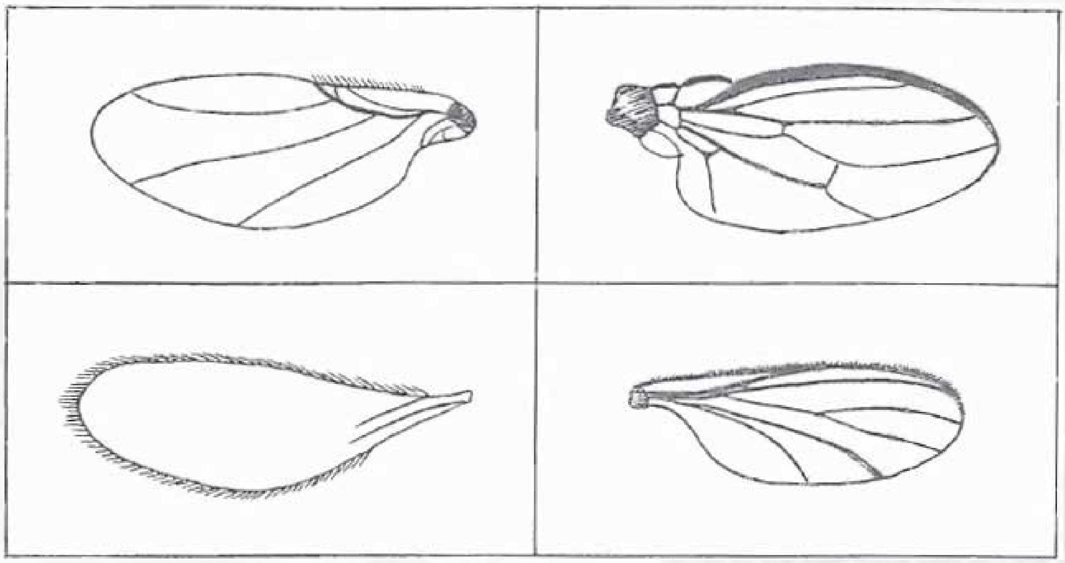

Figure 234 - Wing venation of mushroom flies: clockwise from top right, *Leptocera*, Sciarid, Cecid and Phorid.

Order: *Diptera*

Family: *Sphaeroceridae* (*Borboridae*)

Genus/Species: *Leptocera heteroneura*

Natural Habitat: Associated with manure, compost piles and decaying organic matter.

PHYSICAL CHARACTERISTICS:

Mature Stage: *Leptocera* has large red compound eyes and with a yellow and black striped abdomen. *Leptocera* flies are very similar to phorid flies but are smaller and have a distinctive wing venation. They somewhat resemble the common fruit fly.

Larval Stage: Larvae have a blunt posterior end tapering to a slender head which is equipped with mouth hooks. *Leptocera* larvae are very similar to house fly maggots in appearance.

Pupal Stage: Pupae are golden brown and barrel shaped.

Life Cycle: Developmental period in days		
Egg	**Larva**	**Pupa**
3	14-28	10-14

Comments: The *Leptocera* fly acts as a vector for disease organisms and is frequently associated with bacterial infections. It is a known carrier of mites.

Mushroom Mites

Mites are very small spider-like insects that live and breed in decomposing vegetable matter, feeding on molds present therein. Optimum breeding environments are moist and warm, giving rise to a rapid succession of generations and exponential growth. Under adverse conditions certain mites have the ability to change into an intermediate stage called a "hypopus". The hypopae have flattened bodies, short stubby legs and a sucker plate with which they attach to moving objects. These attributes facilitate dispersal. An excellent survival mechanism, it is the hypopae that are commonly carried by flies. A typical life cycle for mites in days is:

Temperature	Eggs	Larvae	Protonymph	Tritonymph	Total
75°F.	6	2	2	3	13
60°F.	11	8	6	11	36

Mites are known to eat mushrooms and their mycelia. Additionally they devalue the crop and crawl onto pickers, causing temporary discomfort. Their presence is an indication of unsatisfactory substrate preparation and insufficient pasteurization times and/or temperatures.

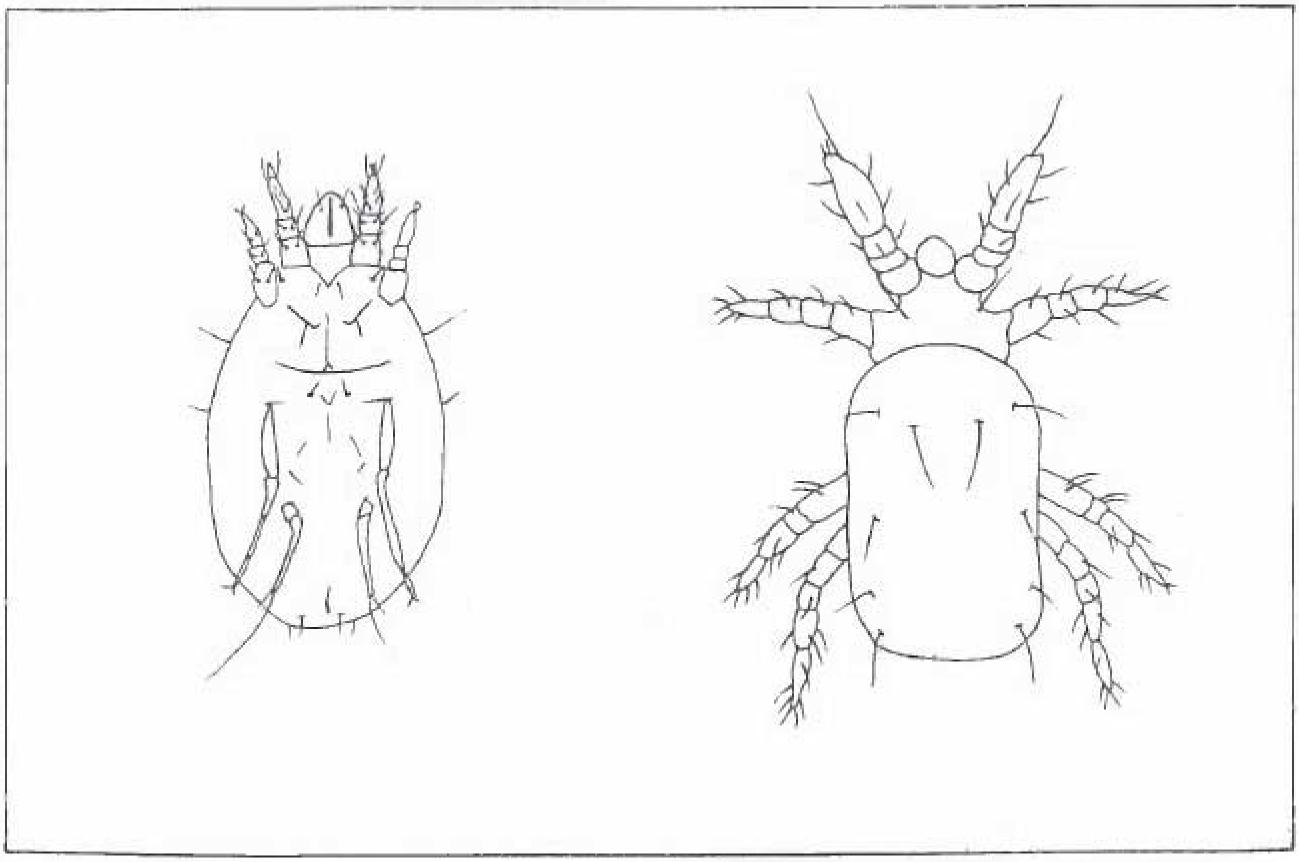

Figure 235 - Straw mites.

Order: *Arcana*

Family: *Tyrogelyphidae*

Genus/Species: *Tyrophagus putrescentiae, Caloglyphus mycophagus*

Common Names: Straw or Hay Mites.

Discussion: Straw mites have soft translucent pinkish or yellowish bodies punctuated by long flexible hairs. One female is capable of producing 500 eggs in a lifetime. Commonly found in hay or straw piles, these saprophytic mites are endemic to foul compost. They feed on molds and bacterial contaminants of the mushroom crop and also eat mycelium and mushrooms, making small irregular pits in the stem and cap. These pits can later become infected by bacteria.

Order: *Arcana*

Family: *Eupodidae*

Genus/Species: *Linopodes antennaepes*

Common Name: Long Legged Mushroom Mite.

Discussion: This mite is easily recognized by its long front legs which are twice the length of the light, yellowish brown body. It is not believed to be directly injurious to the mushroom crop and in fact is a predator on other mite species.

Order: *Arcana*

Family: *Tarsonemidae*

Genus/Species: *Tarsonemus myceliophagus*

Common Name: The Mushroom Loving Mite.

Discussion: *Tarsonemus* mites are very small, 180-190 microns long, with pale brown, shining, oval bodies. They occasionally swarm in masses on mushroom caps but otherwise are rarely seen except by microscopic examination. Females produce an average of 22 eggs in a lifetime of 2-8 weeks. These mites cause a bright reddish-brown discoloration at the base of the mushroom stem and may cut the stem's mycelial connections. Known to survive normal compost pasteurization temperatures, they can carry a virus disease to *Agaricus brunnescens*.

Order: *Arcana*

Family: *Pyemotidae*

Genus/Species: *Pygmephorus sp.*

Common Names: Red Pepper Mites; Pygmy Mites.

Discussion: Pepper mites are small (250 microns long) with yellowish brown, wedge-shaped bodies, crossed by a central whitish band. Red pepper mites are often seen as a swarming jostling mass, on mushroom caps or the surface of the casing. These mites are commonly associated with *Penicillium* and *Trichoderma* molds, upon which they feed.

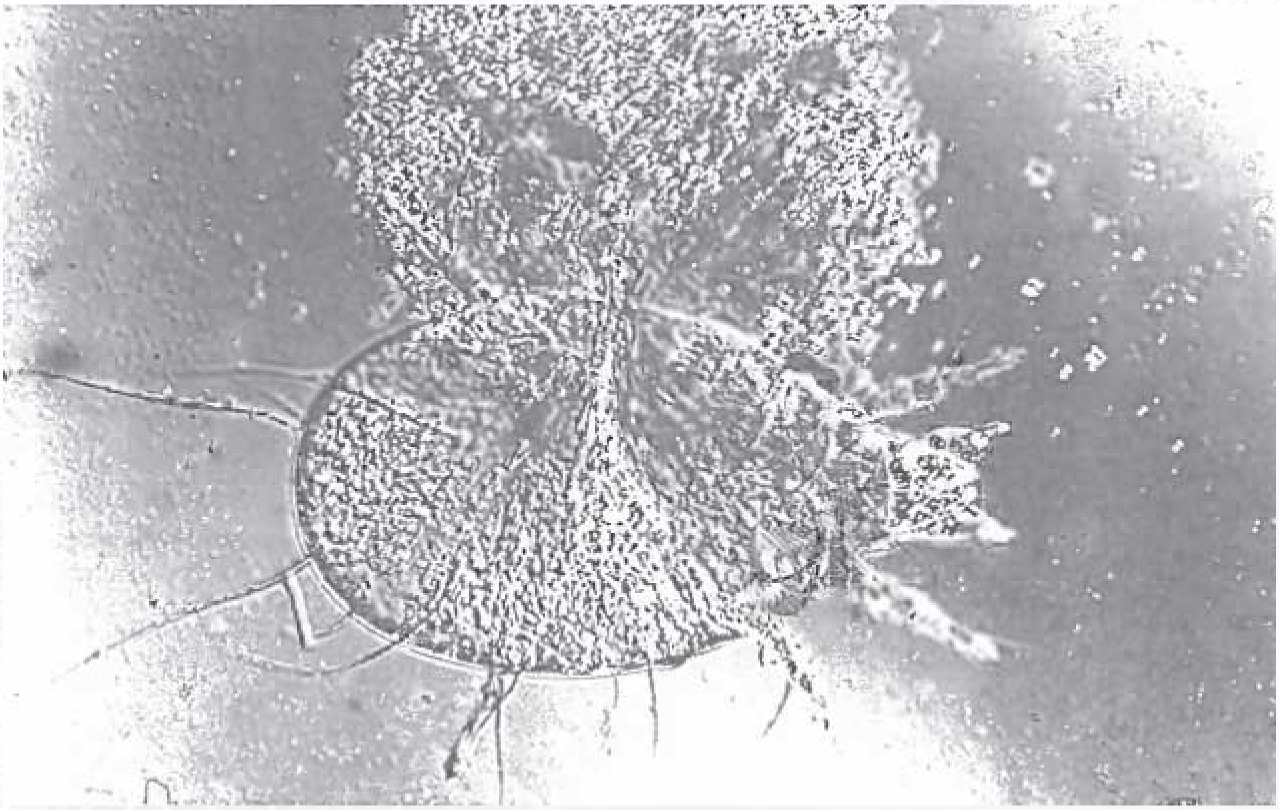

Figure 236 - Light micrograph of Red Pepper Mite. Note that darkened shapes by front leg are *Panaeolus subbalteatus* spores. See also Figure 230.

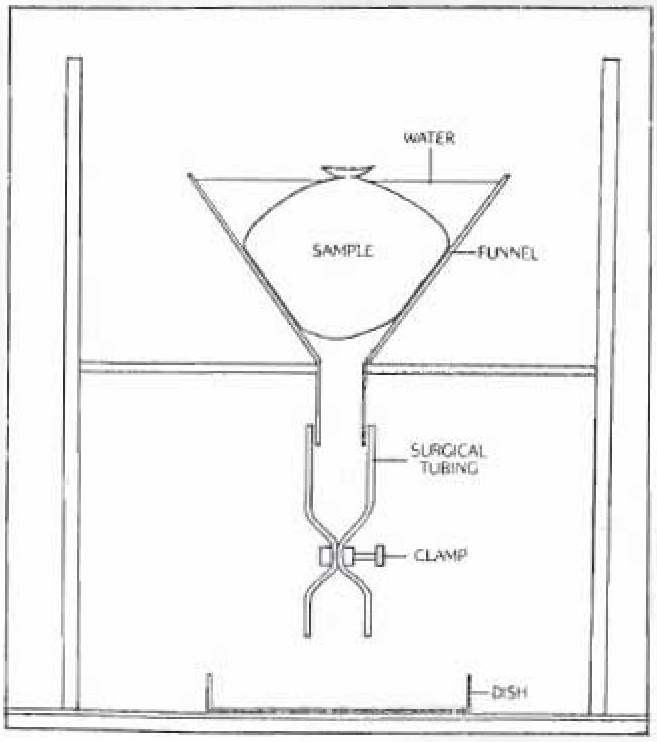

Figure 237 - Nematode testing apparatus. Sample is wrapped in gauze and submerged in a water filled funnel. After twenty-four hours, a small amount of water is drawn off and examined with a magnifying lens or dissecting scope.

Nematodes (Eelworms)

Nematodes or eelworms are microscopic roundworms which live in soil, decomposing organic matter, fresh or salt water, or on living host plants, fungi, insects and animals. Nematodes can survive up to six weeks without food and are unaffected by freezing. With eight billion nematodes in each acre of soil, they are one of the most numerous creatures on earth.

Water is essential for locomotion and breeding. Swimming in an eel-like fashion and because of their minute size, nematodes can live in the thinnest films of water. With sufficient water, nematodes rise to the surface of their environment. In moist casing, large numbers of nematodes are visible as a shimmering veneer on the casing surface. This behavior is called "winking" and is caused by the nematodes standing on their tails and waving their bodies in the air. Considered to be an adaptation for dispersal, the winking nematode adheres by means of a sticky outer skin to whatever they come in contact with, be it a fly, mite, human hand or clothing. This same outer skin protects the nematode from adverse conditions.

If dried slowly, nematodes can change to a "cryptobiotic" or "cyst" state, thereby preserved for years until reactivated by water. In this cyst state, nematodes are also able to persist in high temperatures that would otherwise be lethal.

Parthenogenesis, the ability for females to breed asexually without males, is common among nematodes and leads to very rapid population expansion. By this means, a single nematode can breed millions of descendants within a few weeks. Nematodes can also reproduce sexually, but not as rapidly.

Nematodes present in mushroom culture can be classed into two basic types according to their feeding habits: **saprophagous** and **mycophagous**.

Saprophagous Nematodes

Genus/Species: *Rhabditus spp.*

Saprophagous eelworms are characterized by a tube-like mouth through which they suck nutrient particles suspended in water. These nutrients are comprised of organic matter and its accompanying microorganisms, particularly bacteria. Because bacteria occur in large numbers in both mushroom compost and casing soil, these materials provide excellent breeding grounds for saprophagous eelworms.

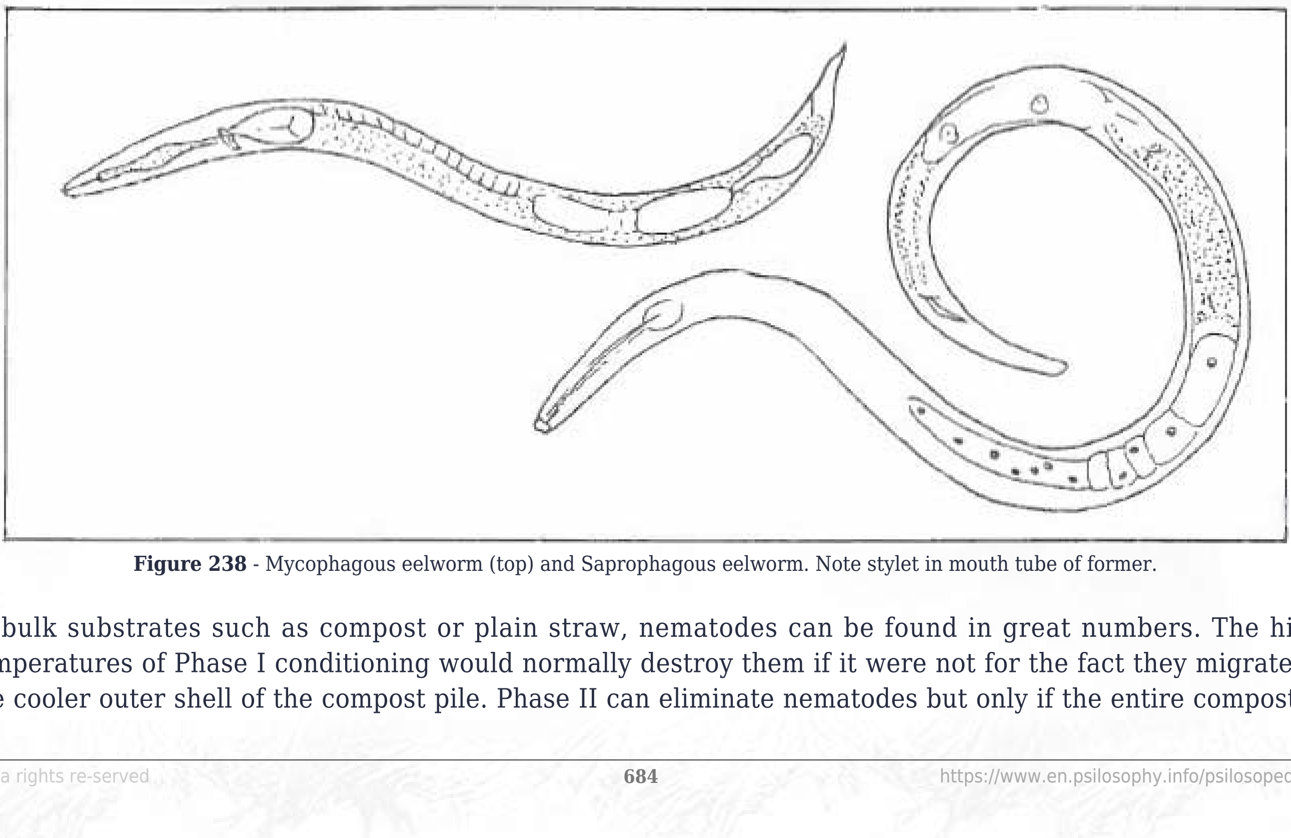

Figure 238 - Mycophagous eelworm (top) and Saprophagous eelworm. Note stylet in mouth tube of former.

In bulk substrates such as compost or plain straw, nematodes can be found in great numbers. The high temperatures of Phase I conditioning would normally destroy them if it were not for the fact they migrate to the cooler outer shell of the compost pile. Phase II can eliminate nematodes but only if the entire compost is subjected to pasteurization temperatures. In a properly prepared and thoroughly pasteurized substrate, the mushroom mycelium consumes all free water and then feeds on the bacterial population. This creates a "bacteriostatic environment", which effectively limits nematode growth capabilities. In an uneven substrate with overly wet and dry areas, however, the nematode's ability to breed increases. Wet areas are particularly suitable for eelworms to breed and feed. And, as their population increases, the build-up of waste material from metabolic excretions soon fouls the substrate, rendering it unsuitable for mycelial growth. These excretions result in similar damage to infested casing soils.

Although saprophagous eelworms are not primary pathogens, their presence indicates improper hygiene or imbalanced growing conditions. For this reason, control measures focus on prevention rather than treatment. In fact, there are no practical means to treat infested areas that would not likewise harm the mushroom mycelium.

Mycophagous Nematodes

Genus/Species: *Ditylenchus myceliophagus*; *Aphelenchiodes composticola*

Mycophagous eelworms feed directly on mushrooms. They are characterized by a mouth stylet or needle with which these eelworms puncture hyphae, inject digestive juices and then suck out the cellular contents. The damaged cell, drained of its cytoplasm, soon dies. Feeding continually and moving from cell to cell, mycophagous eelworms can soon destroy whole mycelial networks. In infected substrates, the fine mycelial growth disappears, leaving only the coarse strands which give the appearance of stringy growth. Eventually the substrate becomes soggy and foul smelling, a condition further promoted by the build-up of anaerobic bacteria. Often the nematode trapping fungi, *Arthrobotrys* spp. develop in association with them. It is visible as a fine grayish mold-like growth. Although the presence of this mold is a useful indicator of nematode infestation, it is not a true control for these organisms.

Mycophages differ from saprophages in their slower non-parthogenetic reproduction and their lack of the "winking" behavior mentioned earlier. Both Mycophagus species can reproduce 30-100 fold in about two weeks at 70-75°F.

XV. MUSHROOM GENETICS

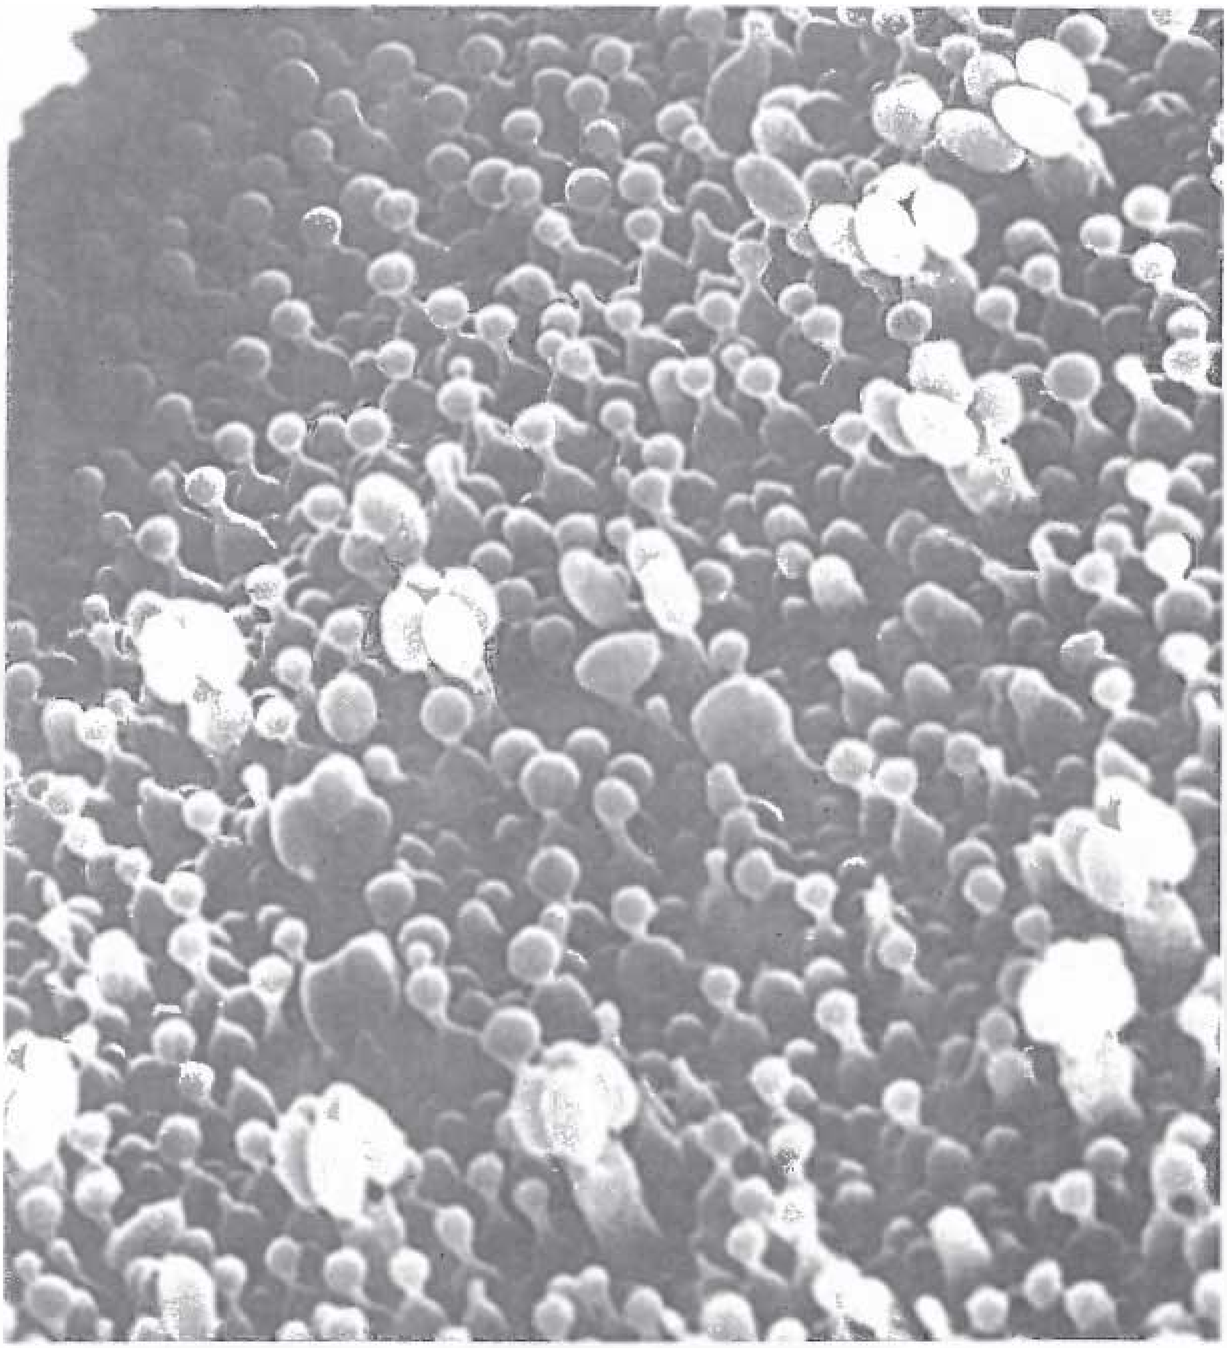

Figure 239 - Gill face of *Psilocybe cyanescens* populated with fertile spore-bearing basidia and sterile cells called pleurocystidia.

Introduction

This chapter discusses what genes are and what they do. It addresses the relationship between an individual's set of genes and the characteristics of that individual. The implications of genetics for the grower or breeder of mushroom strains are examined and an improved, easy technique for generating cultures from spore prints will be presented.

What Are Genes?

Genes contain specific sequences of nucleotides, the nitrogen-based building blocks of the DNA molecule. These sequences specify the order of nucleotides in messenger RNA molecules, which in turn determine the sequence of the amino acids in a protein chain. For the purposes of this discussion, genes may be regarded as indivisible units, although in fact, they can on rare occasions be split or altered. A **mutation** is the permanent alteration of a gene caused by some outside force (chemicals, radiation, mistakes by the DNA copying mechanism of the cell, etc.). In discussions of genetics, a gene is often referred to as a genetic **locus**, emphasizing the fact that genes are regions of a DNA molecule. Within a population of a species, there are many differing copies of each gene. Each copy is referred to as an **allele** of that gene.

What Do Genes Do?

Genes are the blueprints of life. They specify the structure of RNA and protein molecules; these molecules create all the other compounds and structures which make up a living organism. An individual organism is an emergent property of its genes in that not only is it the result of gene products, but also the interactions of gene products. The expression and interaction of genes, that is the characteristics of an individual, are known collectively as the phenotype of that individual, whereas the sets of genes which produce the **phenotype** is known as the **genotype**.

The Advantage of Multiple Copies of Genes

Many genes are present in the genotype in several copies, and these copies are often different from one another. This is because the protein specified by any one gene copy has unique physical and chemical properties of its own. It functions most efficiently at a certain temperature, pH and salt concentration. If an important protein is represented in several different gene versions, a broad band rather than a narrow range of temperatures and chemical conditions will be optimal.

Chromosomes

Chromosomes are collections of genes. They are long DNA molecules, each of which contain several thousand genes. For this discussion, the genes are best visualized as beads on a string, so that the string can be cut at any point *between* the beads, and can be rejoined at the place of the cut or to any cut "string portion" or the chromosome.

Chromosomes are very small. With special stains and high powered microscopes, the larger ones can be seen. Unfortunately, the chromosomes of fungi are extremely small, and the number of chromosomes, something characteristic of each species, has never been determined for most fungi.

There is a complete set of chromosomes in every cell of every organism. This means that every time a cell divides, a complete copy must be made of every chromosome, and hence of every gene in the organism's genome. The cellular copying process is very nearly perfect, with errors being made at about the rate of one per million genes. That is, to find a random mutation of a particular gene, you would have to look at a million cells. Factors which produce mutations will, of course, increase this rate. These copy errors are the source of background mutations, which are always appearing in every organism.

Mitosis

Mitosis is the normal process of chromosome duplication which takes place every time that a cell divides. In it, all the chromosomes are duplicated, and in the early stages of the process, the copies stick together. All of the duplicated chromosomes line up in the middle of the cell, and one of the two copies of each is pulled to either end of the cell, resulting in two complete sets of chromosomes.

Meiosis

Meiosis is the unique series of events which takes place when a cell is involved in sexual reproduction. In meiosis, the chromosomes are copied just as in mitosis, but the genes are shuffled in a process called **recombination**. Sexually reproducing organisms have two sets of chromosomes, one from each parent. In meiosis, these two sets line up side by side, and reciprocal exchanges of sections of chromosomes take place. That is, a section of the maternal copy of a chromosome is transferred to the paternal copy, and a section of the paternal copy is simultaneously transferred to the maternal one. This happens to all of the chromosomes, usually once per chromosome, but sometimes more than once.

After these reciprocal exchanges take place, two successive cell divisions occur, resulting in four cells, each with ONE copy of each chromosome. None of these cells are identical to any of the others. They each have unique sets of genes. These cells are known as **gametes**, and are basidiospores in a mushroom, ascospores in a cup fungus or a yeast and sperm or egg cells in an animal.

It is this act of recombination of genes within the genome and the combination of genomes from two parents which is the genius of sexual reproduction. By this mechanism, variety is constantly introduced into the population of a species. A bacterium, which can reproduce very rapidly by mitosis, can generate vast numbers of bacteria in a very short time, *but all of the offspring are identical*. The importance of this difference cannot be overstated. If conditions fall below optimal or into the lethal range for the parent bacterium, all of the progeny soon die or are equally affected (unless, of course, there has been a favorable random mutation). Chance favorable mutations are, in fact, the major means of evolution available to bacteria.

Sexual reproduction, on the other hand, constantly spins off variation. Some of the progeny are substandard and do not survive, or do poorly, most are average and some are clearly superior, flourishing and leaving behind a greater number of offspring than the other groups. In this way, the population is enriched in gene combinations which are better adapted to the environment.

Reproductive Strategies

The two aforementioned modes of reproduction lead to three primary reproductive strategies. These are the primary use of asexual reproduction, the primary use of sexual reproduction and the sequential or seasonal use of both methods of reproduction.

1. Asexual (mitotic) reproduction allows an organism to produce large numbers of offspring in a very short period of time. This makes possible the rapid exploitation of any ecological niche which becomes available. This strategy is used by bacteria, yeasts, many molds (Fungi Imperfecti) and a surprising number of plants.
2. Sexual reproduction is not as rapid, since meiosis, gamete production and fusion and zygote growth are relatively slow processes. The progeny, however, have built-in variation and are capable of exploiting a wider assortment of niches than the parents. This strategy is used by larger organisms which tend to live for a longer time than those which are primarily asexual. Examples of organisms using this strategy are polypores, most plants and all large animals.
3. Combining sexual and asexual reproductions in different portions of the life cycle results in a highly effective strategy. This method is utilized by most lower plants and most fungi. In this strategy, when a suitable niche is found, asexual reproduction allows it to be rapidly filled and exploited. When that niche has been populated and nutrients become scarce, sexual reproduction is triggered. As well as releasing a number of varied progeny to the environment, sexually produced spores are usually more resistant to the harsh environmental conditions than mitotically produced spores. Often they are specifically adapted to lasting through winter or through a period of dryness, conditions not conducive to the growth of fungi.

Asexual Reproduction in the Fungi

Asexual reproduction in the fungi takes many forms, including buds, conidia, sporangiospores and fragmentation products.

Yeasts reproduce by budding, which is the constant growth of new cells from the surface of a mother cell. The new cells literally "blow out" of the mother cell wall like a balloon.

Conidia are mitotic spores which are continuously produced within or upon special structures called conidiogenous cells. Examples of conidial fungi are represented by *Penicillium* and *Aspergillus* molds, the fungi which attack spoiled foodstuffs, the downy and powdery mildew which attack garden plants, and the hundreds of genera which are involved in the breakdown and recycling of debris and litter in nature.

Sporangiospores (spores formed in batches within saclike structures called sporangia) are found in the water molds and the Zygomycetes. *Rhizopus*, which is often seen on breads and strawberries, reproduces in this manner.

A common mode of asexual reproduction is for portions of vegetative mycelium to thicken and form heavy walls and septae. These reinforced hyphal fragments then break apart and are distributed by natural processes. These vegetative propagules are called by many names, including arthrospores, chlamydospores, gemmae and others.

Sexual Reproduction in Mushrooms

While mushrooms reproduce sexually, they have no sexes. All that the term sexual reproduction means is that two sets of genetic information are carried, and that the genes in those sets are shuffled randomly before one set is provided to each gamete. Two gametes must come together and fuse to form the next fertile generation.

In animals and plants, the notion of sexes is realistic, because there are two kinds of gametes, an egg and a sperm. In mushrooms, all the gametes are physically identical; they are the basidiospores. Because of meiosis, however, there are genetic differences between them.

One of the genetic characters sorted out during meiosis is the **mating type**. The mating type is a character which prevents a spore or monokaryotic hypha carrying a particular allele from fusing sexually with any spore or hypha carrying the same allele, no matter how different the genomes are at all other loci. It takes the presence of different alleles at the mating type locus for sexual reproduction to occur. In any one species, there may be any number of alleles within the population. In general, any one of them is compatible with all of the others, the only prohibition being against fusion with the identical mating type.

If a species of mushroom has only one locus controlling mating type, with varying numbers of alleles for that locus, that species has what is known as an **unifactorial**, **heterothallic** mating system. In such a system, the only physiological requirement for mating to take place is that two differing alleles of the mating type locus be present. Since two alleles must be present in a sexually mature mushroom, and each spore only gets one, any random spore is compatible with half of its siblings. Since there are a large number of alleles for the mating type locus in the population at large, any random spore has a higher probability of being compatible with a spore of another strain. Thus this system increases the percentage of outcrossing by members of the species using it.

The majority of mushrooms, however, are **heterothallic and bifactorial**, a system known as **tetrapolar**. In this system, there are two separate and distinct mating type loci, each of which must have differing alleles present to form a dikaryotic colony. This system produces four distinct types of spores on each basidium, and any random spore from a single strain is fertile with only one fourth of its siblings. This is a strong form of incest taboo, and makes it four times as likely that any naturally formed dikaryon will be from non-related spores. Unfortunately, the two types of spores which are not totally identical or non-identical can form dikaryotic colonies which look like fertile ones. These products of illegitimate matings, though, are incapable of making fruitbodies or basidiospores.

There are strains and species in which the mating type system has broken down. These are known as **homothallic** fungi, and they are fully capable of mating with themselves. In fact, a single spore of a homothallic fungus is usually capable of making a fertile dikaryotic colony. A fair number of spores, however, due to the effects of recombination, will be incapable of forming fertile colonies unless they mate with another strain. This is a system often found in fungi which live in marginal habitats; usually there is a time lag before a monokaryotic colony dikaryotizes itself.

There are two types of homothallism in mushrooms: **primary** and **secondary**. Primary homothallism is the case described above, where the majority of spores, while initially forming monokaryotic colonies, will eventually become dikaryotic and fruit normally. Secondary homothallism is the case where each spore receives one nucleus of each mating type, generating a dikaryotic colony from the moment of spore germination. *Agaricus brunnescens* is the best known example of this type of fungus, while another commonly cultivated mushroom, *Volvariella volvacea*, has a primary homothallic mating system.

Implications for Culture Work

The single most important implication of the genetics that has been described thus far is the occurrence of illegitimate matings. In a tetrapolar fungus, only one fourth of the spores from any one mushroom are fully compatible with any random spore from that same strain. This mechanism exists to encourage outcrossing. When a cultivator is trying to produce a strain from a spore print, establishing a fruiting strain can be frustrating. This is because monokaryotic hyphae with common A factors or with common B factors *can fuse* and form dikaryons, and these dikaryons can even make convincing looking clamp connections. (See Figs. 10 and 182). These colonies, however, are incapable of fruiting. It becomes obvious at this point that two thirds of the random dikaryons formed will be of the illegitimate type. This implies that a large number of dikaryotic cultures must be isolated and tested for fruiting ability. Another, but less precise way around this problem is to inoculate with a large number of spores and take a tissue culture of the first mushroom that appears in the culture. This procedure is the one usually listed in books on mushroom cultivation because it is simple, but the strains produced in this manner still must be tested thoroughly.

The phenomenon of **sectoring** is the production of wedge shaped areas of differing physical or growth characteristics by a colony of mycelium. There are two types of sectoring, one found in young cultures, and one in old ones.

In young multispore cultures, several different strains are all growing together at the same time. Some are the products of legitimate matings, some of illegitimate ones. These strains all have differing characteristics. Some of these strains grow faster than others, some are rhizomorphic and some are fluffy in appearance. Some fruit well, some poorly. Some produce clumps of many tiny mushrooms, some produce a few large ones. They each have a unique set of preferred culture conditions.

Fortunately, the different strains formed from multispore germinations tend to sort themselves out. As the colony grows, strains segregate into sectors of different appearances and growth rates. The repeated separation and propagation of individual sectors, until a colony is obtained which no longer produces new ones is one way of isolating a pure strain. Several strains may be isolated from the same original Petri plate in this way.

As pure cultures grow old and become senescent, they produce ever greater quantities of sectors due to the accumulation of random mutations. Repeated subculturing of the culture gives accumulated mutations a chance to express themselves. A strain which has reached this condition is no longer pure, and should not be used for cultivation.

Culture Trials

When a number of strains have been generated from a sporeprint, they are different because of recombination in the basidium. Some of the strains MAY be identical to the parent strain, but that must demonstrated by some testing procedure. As in any screening operation, the more strains used, the better the chance of a good result. In fact, professional mushroom breeders often do trials with thousands of strains at a time. This kind of work, however, takes large and expensive facilities, and is unnecessary if the purpose is simply to find a strain which fruits well under a certain set of conditions. A strain which fruits well in test batches under uniform conditions has a high likelihood of doing well in larges batches when the same conditions of temperature, humidity and aeration are maintained. How many strains need to be tested? If the mushroom being worked with is tetrapolar, only one third of the dikaryotic colonies picked out will be capable of fruiting at all. In order to make trials often fruiting strains, begin with at least thirty dikaryotic strains.

Many mushrooms, especially the wood-rotters, fruit on enriched agar media in a Petri plate if given proper temperatures and some light. If the mushroom being tested is one of these, the selection of fruiting strains is simple. A mushroom requiring a special substrate or additive to fruit should be provided with the smallest amount allowable. For example, *Agaricus brunnescens* can be fruited on 50 grams of sterilized grain in a pint jar, if it is cased with soil containing certain bacteria. The smallest possible amount of substrate allows the rapid determination of fruiting strains.

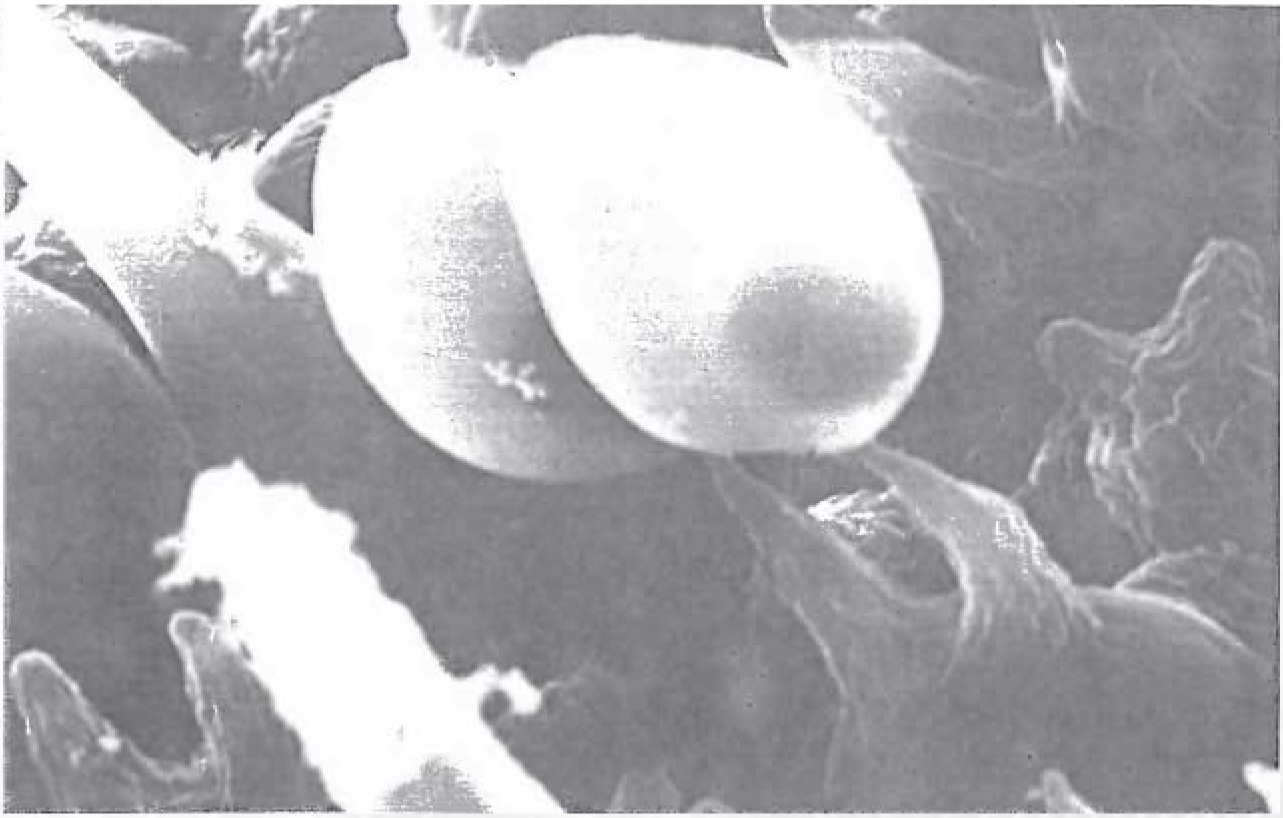

Figure 240 - Two spored basidium of a Copelandian *Panaeolus*.

Once ten to fifteen fruiting strains are in hand, they should be tested in a small scale version of the ultimate culture method. This step allows the strain best adapted to culture conditions to be selected. All strains should be tested at least in duplicates; five replicates per strain are preferable.

If the ultimate cultivation method involves beds of compost, the tests can be made with small boxes filled with compost, but the boxes should be filled to the same depth as the beds will be in the full scale project. If the fungus is fruited in jars (ex. *Flammulina velutipes*), a few jars can be inoculated with each strain. Good records must be kept for comparing the fruiting potential of each strain.

In small scale trials such as these, often several strains look good. In this case, the only way to find the best one is to make full scale trials, with one third or one fourth of the jars or beds inoculated with each of the strains being tested. Once again, good record keeping practices should soon show the differences between the most and least productive strains.

If the mushroom under consideration for cultivation takes a long time to establish its fruiting cycle (ex. *Lentinus edodes*), it is best to simply purchase a culture from a spawn lab or to take tissue cultures from commercially grown mushrooms.

Spore Dilution Technique

A simple technique can be used to physically separate spores so that individual dikaryotic (or even monokaryotic) cultures can be isolated in one step. The necessary equipment includes a bacterial (small) inoculating loop, several screw-cap vials of 20-30 ml. capacity, a flame and several sterile pipettes or small syringes.

To utilize this method, first fill each of the vials with 9 ml. of distilled water, place the caps on loosely and sterilize them. After they have cooled, the caps should be firmly screwed down. The inoculation loop is then flamed, cooled and gently rubbed on the spore print, being careful not to get a large mass of spores. The loop is dipped and twirled in one of the vials, which is then recapped and shaken vigorously. One milliliter of the fluid is then transferred to another vial, which is recapped and shaken, generating a dilute spore suspension. This suspension may be further diluted in the same manner. In this way, the cultivator has generated three suspensions of spores, one of high spore density, one 1/10th as concentrated and one with 1/100th or 1% of the original concentration. Now spread 1/10th of a milliliter of each suspension on a separate media filled Petri plate (or better yet, use several plates for each dilution). The original strength suspension in all likelihood will produce a dense lawn of cultures, which will be difficult to separate. This is the same condition as is produced with normal spore spreading methods. The less dense suspensions, however, should produce many fewer colonies, usually in the range of 20-50 per plate for the 1:10 dilution and 2-5 per plate for the 1:100 dilution.

Look carefully at the plates having only a few colonies. The slower growing monokaryons can be discerned from the faster growing dikaryons. Pick about 25 of the dikaryons to test for fruiting ability and reaction to culture conditions.

If desired, the monokaryotic cultures can be picked out for a breeding program. This is especially valuable if there are spores from several strains available. When spores are simply spread onto a plate, they adhere to one another, so attempts to simply streak spores of two strains on a plate usually do not yield hybrids.

(*The authors grate fully acknowledge Michael McCaw for the contribution of this chapter on genetics*).

APPENDICES

Appendix I
Medicinal Properties of Mushrooms

Mushrooms have long been esteemed for their medicinal properties, especially by Far Eastern cultures, while western cultures have largely been oblivious to the beneficial properties of mushrooms. For centuries, the Japanese have hailed the shiitake mushroom (*Lentinus edodes*) as an elixir of life, a cure-all, revitalizing both body and soul, a cure for cancer, impotency, senility and a host of other ailments. Mazatec shamans of southern Mexico have used *Psilocybe* mushrooms in their divination and healing ceremonies, extolling them for their life-giving properties and calling them "Mushrooms of Superior Reason" for the heightened mental state they induce. Even the very term "agaric," still used to describe all mushrooms with gills, comes from the name of a pre-Scythian people, the Agari, who were skilled in the use of medicinal plants, of which mushrooms were one.

Not until the late 1920's, when Dr. Alexander Fleming published a note in a microbiological journal, did fungi draw the scrutiny of scientists looking for new sources of antibiotics. He observed, quite by accident, the deterrent effect a *Penicillium* mold had on a bacterial contaminant (a *Staphylococcus* species). Years later, fellower researchers pursued his suggestion that antibiotics were being produced by this mold, which shortly led to the discovery of penicillin. Forthwith, molds of all types were examined by W.H. Wilkins (and others) from 1945 to 1954 who systematically tested one hundred species at a time for antibiotic effects against bacteria and bacteria-carrying viruses. Eventually, Wilkins turned his attention to the fleshy fungi and interest within the scientific community grew.

Claims of healing properties in mushrooms have been primarily promoted, until recently, by the commercial mushroom industry and others with vested interests. It appears, however, much of the medicinal claims attributed to mushrooms are not myth, but founded in some truth. Within the last ten years, numerous studies demonstrating the anti-cancer and interferon stimulating properties of *Lentinus edodes* have been published. Individuals can significantly reduce serum choresterol levels by eating these mushrooms for as short a period as a week (Suzuki and Ohshima, 1974). In another study (Hamuro *et al*., 1974), the antitumor influence of hot water extracts of *Lentinus edodes* was demonstrated in mice implanted with sarcoma-180 and other cancers, resulting in a 80% remission from treatment lasting only ten days, and a 100% prevention of growth if the mice were injected prior to implantation. The causal compound is appropriately named lentinan, a antitumor polysaccharide. Extracts from shiitake spores and the isolation of "mushroom RNA" from them have proved effective against influenza (Suzuki *et al*., 1974). Similar antitumor, immunopotentiator and interferon stimulating polysaccharides have been found in *Boletus edulis*, *Calvatia gigantea*, *Coriolus versicolor*, *Flammulina velutipes*, *Ganoderma applanatum*, *Ganoderma lucidum* (the classic "Reishi Mushroom"), *Phellinus linteus*, *Armillaria ponderosa* (*Tricholoma matsutake*) and *Pholiota nameko*. (See Yamamura and Cochran, 1974).

In the treatment of other diseases, Cochran and Lucas (1959) reported *Panaeolus subbalteatus*, a mushroom producing psilocybin and psilocin, provided significant protection from polio virus in mice as did several other edible and inedible mushroom species. Psilocybian mushrooms might be of further usefulness in improving eye sight, hearing, circulation and in activating the self-healing processes within the human body.

With the current emphasis on prevention and natural cures for human diseases, mushrooms are proving to be a convenient, inexpensive and an effective method of sustaining health. Health conscious individuals beginning a daily regimen of eating shiitake, for instance, have been shown to be less susceptible to virus-induced diseases than those abstaining. Until these studies progress and are tested more extensively on human populations, hopes should not be unduly raised for mushrooms might be of further usefulness in improving eye sight, hearing, circulation and in activating the self-healing processes within the human body.

Appendix II
Laminar Flow Systems

Suspended in the air is an invisible cloud of contaminants. These airborne spores are the primary source of contamination during agar and grain culture, and they are the major force defeating beginning cultivators. To control contamination, the cultivator must start with a sterile laboratory. Without pure culture spawn, the prospect for a good crop is slight, no matter how refined one's other techniques.

Creating an absolutely sterile environment, free of all airborne particulates, is extremely difficult, if not impossible. "Nearly sterile" environments are more easily constructed and are quite suitable for the purposes of the mushroom cultivator.

Chemical cleaners like detergents and disinfectants have traditionally been used for this purpose. Unfortunately, the frequent use of these cleaners to maintain hygiene in the laboratory pose some risk to the handler. Ultraviolet lights are likewise dangerous and are difficult to position in a room so that no shadows are cast. By far the least harmful and most effective method is the use of high efficiency filters that screen out airborne particulates when air is pushed through them. These filters are the basis of laminar flow systems. An understanding of the composition of unfiltered air helps put into perspective the problem for which laminar flow systems are designed. The air, the filter, the fan and the laminar flow system will be discussed in that order.

The Air

Air is composed of many suspended and falling particles. A sample of air holds soot or smoke, silica, clay, decayed animal and vegetable matter, and many, many spores. Some are only a fraction of a micron in diameter while other are hundreds of times larger. These particles continously rain down on the earth's surface. In light impact zones isolated from industrial centers, twenty tons per square mile per month fall from the sky (ASHRAE, 1978). Industrial areas have a fall-out that is ten times greater. So-called "clean country air" contains, on the average, one million particles (greater than .3 microns) per cubic foot. But in a room where a cigarette is being smoked, more than one hundred million particles are suspended in the same air space. A sterile laboratory, on the other hand, has less than one hundred particles per cubic foot of air!

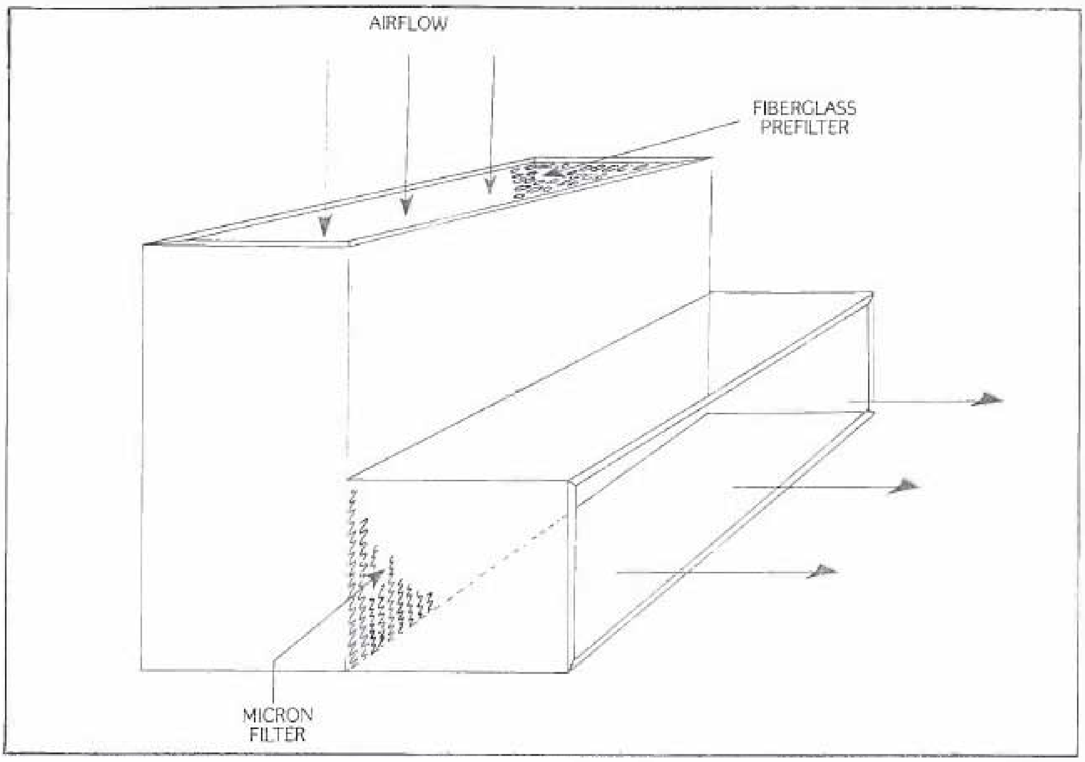

Figure 239 - A standard design of a laminar flow cabinet for tissue culturists.

Most of the spores contaminating mushroom cultures are between .5 and 20 microns in diameter. Generally, particles greater than 10 microns fall out of the air because of their weight. The smallest particles in this group are the airborne spore-forming bacteria which originate from soils. The smallest endospore forming bacteria are around .4 microns in diameter. Viruses which measure even smaller, sometimes a mere .05 of a micron in size, are usually attached to larger particles such as fungal spores. This broad assortment of airborne debris poses the greatest danger to mushroom culture.

The Filter

Two types of high efficiency filters are available today. One is an electrostatic filter which will screen out spores down to 5 microns or less. These filters operate on a charged particle principle where, by a variety of means, airborne particles are passed through an ionizing field and then between two oppositely charged electrical plates. Charged particles are drawn to the grounded plate by the force of the electric field. Because an agglomeration of particles is likely to blow off the retaining plate, they are often coated with a special oil. The advantages of electrostatic filters are that they have little resistance (a low pressure drop) and that they are reusable. But they have several disadvantages. One disadvantage is that they do not screen out the particles of 1 micron or less with a 99+% efficiency in high velocity airstreams. Hence, as air velocity increases, their efficiency decreases. Many electrostatic filters have, as a result, a sliding scale of efficiencies based on air speed. Another problem associated with electrostatic filters is that particles not caught in the filter are still partially charged and stick to the walls of a room, discoloring them. Also, toxic ozone may be generated by the constant arcing in the electrostatic field.

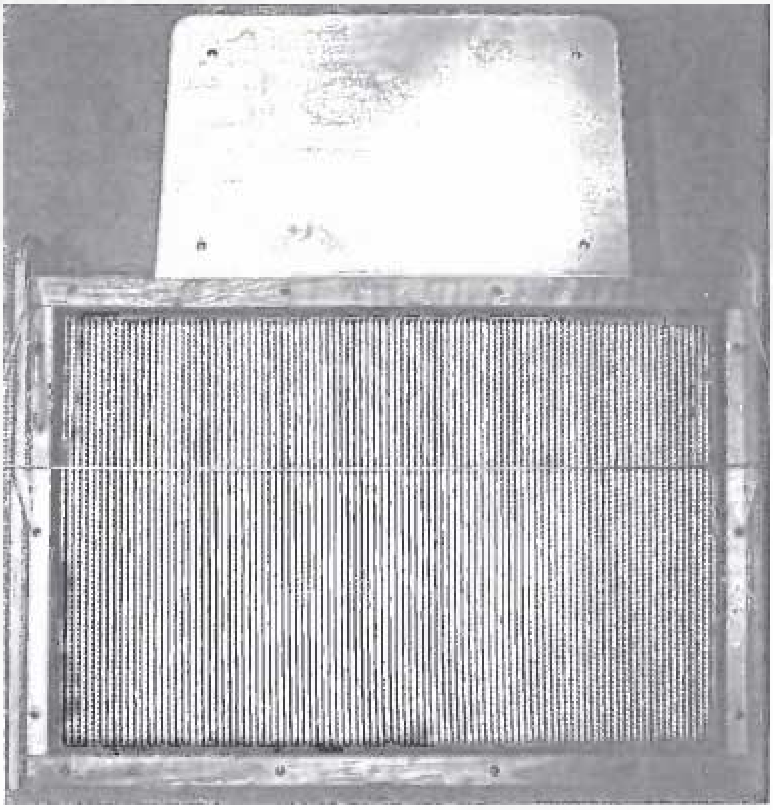

Figure 240 - A commercially available laminar flow hood.

The basic element in an air filter is the media, particularly the dry extended surface kind that is rated to .3 or .1 microns. Extended surface filters are commonly known as HEPA (High Efficiency Particulate Air) filters. First used commercially in 1961, these filters are honeycombed with fine sheets of microporous material that can screen out particulates down to less than one third of a micron size with a rated 99.99% efficiency. All spores of plants, fungi and most bacteria are thereby trapped within the folds of the filter.

The collection media in this type of filter can be composed of various materials including hair, spun glass, wool, paper and asbestos. (In the past, asbestos has been used in the manufacturing of all types of filters.

Since asbestos is cancer causing, be sure to specify a non-asbestos fibre). The extended surface media filter consists of folds of material woven back and forth. Corrugated aluminium or paper separators are inserted perpendicularly to the filter face and separate the folds to help direct airflow in an even, parallel fashion.

The airstream hits the filter material at a perpendicular angle and is forced to pass through the many weaves of the filter before exiting. From the force of impact, inertia and the size of the media web, particles are trapped within the filter. The result is that a very high efficiency is achieved, particularly with small diameter particles.

Extended surface filters have much higher resistance than electrostatic filters but they have a far greater capacity for holding dust. As the filter traps dust, it increases in weight and airflow declines. Generally a HEPA filter is not reused but discarded when, as a rule of thumb, the resistance or "pressure drop" doubles. Extended surface filters are used in hospital surgery rooms as well as culture laboratories and nuclear facilities. Since its efficiency is somewhat dependent on the impact velocity of the particle striking the media web, an appropriate fan must be matched with this type of filter.

The Fan

When constructing a laminar flow hood, the filter size must be precisely fitted with a high pressure fan. All fans are rated by the manufacturer according to the volume of air (CFM or cubic feet per minute) they can push past materials of specified resistance. The type of high pressure fans needed in a laminar flow hood are usually of the squirrel cage type ("furnace blowers").

In turn, the resistance of all micron filters are measured in inches of static pressure at a certain air speed. A standard resistance for a micron filter of this type is .75-1.00 inches of static pressure. Because extended surface filters have a high initial resistance, the housing must tightly hold the HEPA filter so that impure air is not sucked into the exiting airstream.

To calculate the correct fan/filter combination, take the net CFM of the fan at the filter's rated level of resistance and divide that number by the square footage of the filter face. Ideally, that number will be 100 feet per minute, the optimum range for air velocity in laminar flow systems. An example will more clearly illustrate this basic principle.

IF a micron filter measures 2 feet long by 2 feet high by 6 inches deep and has a static pressure rating of 1.0 inches of resistance, the fan required would have to be capable of pushing 400 CFM at 1 inch of static pressure.

IF X = the desired net CFM of a fan at 1" S.P. and
Y = 4 square feet (the square footage of the filter face)
THEN X = 100 feet per minute x Y
X = 100 feet per minute x 4 square feet
X = 400 cubic feet per minute

This means that a fan capable of pushing 400 cubic feet per minute at 1 inch of static pressure is needed to yield the optimum air velocity of 100 feet per minute. (Note that different filters have different static pressure ratings and suggested CFM's). In selecting a fan, it is best to choose one that can deliver more than a 100 feet per minute air velocity. Install a solid state speed control to regulate the fan as needed.

As the filters become laden with particulates, the resistance increases and the airflow declines. If the airflow falls below 20% of the suggested optimum, the 99.99% efficiency rating can not be guaranteed. Filters of the size in the example above can hold four or more pounds of dust and spores before needing replacement! With a few hours of use every week (the time most home cultivators spend conducting sterile transfers), the micron filter should last many years, depending of course, on the ambient spore load in the laboratory.

The life of a HEPA filter can be extended with the placement of pre-filters to screen out coarse particulates. Pre-filters can be made of fibreglass media, the type commonly used for furnace filters, or they can be composed of a thin open-celled foam. Pre-filters of the latter type increase resistance significantly whereas furnace type filters increase resistance only slightly. In this regard, furnace filters are well suited because they are cheap (less than five dollars), readily available, and come in numerous sizes.

Laminar Flow Designs

There are several types of laminar flow systems, each designed for specific applications. The airflow in a biological safety cabinet, built for use with pathogenic organisms, is such that the worker is not endangered if spores from a virulent organism became airborne. The air is drawn from the work area into the hood and then up through micron filters and exited to the outside. Laminar flow hoods for work with radioactive and toxic materials are similarly designed. Because of their intricacy, they are considerably more expensive than the kind needed for mushroom and plant culture.

Laminar flow systems for tissue culturists operate on a reverse principle of the one designed for use with toxic substances. Air is forced through a micron filter to the work area, creating a positive pressure sterile wind in which to conduct mycelial transfers. These types of hoods are perfect for pouring media, maintaining pure mycelia and inoculating spawn containers. Since they greatly reduce the waste caused by contamination, their cost is soon offset by the savings realized. A laminar flow hood is a low maintenance, affordable and appropriate technology for the serious home cultivator.

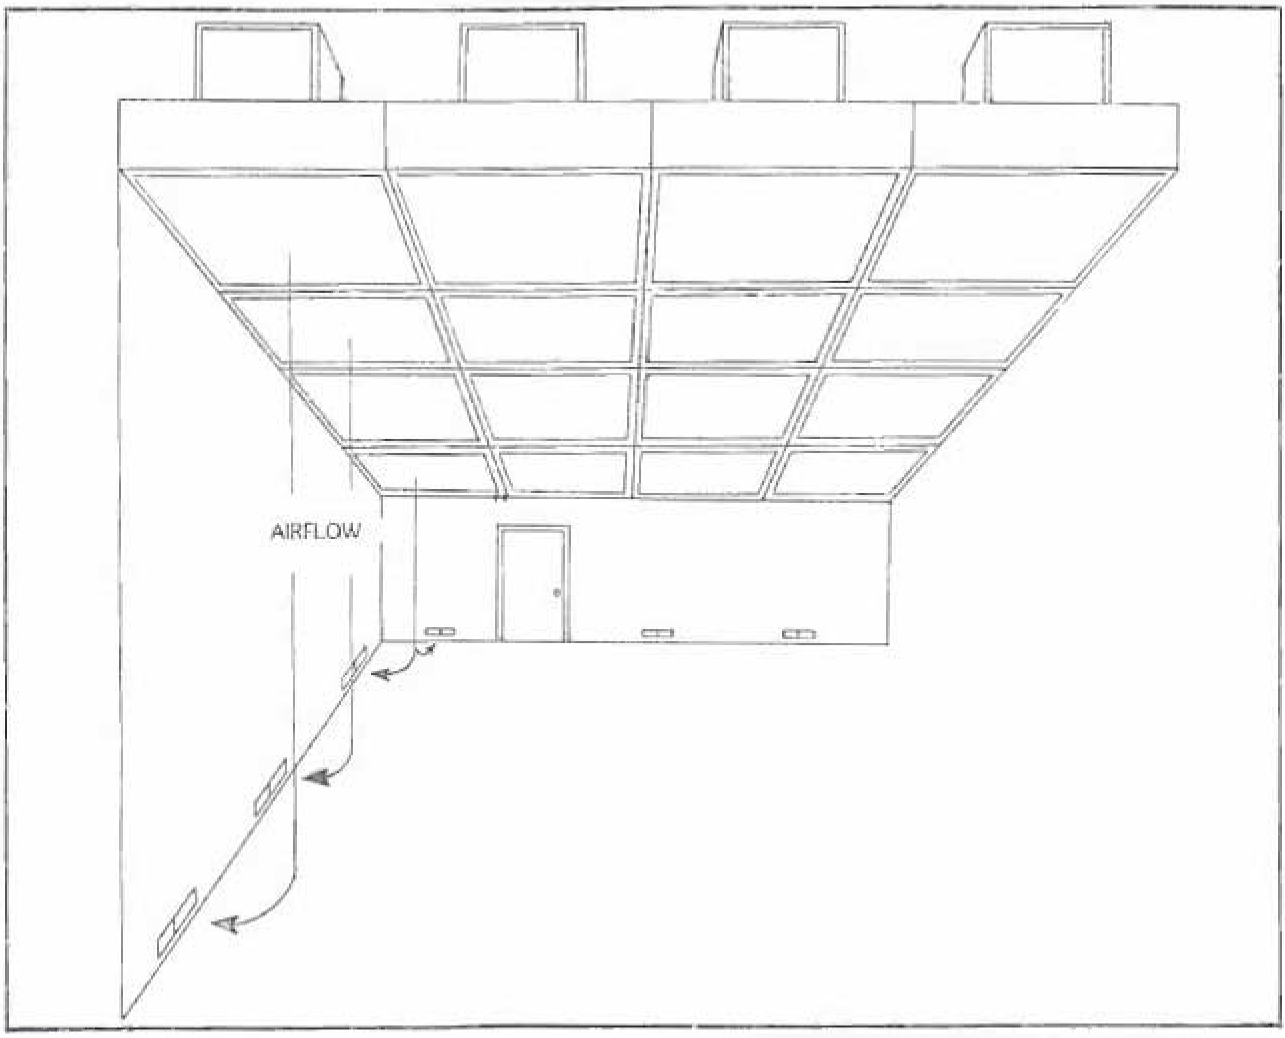

Figure 241 - Sterile room with ceiling composed of micron filters.

An alternative to building a laminar flow hood is the construction of a laminar flow wall or ceiling. A laminar flow ceiling is preferable because the draft is directed downwards to the floor where it exists through evenly placed pressure activated dampers. When a wall or ceiling is composed of micron filters, the air is usually drawn from the outside where the pre-filters can be changed without entering the sterile laboratory. Any contaminant spores tracked in on the shoes of workers are kept close to the floor and is immediately swept away by the flow of sterile air. The atmosphere in a this type of sterile room is fully exchanged 10-20 times per hour.

Foremost, tissue culturists are interested in preventing contamination from occurring, not from spreading. They are concerned with creating sterile media and maintaining the purity of cultures. A laminar flow hood is of little value in helping a cultivator isolate a colony of mushroom mycelium away from, for instance, a green mold on a Petri dish. The turbulence generated from the hood would free thousands of spores, some of which would adhere to the surface of the sterile media, germinate and produce more spores. In these cases, a laminar flow hood is best used as an air cleaner prior to isolating a culture away from a contaminant. Several minutes after it has been turned off and the air currents have settled, transfers can be made away from neighbouring contaminants with little danger of airborne spores.

Although sterile work can be conducted without a laminar flow system, they have become a standard piece of equipment in professional spawn laboratories and increasingly in the sterile rooms of many home cultivators.

Appendix III
The Effect of Bacteria and Other Microorganisms on Fruiting

Although mushrooms have been cultivated for more than two hundred years, little is known about the biological processes of fruiting. For mushroom pinheads to form suddenly and then to enlarge into towering mushrooms within only a few days represents a many hundred-fold multiplication in biomass. This ability to generate tissue so rapidly has few parallels in nature and has been the subject of numerous scientific papers.

Mushrooms are in constant competition with organisms sharing the same habitat. Dung inhabiting mushrooms in particular (like *Psilocybe cubensis* and *Agaricus brunnescens*) live in an environment that teems with other microorganisms feeding on organic wastes and dead cell matter. Dung is by nature a temporary substrate, decomposing completely in only a few weeks. Within this short period of time there is a succession of dominant microorganisms, most notably fungi and bacteria. For a new mushroom colony to grow, its spores must fall, germinate, mate, form a substantial mycelial network and then produce a specialized fruitbody. This series of events is made less likely by poor weather conditions and/or competing microorganisms. The brevity of the generative phase in the mushroom life cycle suggests a highly advanced metabolic system, one that has evolved despite its fiercely competitive environment.

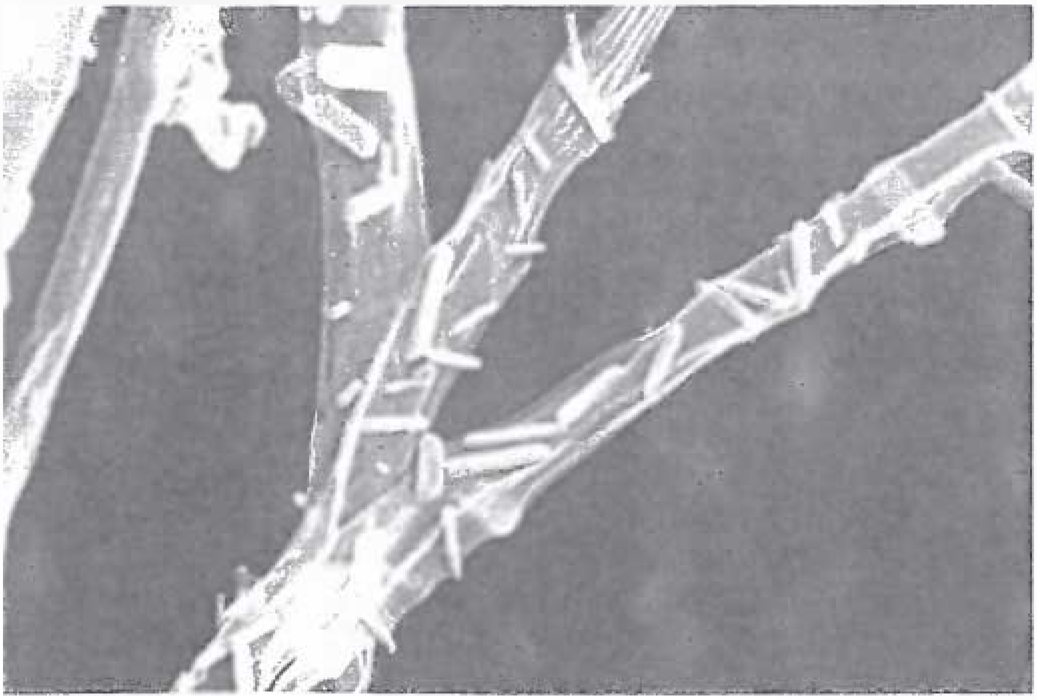

Figure 242 - *Psilocybe cyanescens* mycelium contaminated with bacteria.

The fact that *Agaricus brunnescens* fails to fruit on sterilized substrates has been well documented. It has been shown that if the casing layer is sterilized and applied to grain or compost, mushrooms do not form. On the other hand, if the casing layer is only pasteurized or left untreated, fruiting is unhindered. Obviously something in the peat based casing is essential to the fructification process.

Past investigations have shown the significance of bacteria in mushroom growth. It should not be surprising then to learn that some of these microorganisms are not harmful to the mushroom plant, but beneficial. Under conditions of high humidity, CO_2 and acetone, bacterial populations spiral. In a way not presently understood, some of these bacteria act as a trigger to fruiting. The prevalence of bacteria on hyphae may explain why most dung dwelling mushrooms can be fruited with comparative ease on basic enriched agar media while wood and soil inhabitors can not. The association of these two organisms, a fungus and a bacterium, reflects a tacit agreement for mutual coexistence, one perhaps negotiated by evolutionary necessity.

In 1956 Dr. Takashi Urayama first noted the stimulative influence of bacteria on the fruiting of *Psilocybe coprophila*. (Actually he misidentified the mushroom species as *P. panaeoliformis*). In that paper and ones soon thereafter (Urayama 1960, 1961 and 1967), he reported the isolation of a bacterium he thought responsible for fruiting in not only *Psilocybe* "*panaeoliformis*" but also in *Agaricus brunnescens*. He named that bacterium *Bacillus psilocybe* nom. prov. Apparently unaware of Urayama's work, a German mycologist named Eger similarly isolated a bacterium stimulative to pinhead formation. She first published her notes in 1959. For years this bacterium was known as "Eger's Bacterium" until Hayes (1969) identified the organism in question as *Pseudomonas putida*. This identification set in motion other research projects whose conclusions revealed a subtle but dynamic interplay between microflora in the casing layer and the mushroom mycelium.

Mushroom mycelium releases several metabolites as if grows through a substrate, most importantly CO_2. Other compounds identified by researchers as metabolic waste products include acetone, ethanol and ethylene. Upon casing, the release of volatile metabolites from the spawned compost or grain is drastically inhibited. The casing layer interferes with the free diffusion of acetone, and hence its concentrations in the casing biosphere increase. Since *Pseudomonas putida* grows on media whose sole carbon source is acetone or ethanol (2.5%), cultivators can adopt measures that will enhance the levels of these *Pseudomonas* propagating compounds in the casing layer. Eger first suggested a practical application for commercial cultivators:

"In order to prove our hypothesis, freshly prepared, moist casing soil of a commercial mushroom plant should be incubated with acetone for several days apart from mushroom cultures. If acetone has a stimulative effect on the microflora that induces fructification, soil treated with acetone should allow earlier pinhead formation than control samples." (Eger, 1972, pp. 723.)

Two years later Hayes and Nair (1974) noted that more bacteria flourish in wet casings placed on compost than in wet casing alone. Peak activity occurred ten days after application. Dry casings, as one would expect, had significantly fewer bacteria. Continuing with this work, Hayes and Nair showed that the addition of 5% spawned compost into the casing layer resulted in the largest increase in *P. putida* populations, the most pinheads and the greatest overall yields.

Stanek (1974), a Czech mycologist, studied the bacteria associated directly with mushroom mycelium, in the zone he called the "hyphosphere". These hyphosphere bacteria differed from other bacteria in that they were predominantly Gram-negative (as is *Pseudomonas putida*) and they utilized nitrogenous compounds secreted by the mycelium. Both the growth of mycelia and bacteria were stimulated by extracts of one another, suggesting a mutually enhancing relationship much like the one between nitrogen fixing bacteria and the roots of many plants. Stanek further determined that mycelium infected with bacteria grew more quickly through compost and would, therefore, give mushroom mycelium a decided advantage over other competing microorganisms. From this author's experience (Stamets') in the course of studying the hyphosphere of several *Psilocybe* species, bacteria are not uncommon and may play a similarly beneficial role.

Not all strains of *Pseudomonas putida* cause pinheads to form in *Agaricus brunnescens*, nor do all strains of mushrooms respond similarly to the presence of selected bacteria. The two proven stimulative strains, ATCC #12633 and #17419, are deposited with the American Type Culture Collection. Some strains of *Pseudomonas putida* have no effect whatsoever, while others are most stimulative if the bacterial colonies are grown on a 2.5% acetone based liquid media (see Eger, 1972). After incubating for 10 days at 25°C. in 30-40 ml. of nutrient broth, a density of 1,000,000 to 2,000,000 cells/milliliter is achieved. Ten milliliters of this concentrated solution is recommended for each square meter of casing surface. (For ease of application, one milliliter of concentrate can be diluted in 100 milliliters of sterilized water).

Eger, Hayes and Nair have demonstrated the stimulative effect of *Pseudomonas putida*. But why *Pseudomonas putida* stimulates primordia formation is a question yet unanswered. Some believe its effect is indirect, removing chelating compounds that inhibit mushroom initiation. Others (Fritsche, 1981; Visscher, 1981) suspect its influence is more direct and biologically oriented.

Pseudomonas putida is not the only microorganism implicated in the phenomenon of fruiting. Park and Agnihorti (1969) published a short note where they compared bacteria introduced to soils that had been autoclaved, gamma sterilized and untreated. Three other bacteria (*Bacillus megaterium*, *Arthrobacter terregens* and *Rhizobium meliloti*) stimulated abundant fruitbody formation and development on sterilized soils. (Interestingly, these same nitrogen fixing bacteria are presently being marketed to farmers for increasing crop production). In yet another study, Curto and Favelli (1972) examined a gamut of microorganisms (bacteria, yeasts and microalgae) and their effect on potentiating yields. Again, *Bacillus megaterium* significantly increased mushroom formation. Even more remarkably *Scenedesmus quadricauda* (a common pond dwelling blue-green alga) enhanced production by nearly 60% over and above the control. This alga seemed to have a particularly influential effect on the number of primordia generated on the first flush. Although as exciting as these findings may at first appear, it must be noted that other researchers have not yet confirmed the findings of Curto and Favelli. For reasons not presently understood, activated charcoal mimics the primordia stimulating properties of *Pseudomonas putida* and other beneficial microorganisms. (See Chapter VIII). Its addition to unsterilized casings seems wholly unnecessary considering the ease with which *Agaricus brunnescens* and *Psilocybe cubensis* form pinheads. But, in sterilized casings or in casings applied to difficult to fruit species, the use of activated charcoal and select bacteria gives the cultivator another means to promote fructification. Although many studies have been published, work with fruiting potentiators is still in its infancy. Specific mushroom strains must be carefully matched with specific strains of potentiators. And the potentiators themselves, while of value at fruiting, can be formidable competitors to sterile culture in the laboratory. Nevertheless, utilizing these benevolent microorganisms holds great promise for the future of mushroom culture.

NOTE: Bacteria, if cultured, must be kept separate from the mushroom culture laboratory. *Pseudomonas* and *Bacillus* grow well on standard 2% malt agar media.

Appendix IV
The Use of Mushroom Extracts to Induce Fruiting

The search for the biochemical means by which mushrooms fruit has been ongoing for years. Several researchers have demonstrated the influence of hormones in regulating mushroom formation and development. From this work, it is clear that no one mechanism, but many, cause the phenomenon of fruiting.

Urayama (1972) found that live extracts from young buttons of *Agaricus brunnescens* and from other species would induce pinhead initiation in a *Marasmius* species that otherwise failed to fruit on a specified agar medium. He determined that this particular *Marasmius* failed to form fruitbodies on agar media that had a carbon:nitrogen ratio of 1:10 with sucrose levels maintained at 1%. Given the inability of pinheads to form at this Sucrose/Peptone ratio, he could introduce standardized cell free extracts of other mushroom species to gauge their effects. Species from which crude extracts were taken were: *Agaricus brunnescens*, *Lentinus edodes*, *Flammulina velutipes* and *Pleurotus ostreatus*. The extracts were performed by washing 200 grams of homogenized live mushroom tissue (primordia less than 1 cm. tall) with four successive baths of 80% methanol. The residue was discarded each time and the methanol solution allowed to evaporate, under a slight vacuum, until a dried filtrate remained. One gram of this crude extract was then immersed into 10 milliliters of water and applied in 1/10th milliliter increments to each culture tube, except for the controls.

The results of Urayama's work showed that each of the four fractionations induced primordia formation provided aqueous methanol (80%) and only young mushrooms were used. Extracts from older fruitbodies, especially that of *Agaricus brunnescens* and *Lentinus edodes*, had no effect whatsoever. Urayama tried other solvents to isolate the mysterious "fruiting hormone" and discovered that it was soluble in water and not soluble in absolute methanol, chloroform or petroleum benzine. He worked on his "Substance X", as he liked to call it, for many years until his death in 1980.

Shiio et alia (1974) realized that young mushroom buttons contained high concentrations of the fruiting hormones and applied this knowledge to the commercial cultivation of *Flammulina velutipes*. Pieces of *Flammulina velutipes* primordia were immersed into sterile water and sprayed over sawdust/bran beds. Not only were yields substantially increased by this crude procedure, but initiation occurred much earlier, and the overall fruiting cycle was narrowed considerably. Clearly these mycologists were on the road to discovering an important link in the biochemistry of fruiting.

Around the same time as the work of Shiio et alia, two other Japanese mycologists published related studies (Uno & Ishikawa, 1971, 1973) whereby pinheads of *Coprinus* formed if a "cell free extract" from young mushrooms was added to the culture. They and others isolated the causal compounds - cyclic adenosine monophosphate (c AMP) and related enzymes. They further found that light stimulated the production of c AMP in the mycelium of phototropic mushroom species. Conversely, the absence of light in phototropic mushroom species resulted in no production of c AMP.

Wood (1979) tried to substantiate the findings of Uno and Ishikawa with *Agaricus brunnescens* and failed. He could not induce primordia to form using c AMP. However, this fact does not bear any significance on the importance of cyclic adenosine monophosphate in phototropic species since *A. brunnescens* is a mushroom needing no light whatsoever for primordia formation and development.

The question of how mushrooms fruit is not simple; nor will there be one answer explaining the mechanisms in all species. What is apparent at this early stage of research is that photosensitive and non-photosensitive species have developed different means for mushroom development. The information most useful for home and commercial cultivators will come in the areas of yield enhancement and the growing of exotic mushrooms on readily available, cheap materials. By good fortune, this is one area of research that is not beyond the means of the innovative home cultivator.

Appendix V
Data Collection and Environmental Monitoring Records

Success in mushroom growing requires a consistent and repeatable methodology. Because there are so many variables that affect the crop, careful record keeping is essential for good management. With a data collection system, the cultivator can learn from mistakes and gain a deeper understanding of the factors that influence healthy mushroom growth.

The following data collection records reflect years of mushroom growing experience and are therefore quite detailed. Each cultivator must evaluate his or her particular circumstance to decide which categories are most appropriate. In turn, these data sheets can be modified to meet an individual's requirements.

Appendix VI
Analyses of Basic Materials Used in Substrate Preparation

Dry Roughages of Fibrous Materials

Material	Total dry matter Per ct.	Protein Per ct.	Fat Per ct.	Fiber Per ct.	N-free extract Per ct.	Total minerals Per ct.	Calcium Per ct.	Phosphorus Per ct.	Nitrogen Per ct.	Potassium Per ct.
Alfalfa hay, all analyses	90.5	14.8	2.0	28.9	36.6	8.2	1.47	0.24	2.37	2.05
Alfalfa hay, very leafy (less than 25% fiber)	90.5	17.2	2.6	22.6	39.4	8.7	1.73	0.25	2.75	2.01
Alfalfa hay, leafy (25-28% fiber)	90.5	15.8	2.2	27.4	36.6	8.5	1.50	0.24	2.53	2.01
Alfalfa hay, stemmy (over 34% fiber)	90.5	12.1	1.4	36.0	33.4	7.6	1.10	0.18	1.94	1.68
Alfalfa hay, before bloom	90.5	19.0	2.7	22.6	36.7	9.5	2.22	0.33	3.04	2.14
Alfalfa hay, past bloom	90.5	12.8	2.1	31.9	36.2	7.5	-	-	2.05	-
Alfalfa hay, brown	87.9	17.3	1.6	24.5	35.1	9.4	1.37	0.26	2.77	-
Alfalfa hay, black	83.1	17.5	1.5	29.1	25.3	9.7	-	-	2.80	-
Alfalfa leaf meal	92.3	21.2	2.8	16.6	39.7	12.0	1.69	0.25	3.39	-
Alfalfa leaves	90.5	22.3	3.0	14.2	40.5	10.5	2.22	0.24	3.57	2.06
Alfalfa meal	92.7	16.1	2.2	27.1	38.2	9.1	1.32	0.19	2.58	1.91
Alfalfa stem meal	91.0	11.5	1.3	36.3	34.8	7.1	-	-	1.84	-
Alfalfa straw	92.6	8.8	1.5	40.4	35.1	6.8	-	0.13	1.41	-
Alfalfa and bromegrass hay	89.3	12.4	2.0	28.6	38.1	8.2	0.74	0.24	1.98	2.18
Alfalfa and timothy hay	89.8	11.1	2.2	29.5	40.3	6.7	0.81	0.21	1.78	1.78

4.5	22.0	9	22.86
5.0	24.4	10	25.40
5.5	27.0	11	27.94
6.0	29.0	12	30.48
6.5	31.4		

Length

Inch = 2.54 centimeters
Centimeter = 0.3937 inches
Foot = 0.3048 meters
Meter = 3.2808 feet
Yard = 0.9144 meters
Meter = 1.0936 yards

Area

Sq. in. = 6.4516 sq. cm.
Sq. cm. = 0.1550 sq. in.
Sq. ft. = 0.0929 sq. m.
Sq. m. = 10.7639 sq. ft.
Sq. yd. = 0.8361 sq. m.
Sq. m. = 1.1960 sq. yd.

Volume

Cu. in. = 16.3872 cu. cm.
Cu. cm. = 0.0610 cu. in.
Cu. ft. = 0.0283 cu. m.
Cu. m. = 35.3145 cu. ft.
Cu. yd. = 0.7646 cu. m.
Cu. m. = 1.3079 Cu. yd.

Capacity

Cu. in. = 0.0164 liters
Liter = 61.0250 cu. in.
Cu. ft. = 28.3162 liters
Liter = 0.0353 Cu. ft.
Cup = 0.2366 liters
Liter = 0.2642 gal.
Quart = 0.9463 liters
Liter = 1.0567 qt.
Gallon = 3.7853 liters
Liter = 1000 ml.

A liter of distilled water weighs 1000 grams or 1 kilogram.

Weight

Grain = 0.0648 grams
Gram = 15.4324 grains
Ounce = 28.3495 grams
Gram = 0.0353 ounces
Pound = 454 grams
Kilogram = 2.2046 pounds
Pound = 0.4536 kilograms
Metric Ton = 2.204 pounds
Ton = 907.1848 kilograms

Pressure

1 kg. per sq. cm. = 14.223 lb. per sq. in.

1 lb. per sq. in. = 0.0703 kg. per sq. cm.

1 kg. per sq. m. = 0.2048 lb. per sq. ft.

1 atmosphere = 1.0332 kg. per sq. cm. = 4.696 lb. per sq. in. = 1.0133 bars

ACKNOWLEDGEMENTS

The authors are indebted to many who have made this work possible. Foremost amongst those are our spouses Cruz Stamets and Janice Leighton. They provided more than just technical assistance. Their encouragement, companionship and endurance has been critical to the success of this project.

Besides the artists and photographers whose contributions are most appreciated, we would like to express our thanks to John Stamets for editing the manuscript and printing the black and white photographs, to Mike McCaw for his chapter on genetics, to Rick Kerrigan for his unwavering support, to Dr. Michael Beug for his encouragement and sponsorship, to The Evergreen State College for the use of the scanning electron microscope, to Bill Street of Ostrom Mushroom Farms for his generosity in allowing photographs to be taken of his facilities, to Kathy Harvey and Steve Raynor for their contributions to the contamination section, to P.J.C. Vedder for his tutelage and contribution to practical mushroom cultivation, to Dr. Daniel Stuntz for his guidance and his teaching of tissue culture techniques and to Chris W. Nelson of Sound Media Productions for his work in photographic development and printing.

Others who have helped us, in one way or the other, to complete this arduous endeavor are Janet McCaw, Paul Kroeger, Dale Leslie, Heidi Stamets, Mike Maki, Jim Jacobs, William Raves, Bob Chieger, David Tatelman, Samuel and Victoria, Mike, Michael, Gary, and mycophiles too numerous to mention who, through their questions and curiosity, have determined much of the direction, content and scope of this book. We thank you.

GLOSSARY

a

acute Pointed, sharp.
adnate (of the gills) Bluntly attached to the stem.

adnexed (of the gills) Attached to the stem in an ascending manner.

agar A product derived from seaweed and valued for its gelatinizing properties. Commonly used to solidify media in any type of sterile tissue culture.

Agaricales The order of mushrooms which includes all mushrooms with true gills.

amyloid The characteristic bluish reaction the flesh or the spores of a mushroom exhibits in Melzer's iodine.

anastomosis (*pl. anastomoses*) The crosswise fusion of hyphal systems to form a network of mycelia.

angstrom 10^{-10} microns, 1 ten thousandth of a micron.

annular Resembling an annulus, appearing as a ring-like zone.

annulus The tissue remnants of the partial veil adhering to the stem and forming a membranous collar or ring.

apex The top or highest point.

apiculus a term (misused) for the hilar appendix, the nipple-like projection by which a spore is attached to the strerigmata ("arms") of the basidium.

appendiculate Hanging with fragments of tissue.

appressed Flattened.

Ascomycetes Fungi that produce spores in an ascus.

ascus A sac-like organ in which eight spores develop and is characteristic of the perfect stage of ascomycetous fungi.

autoclave A steam pressurized vessel used to sterilize media.

b

bacillus (*pl. bacilli*) A general term for any rod-shaped bacteria forming spores in free oxygen environments. (The genus *Bacillus* is more narrowly defined).

bacterium (*pl. bacteria*) The simplest group of non-chlorophyll plant-like organisms.

Basidiomycetes All fungi which bear spores externally upon a club-like cell known as a basidium.

basidium, basidia A unique fertile cell, club-like in form, in which meiosis occurs and by which sexual spores are produced.

basidiocarp The fruiting body of fungi that reproduce through basidia.

binucleate Having two nuclei in one cell.

border break The early occurrence of mushrooms along the edge of a substrate container.

C

campanulate Bell shaped.

carpophore The fruiting body of higher fungi.

carpophoroid Analogous to a fruitbody, although usually a poorly differentiated mass of tissue, not well developed ("aborted") and sterile.

cartilaginous Brittle, not pliant.

casing A layer of water retentive materials applied to a substrate to encourage and enhance fruitbody production.

caulocystidia Sterile cells covering the mushroom stem.

cellular Composed of globose to rounded cells, not thread-like.

cespitose Growing clustered, appearing to arise from a single base.

cheilocystidia Sterile cells on the mushroom gill edge, sometimes called marginal cystidia.

chlamydospores A thick walled spore, typically of a secondary type, that arises directly from the mycelium and having the full complement of chromosomes for producing off-spring. Chlamydospores are typically ovoid and heat resistant.

chrysocystidia A type of cystidia that is highly refractive in once dried tissue revived with a potassium hydroxide (KOH) solution and appearing as a yellowish brown amorphous mass within the cell.

clamp connection An elbow-like protuberance which arches over the walls separating cells in mated (dikaryotic) mycelia of some mushroom species.

compost A biological matrix of microorganisms combined with straw, manure and other organic substances and designed for mushroom fruitbody production.

concolorous Having the same color.

conditioning The final conversion of mushroom compost by selected microbial groups.

conic Shaped like a cone.

conidia A uninucleate exteriorly borne cell formed by constriction of the conidiophore.

conidiophore A specialized stalk arising from mycelium upon which conidia are borne.

conidium (*pl. conidia*) An asexual spore formed by the constriction of hyphae to chains of cells.

context The flesh of a mushroom.

convex Regularly rounded.

Coprinaceae A family of mushrooms containing the genera *Coprinus*, *Panaeolus* and *Psathyrella*.

coprophilous Growing on dung.

cortinate A type of veil consisting of fine cobweb-like threads of tissue, extending from the mushroom cap margin to the stem.

cropping The time of mushroom formation, development and harvesting.

cuticle The surface of cells on the cap that can undergo varying degrees of differentiation.

cystidia Microscopic sterile cells adorning the mushroom fruitbody.

d

decurrent The attachment of the gill plates to the stem of mushrooms where the gills are markedly downcurved, partially extending down the stem.

decurved Curving in a downwards fashion.

deciduous Describing trees that seasonally shed their leaves.

deliquescing The process of autodigestion by which the gills and cap of a mushroom melt into a liquid. Most typical of the genus *Coprinus*.

dikaryophase The phase in which there are two individual nuclei in each cell of the mushroom plant.

dikaryotic The state of cells in the dikaryophase.

diploid A genetic condition where each cell has a full set of chromosomes necessary for sexual reproduction (2N).

disc The central portion of the mushroom cap.

e

eccentric Off-centered.

ellipsoid Shaped like an oblong circle.

endospores Spores formed internally.

entheogenic A term to describe substances that induce god inspiring feelings or experiences.

equal Evenly proportioned.

eroded Irregularly broken.

evanescent Fragile and soon disappearing.

f

fibrillose Having fibrils.

fibrils Fine delicate 'hairs' found on the surface of the cap or stem.

fibrous Composed of tough, stringy tissue.

filamentous Composed of hyphae or thread-like cells.

flexuose, flexuous Bent alternately in opposite directions.

floccose Wooly tufts or cottony veil remnants, typically adorning the cap or stem of some mushroom species.

flush The collective formation and development of mushrooms within a short time period, often occurring in a rhythmic manner.

fructification The act of fruitbody formation.

fruitbody What is commonly called the mushroom. The sexual reproductive body of the mushroom plant.

fugacious Impermanent, easily torn or destroyed.

fusoid Rounded and tapering from the center.

g

gelatinous Having the consistency of jelly.

genotype The genetic heritage or constitution of an organism. The genotype produces the phenotype.

geotropism Growing oriented towards or in response to gravity.

glabrescent Becoming smooth.

glabrous Smooth, bald.

glutinous Having a highly viscous gelatinous layer, an extreme condition of viscidity.

Gram (Gram's Stain) A method for separating bacteria whereby bacteria are stained first with crystal violet (a red dye) and then washed with an iodine solution. Gram positive bacteria (*Bacillus*) retain the dye. Gram negative bacteria (*Pseudomonas* and some *Bacillus*) lose the dye.

gregarious Growing numerously in small groups but not in clusters.

h

habitat The substrate in which mushrooms grow.

heliotropic Growing or turning towards the sun.

heteromorphic Composed of different cell types, usually describing the type of mushroom gill edge.

heterothallic Having two or more morphologically similar pairs of strains within the same species. The combination of compatible spore types is essential for producing fertile off-spring. Typically a spore on a four spored basidium is compatible with only one of its counterparts.

hilar appendix The stub-like protrusion on the spore that connects the spore-producing cell (ex. the basidium) to it.

hilum A marking on the spore where it was attached to a spore-producing cell.

homomorphic Composed of similar cell types.

homothallic Having one strain type that is, by nature, dikaryotic and self-fertile; often arising from two spored basidia.

humicolous Growing in humus, soil.

hygrophanous Markedly fading in color upon drying, used to describe the condition of the mushroom cap.

hymenium The layer of fertile spore-bearing cells on the gill.

hypha, hyphae Individual cells of mycelium.

hyphal aggregate A concentration of mycelium; a "knot" in the mycelial network which often differentiates into a primordium.

hyphosphere The region immediately on and surrounding hyphae.

i

indicator mold A mold, usually non-destructive, whose occurrence indicates an improperly balanced condition in the substrate or environment.

instar An insect in any of its stages of post embryonic growth.

k

karyogamy The fusion of two sexually opposite nuclei within a single cell.

KOH Potassium Hydroxide, an agent commonly used to revive dried mushroom material for microscopic study at a concentration of 2,5%.

l

lamellae Mushroom gills.

lignicolous Growing in wood or on a substratum composed of woody tissue.

lignin The organic substance which, with cellulose, forms the basis of most woody tissue.

linear Considerably longer than wide, with edges parallel.

lubricous Smooth.

lumen The amount of the flow of light emitted from a single international foot candle.

lux The amount of illumination received by a surface one meter from 1 foot candle, equal to 1 lumen/square meter.

m

macroscopic Visible to the unaided eye.

matting A condition of a mycelium casing-run that has become appressed from overwatering. Similar to overlay except that matting infers the mycelium has formed a dense, dead layer of cells on the casing's surface.

meiosis The process of reduction division by which a single cell with a diploid nucleus subdivides into four cells with one haploid nucleus apiece.

membranous Being sheath-like in form.

mesophile An organism thriving in moderate temperature zones, usually 40-90°F.

metuloid Used to describe a sterile cell encrusted with a crystalline (calcitized) substance.

micron One millionth of a meter, 10^{-6} meters, one thousandth of a millimeter.

microscopic Visible only with the aid of a microscope.

mitosis The non-sexual process of nuclear division in a cell by which the chromosomes of one nucleus are replicated and divided equally into two daughter nuclei.

monkaryon, monocaryon (*adj. monokaryotic, monocaryotic*) The haploid state of the mushroom mycelium, typically containing a single nucleus.

mottled Spotted, as in the uneven ripening of spores on the gill surfaces that so characterizes species in the genus *Panaeolus*.

mushroom A fleshy fungus that erects a body of tissue in which sexual spores are produced and from which they are distributed.

mycelium (*pl. mycelia*) A network of hyphae.

mycology The study of fungi.

mycophagist A person or animal that eats fungi.

mycophile A person who likes mushrooms.

mycophobe A person who fears mushrooms.

mycorrhizal A peculiar type of symbiotic relationship a mushroom mycelium forms with the roots of a seed plant, typically trees.

n

nanometer 10^{-8} meters, one thousandth of a micron.

natural culture The in vitro cultivation of mushrooms by transplanting living mycelium, usually from a natural habitat.

nomenclature Any system of classification.

nucleate Having nuclei.

nucleotide One of the four nitrogenous bases in DNA; often called the building blocks of the DNA molecule.

nucleus, nuclei A concentrated mass of differentiated protoplasm in cells containing chromosomes and playing an integral role in the reproduction and continuation of genetic material.

o

obtuse Bluntly shaped.

ochraceous Light orangish brown to pale yellowish brown.

oidia Conidia (spores) borne in chains.

olivaceous Olive gray-brown.

overlay A condition of the casing where mycelium been allowed to completely cover the surface. Overlay is caused by prolonged vegetative growth temperatures, high CO_2 levels and excessive humidity. Overlay, if overwatered, becomes matted.

ovoid Oval shaped.

p

pallid Pale in color.

parasite An organism living on another living species and deriving its sustenance to the detriment of the host.

partial veil The inner veil of tissue extending from the cap margin to the stem and at first covering the gills of mushrooms.

pasteurization A process by which bulk materials are partially sterilized through contact with live steam, hot water or dry heat at temperatures of between 140-160°F.

pellicle A skin-like covering on the cap, sometimes gelatinous and separable.

penicillate Resembling a broom or brush; *Penicillium*-like.

perithecium A flask shaped or pear shaped saclike fruitbody of some Ascomycetes that encloses asci.

persistent Not disappearing with age.

Phase I The steps taken in the outdoor preparation, assemblage and conversion of raw materials into a nutritious medium for mushroom growth.

Phase II The pasteurization and final conditioning of a mushroom compost.

phenotype The observable physical characteristics resulting from interaction between the host environment and the genotype.

photosensitive Sensitive to light.

phototropic Growing towards light.

pileus The mushroom cap.

pith The central cottony "stuffing" in the stems of some mushrooms.

pleurocystidia Sterile cells on the surface of mushroom gills. Sometimes called facial cystidia.

pliant Flexible.

pore A circular depression at the end of spores in many species.

primary mycelium The haploid and uninucleate mycelium originating from the germination of a spore which is otherwise not capable of producing a sporulating organ.

primordium (*pl. primordia*) The first recognizable but undifferentiated mass of hyphae that develops into a mushroom fruitbody. Synonymous with "pinhead".

pruinose Having a powdery appearance.

pseudorhiza A long root-like extension of the stem.

pseudosclerotium (*pl. pseudosclerotia*) A conglomerated mass of mycelial tissue resembling a sclerotium but which can not produce a fruifbody or new mycelial growth.

psilocybian Having psilocybin and/or psilocin. (Not necessarily belonging to the genus *Psilocybe*).

psilocyboid Resembling a *Psilocybe* mushroom.

r

radicate Tapering downwards. Having a long root like extension of the stem.

reticulate Marked by lines or ridges.

rhizomorphs Cord-like or strand-like hyphae.

s

SACing Nutrient supplementation of bulk substrates at the time of casing.

saprophyte A plant (fungus) that lives on dead organic matter.

saltation The mutation developing from an isolate of mycelium having a known pure genotype.

scanning electron microscope An electronic microscope which scans an object in a vacuum with a beam of electrons resulting in an image of high resolution and magnification that is then displayed on a television-type monitor.

sclerotium (*pl. sclerotia*) A hardened mass of mycelium, usually darkly pigmented, that is the resting (vegetative) phase in some fleshy and non-fleshy fungi, and from which fruitbodies or viable mycelium can arise.

scratching Ruffling of the substrate or casing surface in order to maintain an open, porous condition conducive to primordia formation.

seceding Describing the condition where the gills have separated in their attachment to the mushroom stem and have torn free, usually leaving longitudinal ridges at the stem's apex.

sector A geometric growth of diverging mycelium (most visible on media filled Petri dishes), the appearance of which contrasts with that of neighboring mycelia, usually indicative of genetic mutation.

secondary mycelium A dikaryotic and binucleate mycelium characterized by clamp connections, crossing (anastomosis), and which is assimilative, not generative, in function.

senescent Having grown old.

septate Having walls dividing cells.

sinuate Describing the attachment of the mushroom gill to the stem at the junction of which the gill appears notched.

somatic Being in the assimilative phase of mycelial growth.

sordid Dirty looking.

spawn The aggregation of mycelium on a carrier material which is usually used to inoculate prepared substrates.

spores The reproductive cells or "seeds" of fungi, bacteria, and plants.

sporocarps Any fruitbody that produces spores.

sterigmata (*pl. sterigmatae*) Elongated appendages or "arms" extending from the apex of the basidium and upon which spores form.

stipe The stem or stalk of a fungus.

strain A race of individuals within a species sharing a common genetic heritage but differing in some observable features of no taxonomic significance.

stroma A dense, cushion-like aggregation of mycelium forming on the surface of composts or casings and indicative of somatic (vegetative), not generative growth.

Strophariaceae The family of dark brown spored mushrooms containing the genera *Melanotus*, *Naematoloma*, *Pholiota*, *Psilocybe* and *Stropharia*.

stropharioid Resembling a species of *Stropharia*, i.e. having a membranous ring on the stem, a convex cap, and purplish brown spores.

substrate Straw, sawdust, compost, soil, or any fibrous material on which mushrooms grow.

t

terrestrial Growing on the ground.

tertiary mycelium Mycelium arising from secondary mycelium that is involved in mushroom fruitbody formation.

tetrapolar Having or located at four poles, as with the four spored basidia in most mushrooms.

thermogenesis The process of heat generation by microorganisms.

thermophile An organism thriving in 75-140°F. temperature zone.

trama The fleshy part of the cap between the cap cuticle and the fertile spore bearing layers of the mushroom gill.

translucent Transmitting light diffusely, semitransparent.

u

umbilicate Depressed in the center region of the mushroom cap.

umbo A knob-like protrusion on the top center of the mushroom cap.

umbonate Having an umbo.

uncinate A type of gill attachment.

undulating Wavy.

universal veil An outer layer of tissue enveloping the cap and stem of some mushrooms, best seen in the youngest stages of fruitbody development.

V

variety A sub-species epithet used to describe a consistently appearing variation of a particular mushroom species.

vector The pathway by which a disease is spread; the "vehicle" for distributing a pathogen.

veil A tissue covering mushrooms as they develop.

vesicle A small bulb-like swelling (sometimes bladder-like).

viscid Slimy or slippery when moist, sticky to the touch when partially dry. A characteristic of the mushroom cap or stem.

Z

zonate Having a band-like region darker in color or different in form than the surrounding tissue.

COLONIZATION

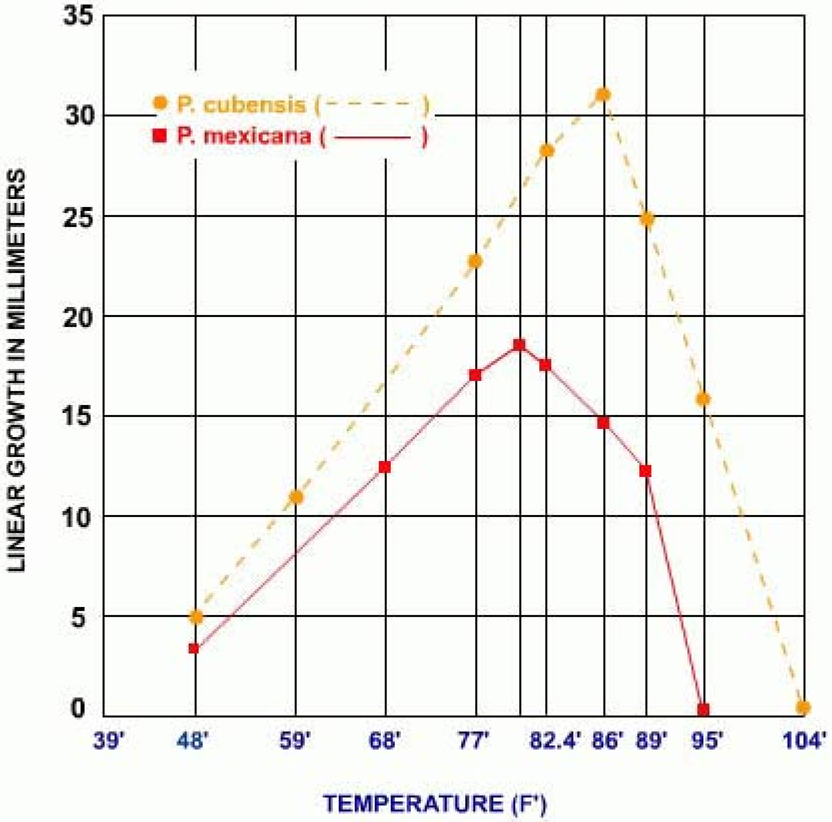
LIGHTING COLONIZATION - Incubating dark is another thing in Paul Stamets 'The Mushroom Cultivator' that needs to go away. The old advice of "incubate in total darkness" is bunk. Those words were written by Stamets in TMC 20 years ago, and he disavows that advice today. There is no harm or benefit from keeping jars in the dark. Expose them to normal room lighting from day one. There is no reason at all to ever have your mycelia in the dark. Darkness will only delay pinning. If you give light from day one, your yields will go up, and you won't face overlay problems. I've found no benefit or harm from allowing the grain jars to be exposed to light from day one. If a few pins form in the grains, it is actually a good thing. Contrary to popular belief, a few pins in the grains can be spawned right into the manure or straw (or used in grain to grain transfers) and they do not rot or otherwise cause contamination. There is evidence they actually help to give a faster, more uniform pinset in the eventual flushes. Stamets believes it's the hormones or other chemical triggers in the pins that do this. Exposing light from day one, one jar out of a hundred will make an early pin or two, but I simply spawn those pins right into bulk substrate along with the grains with zero ill effects. (In other words, small pins don't contaminate when spawned to bulk along with the grains). Twenty years ago, Stamets wrote in TMC to "incubate in total darkness" and people stick to that as if they were the words of god. However, Stamets no longer teaches incubation in darkness, and I agree. If you visit fungi perfect, you'll see 10,000 square feet of incubation area, with 8' fluorescent tubes lighting the entire area for ten to twelve hours per day. Of course myc will grow in the presents of light. IME myc grows faster in the absence of light also in nature myc colonizing substrate is most always not exposed to light so when we do not know for sure we will try to mimic nature which IMHO is the intelligent thing to do. Paul is a pioneer and is always learning as are we and things (ideas) will change again as we begin to really understand better what nature has given us.

COLONIZATION - And I've been trying to correct that disinformation for years. It's all based on a chart somebody mailed to Stamets many years ago showing 86F to be the peak temperature for growth of cubensis on a Petri dish, and everybody just accepts it as though Moses carried it down from the mountain on a tablet of stone. However, every single experiment I did to try to duplicate that with extremely accurate temperature monitoring was unable to verify that bogus 86F figure. What I have repeatedly found regardless of strain is that cubensis colonization remains rather flat from about 75F through 81F. Beginning at 83F, the rate of growth falls off sharply. By 86F, growth has slowed down nearly 50% what it was between 75f and 81F. These experiments were conducted on Petri dishes that produce little to no heat because of the very thin layer of mycelium. In jars, up to several degrees of heat is produced by the colonizing mycelium; so definitely don't go over 80F to 81F if you're looking for maximum rate of growth. Furthermore, bacteria and thermophilic molds such as *Mucor*, the black pin mold are stimulated by higher temperatures. Therefore using an incubator set to 86F is certainly favoring bacteria and molds, while slowing down mushroom mycelium growth. Below is a picture of one of my colonization shelves.

It sits in my bedroom at normal room temperature and quart jars of rye berries colonize fully in ten days, and pf jars colonize fully in 14 to 21 days, but usually closer to 14. How often do we see posts where people have incubators set at 86F, and they're asking why their jars aren't colonized after four to five weeks, and they have large spots of yellow liquid forming? The liquid is metabolites that the mycelium secretes in response to stress, usually from competitor molds and/or bacteria. What has happened, is they've slowed down the mycelium while stimulating the competitors.

COLONIZATION - I have found little to no difference in colonization speeds between 75 and 81F. Growth falls off rapidly at 83F and above, not 87F. That chart above [see below] is bogus, period.



I have tried dozens of times to duplicate it and it can't be done. It was apparently made by someone who did ONE grow with sloppy note taking, and sent the results to Paul. Growth is much slower in cold temperatures until you hit 69F, where it speeds up quite a bit until about 75F, where it remains 'flat' until 81, then is flat again until 83, where it falls off fast beginning at 84. By 'flat' I mean there is no discernible increase or decrease in rate of growth within those ranges. Jars will colonize as fast at 75F as they will at 80F. I've proved this time and time again with every strain in my collection. Growth also falls off rapidly above 84, and this is why so many new folks have problems with incubators set at 86F, and jars that 'won't colonize'. The figures I give are substrate temperatures, not air temperatures. The temp inside the jar is 1 to 5 degrees higher than the surrounding air, depending on where in the colonization cycle the jar is. The heat produced falls off fast as the jar approaches full colonization. If you live in an igloo, (or near the waterfront) by all means build an incubator, but keep it in the normal room temperature ranges for best results. I see no reason to set one above 80F, and lots of reasons not to. Here's a picture of one of my shelves for colonizing jars. The substrate bags are there because I ran out of room on the other shelf. These are in a room at normal room temperature, and exposed to light nearly all day. I don't even put the pf jars on a top shelf where it's warmer. Of course, I had a good teacher on how to make them up, as everyone will soon know.

COLONIZATION - I've been saying that for years. My Petri dish studies a few years ago showed that cubensis reaches peak linear growth between 75F and 80F, then is flat until 83F, where it starts to slow down. Mycelium at 86F is growing at about 2/3 the speed of mycelium at 80F. In addition, the higher temps tend to stimulate thermophilic molds and bacteria. There's LOT'S of good information in TMC, but that 86F figure is one of the errors. When I did it there were ten Petri dishes colonizing at each temperature, in separate containers. I went through well over 200 Petri dishes of mycelium for no other reason than to determine the temperature that stimulates fastest growth, other factors being equal. That was a far more controlled study than the one reported over 20 years ago. If someone else wants to repeat the experiment, go for it. I consider the matter closed. Paul doesn't even repeat that 86F figure, which someone else sent him. Bottom line was the tubs that had Petri dishes between 75F and 81F showed no difference in growth. Below 75F, and above 81F growth slowed down, with a rapid drop in colonization speed below 70F and above 83F. At 86F, a Petri dish would be 2/3 colonized, while its sister at 75F would be fully colonized. Rate of growth at 86F was exactly the same as rate of growth at 72F, with fastest growth as said, occurring between 75F and 81F. Note that these tests were for linear growth in the two-dimensional plane of a Petri dish. In three-dimensional space such as in grain jars or bulk substrates, the effects of thermogenesis need to be considered, so ambient temps should be lowered slightly to compensate.

TEMPERATURE COLONIZATION - 80-83F is optimal growth incubation temperature but anything past 81-83F increases the chances of thermophiles a.k.a contamination/bacteria. The 86F myth is based on a flawed agar study where heat isn't generated on Petri dishes. Mycelia growth declines rapidly at 86F and above. Paul Stamets later reviles that that is misinformation and should be lower. If it drops into the 60's however your speed of colonization will go slowly. 75-78F or at room temperature in the 70's is perfect for jars. If you're comfortable in a t-shirt in your house the jars are ok. Heating jars in incubator causes a lot of condensation, condensation is where the inside 'Temperature' differs from the outside. This has nothing to do with humidity. Condensation is the enemy of mushroom cultivation. It breeds bacteria and any moisture that is stuck to the walls is moisture that is NOT in the air any more, making your crop suffer. You should read up every week about how many noobs come in asking if they've cooked there jars because there temperature met all the way to the 100F +. This is why I disagree as well as speeding up a few days later, why? To run into more problems? For bulk substrates I wouldn't go higher then 80F as they already create enough heat by themselves.

COLONIZATION - 80F is fine for incubating, but don't exceed 81F or growth will slow. 86F is not optimal for cubensis. Stamets quoted somebody else who supposedly put out some Petri dishes in various temperatures and reported that to him, so he printed it. I've tried to duplicate that experiment, and after several times, I reached the positive conclusion that mycelium rate of growth is fairly flat from 75F to 83F, with it falling off sharply at 84F and above. It should also be noted that glass is an insulator, so the heat produced by the mycelium has no place to go and can easily spiral up into the range where growth falls off and thermophilic molds are encouraged. That's why I recommend normal room temperature for incubation, even if it is a tad slower. The benefits of a lower contamination rate far outweigh the extra day or two earlier they might colonize at a slightly warmer temperature. Besides, you should be waiting a week after full colonization anyway before birthing or spawning in order to allow the mycelium to consolidate its hold on the substrate.

COLONIZATION - I have not used an 'incubation chamber' in several years. If you maintain your house at normal indoor temperatures, your projects will do just fine. There is certainly no need to incubate jars over 80F, and to do so raises contaminant risks considerably. The inside of your jars will be 3 to 4 degrees warmer than the surrounding air. If you heat a chamber up to 86, your jars will be near 90, and much more likely to contaminate. I colonize on a bookshelf in a spare bedroom, and no attempt is taken to prevent the jars from receiving normal room lighting. I then fruit in a small greenhouse type enclosure with no heat applied during the growing process. If it's deep winter and your room is a bit cold, run a small space heater to heat the entire room to 75 or so. That temperature will work just fine for colonization, as well as fruiting. There's no need to make growing any harder than it already is. Keep it simple.

COLONIZATION - Do you know of one place in nature where cubes fruit naturally that does not have a difference between daytime and nighttime temperatures? I've read ever since 1985 that 86F is best, usually because of somebody simply repeating what they've read somewhere, then somebody repeats that, and so on and so on. Now, over 20 years later, they're still repeating it, and it's still wrong. In my grow room, the day and night temperatures fluctuate as much as 20F. When I say normal room temperature that means 72F to 78F. There is zero increase in rate of growth of cubensis above 80F, and mushroom mycelium often stalls out and bacteria is encouraged in warm anaerobic environments, such as is found in the bottom of non-vented tubs commonly used as 'incubators'.

COLONIZATION STORY - Let me tell you guys a story. My fellow moderator Roadkill and I were filming a video segment on pf jars over at my brother's house a month or two ago. Later that day, my non-mycologist brother moved everything we left behind out to his garage, jars included, just to get them out of the way. I told him it didn't really matter, as I just wanted to film the process of making/inoculating the jars. Three weeks later, I went over there and guess what? All of the jars were fully colonized. The temperature of his garage during this time varied from the mid 30's to the low 50's. (He lives about 50 miles from the Canadian border) So, if properly made pf jars can colonize in three weeks at those low temps, why bother with silly incubators?

INCUBATION - Mycelium will not colonize faster at 86F. That is flat out wrong. The state of growing mushrooms has progressed way past what was thought 25 years ago. Furthermore, the incorrect information presented 25 years ago said that 86F was an optimal SUBSTRATE temperature, not air temperature. Since there is up to a ten-degree increase in substrate temp over air temp, based on those 25-year-old figures, you should colonize at no more than 76F ambient air temperature. However, maximum mycelium growth occurs at a substrate temperature of 80F to 82F, with a drop off in colonization speed above that. Anyway, this has all been covered to death already, so there's no need to repeat it all over again.

COLONIZATION - Incubators cause way more problems then they solve. I haven't used one in years. Glass is an insulator and holds heat very well. I've seen up to a ten-degree increase over ambient in the temperature inside the quart jars of grains, when a thermocouple is inserted into the center of the jar. The other problem with using a tub as an incubator is stale air. It does little good to have filters and holes in your lids if they all just vent into a sealed tub. Normal room temperature is fine for colonization of mycelium. Colonization speed peaks in the 75F to 81F range, and falls off dramatically above 83F. Stamets published a chart in one of his books that said 86F is the fastest for growth, and that is just plain wrong.

INCUBATING/COLONIZATION - Normal room temperature is the way to colonize jars. People who build incubators have a higher rate of contamination and other problems and those who succeed only have a minor decrease in colonization times. 75F to 80F is perfect for colonizing, and you should be able to find a nice place in your house that has that temperature, such as a top cupboard shelf in your kitchen or an upper bookshelf in the den. Colonizing jars need gas exchange that they don't get in a sealed tub.

COLONIZATION - A fan helps humans to cool off because it speeds up the evaporation of sweat from our skin. A fan will not make your jars any cooler at all because there are no sweat glands on glass. Find a cooler spot. That could be against the concrete floor in the garage or wherever. Placing your jars on a cookie sheet full of cold tap water should help bring the temp down as well. You could fill it just before you go to work and by the time the water heats to ambient, you'll be home to change it out with cool water again. Get creative. Just try to keep the temp in the low 80's or less.

COLONIZATION STORY - Last year, while visiting my brother, I inoculated a bunch of jars for him, thinking he was actually interested. This was in December. I went back in February, and found he didn't have time to bother with them, so put them out in the garage. Temps outside were in the teens and twenties, and in the unheated garage, 30's to low 40's. The jars were fully colonized. I took them home and they fruited like mad. Low temps slow things down, but that's all. I keep master culture slants in the refrigerator for years.

COLONIZATION - There is no need to keep them dark. I'd suggest tossing out that sweet looking incubation chamber and let them colonize on a bookshelf at 74F to 78F. Don't shake ANY jars at inoculation, and don't shake pf jars ever. I also don't buy into the turning them upside down thing either unless you made them too wet or they're water logged on the bottom. The CO_2 exchanges just fine out the top during colonization via the air currents that are created by the heating that is caused by thermogenesis.

COLONIZATION - The science of mycology is progressing very fast, and what was written 25 years ago isn't necessarily accurate today. Perhaps if you got one of stamets' later works, you'd see he no longer uses that 84F to 86F figure, nor does he recommend incubating in total darkness. I take it a step farther by recommending against 'incubating' at all, having found over my 35+ years of experience that room temperature is the best compromise between speed of colonization, and contamination prevention.

COLONIZATION - 81F should be considered the maximum 'good performance' ambient temperature in the colonization area for colonizing jars of mushroom mycelium. If your temp is higher than that, try finding a cooler place. Thermal death doesn't occur until much higher than that, but thermophilic molds and bacteria are encouraged at higher temperatures, and the 'rate of growth' of mushroom (cubensis) mycelium falls off sharply beginning at 83F. The oft-quoted figure of 86F is just plain wrong.

COLONIZATION - Wild swings in temperature cause air exchanges between the jars and the outside. If the changes are rapid, they can easily be too much for the filtering material, especially if only dry vermiculite is used. I don't recommend incubators, but find a nice room that holds at least to within five degrees or so. 75F to 81F is ideal. Above that, the returns are not worth the increased rate of contamination that will be experienced.

COLONIZATION - 80 to 84 is way too hot to incubate grains. Any temp over 80 will favor molds and bacteria and not mushroom mycelium. One must bear in mind the mycelium produces heat as it grows. If your jars are in an environment of 84F, the inside temp will be over 90F. That reduces the growth of the mushroom mycelium and encourages bacteria. Always incubate grain jars at room temperature. Good luck!

COLONIZATION - Actually, from my experiments, rate of growth falls off rapidly above 83F with cubes. I've found fastest colonization temps to be in the 78F to 81F range (ambient temp). Temperatures above that will stimulate molds and thermophilic bacteria, while actually slowing down mushroom mycelium. A lower colonization temp will give you reduced contamination percentages.

COLONIZATION - My quart sized grain jars from agar wedges or grain-to-grain transfers are fully colonized in ten days to two weeks at normal room temp of 72F to 77F, depending on time of day. If it takes longer than that, something else is wrong. Higher temps slow down mycelium growth while stimulating competitor molds and bacteria.

COLONIZATION - 86F is too hot. That figure comes from an error in Paul Stamets TMC, which was corrected in later books. However, many growers only have TMC, thus refer to it as the bible, as if everything we've learned about mushroom growing since 1985 when artificial cultivation at home was in its infancy is void.

COOLING COLONIZATION/FC - You can also freeze quart sized plastic bottles of water, and place them in your terrarium to absorb heat. If you can keep five or six in your freezer, you can rotate as necessary to keep one or two in the FC at all times during the hot months.

COLONIZATION - Light has little to no effect on colonizing mycelium. I colonize all of my substrates in an open room exposed to ambient room light the whole time. Pinning only begins when fruiting conditions are introduced, other than when something goes wrong.

COLONIZATION - Foil should be removed as soon as they're sterilized. It's important to have gas exchange during colonization, so I don't put them in a box of any kind. My jars colonize on an open bookshelf at normal room temperature.

COLONIZATION IS FOR NOOBS - Get rid of the incubator, and put the jars on a shelf where they can receive normal room light during colonization. This will speed up pinset once you case them. (or birth or whatever)

COLONIZATION - Thus, any ambient temp over 81 for jars or 78 for trays of manure, and you're slowing down mycelium growth while promoting bacteria and thermophilic fungi.

COLONIZATION - Darkness is irrelevant to colonizing mycelium. Don't go over 81F. Room temperature is just fine as long as you keep your house t-shirt warm in winter.

BULK SUBSTRATE COLONIZATION - 80F is too hot for colonization of bulk substrates. The interior of your substrate is well over 90F when ambient is 80F.

COLONIZATION - Mycelium growth slows down at 83F and above, so you're hindering growth with that incubator. Use room temperature

GRAINS/JARS/LIDS/SOAKING/SHAKING/G2G

JAR FILTERS - When you use type or polyfill or synthetic filter disks (best) you drill three or four 1/8" (1mm) holes for gas exchange and screw the lid down tight. I use the lids upside down, so the metal is against the glass, but that is just to make them easier to get off later. The rubber tends to stick, making it a chore to lift the lid when you need to open the jar. The jar will always be at the same pressure as the rest of the PC, so there is no problem there. When I sterilize water or test tube slants, I screw the lid down tight with no filter or vent holes. It's not a problem, provided you don't ever pop the weight off the PC at the end of the cycle before pressure has returned slowly to zero on its own.

FILTERS GRAINS - Tyvek is functional and cheap or free. However, synthetic filter disks last for many years and thousands of uses. Tyvek tends to get ripped at the edges of the lid, often resulting in only one use. It can also twist, making the lid very hard to get off later for G2G or other procedures. The time spent cutting tyvek to shape each time will easily outweigh any cost advantage. Even though I sell tyvek on my website, I still prefer filter disks.

FILTERS - Mycologists have used cotton filters at least since the 1930's. It's a proved filter material. The cotton must be kept totally dry, as must any filter material. Synthetic pillow stuffing is better, as are synthetic filter disks and/or tyvek. Coffee filters are for coffee. Using one as a contaminant barrier would be like trying to use a chain link fence as a mosquito barrier.

FILTERS - I think you should run an experiment and give us a report. It's so cheap, I toss it out after a use or two. One pair of XXXL coveralls will make over 200 filters. Synthetic filter disks, which are PFTE, can withstand bleach hundreds of times, which I know for a fact.

FILTER - We filter our colonizing jars because sterile, uncolonized substrates will grow whatever lands on them. There is no reason or need to filter a fruiting chamber. Aquarium pumps and air stones will not deliver nearly enough air exchange for good results.

COFFE FILTER GRAIN JARS - In addition, trying to stop contaminants with a coffee filter is like trying to stop a bird with a barbed wire fence. Look at a coffee filter under a microscope. The holes in it are ten times or more the size of contaminant spores.

COFFEE FILTER - First of all, trying to stop contaminants with a coffee filter is like trying to stop a mosquito with a barbed wire fence. Two coffee filters are like having two strands of barbed wire. Is that going to stop a mosquito???

COFFEE FILTERS AS BACTERIA PROTECTORS - Trying to use coffee filters to stop bacteria and trich is like trying to catch a mosquito with a fish net. Isn't going to work.

FILTER - If you're going to use micropore tape as a filter, use two layers.

TAPE - Actually, The tape is only for the sterilization cycle. After that, you can take it off because the dry vermiculite is the filter. Masking tape won't breath. The tape is simply to help keep water out of the holes. If you'll elevate the jars totally out of the water during sterilization, you don't need tape. Simply cover the lids with foil to prevent the condensation that drips off the lid of the kettle or pressure cooker from entering the holes. If you use medical tape such as micropore or other 'breathable' tape, you can leave it in place and inoculate right through it.

MICROPORE TAPE - Probably. The 'micropore' tape is a 3M product. I don't know if it's a trademarked name or not. I suspect breathable medical tape is going to be the same thing, whatever the brand.

MICRO PORE TAPE - The tape goes on BEFORE sterilization. It has no purpose afterwards. It's to prevent water that gets under the foil from penetrating your jars during the sterilization process.

POLYFILL - 'Synthetic cotton' = 'polyfill'

SYNTHETIC FILTER DISK - The bands are what hold the metal lid on. The lid itself isn't threaded with two-piece lid mason jars. You don't want the rye grains to come into contact with the filter disk. Be sure to put the metal lid on first with two 1/8" holes (1mm), then put the filter disk above that, then the metal ring goes on last. This way, when you shake the jars, the grain doesn't get the filter wet with grain juice. A wet filter is a vector for contaminants because they can colonize right through the interior of the filter. Be sure to keep your filter disks dry for best results. Use a glove box, and simply lift one side of the lid enough to squirt the solution in. Squirt it down the side of the glass. Do that in two or three places, then tighten lid. Be sure to use a glove box.

SYNTHETIC FILTER DISKS - I soak synthetic filter disks in a ten percent bleach solution for fifteen minutes before using. It's probably not necessary though since they'll be pc'd anyway on the next cycle. Bleach doesn't hurt them. I have hundreds of synthetic filter disks that are well over ten years old and have yet to have a single one fail.

SYNTHETIC FILTER DISKS GRAIN JARS - They're the best filters you can get. Don't inoculate through them though. Use a glove box and simply lift the lid up and squirt under it. I have some that are six or seven years old and still being used after hundreds of times.

SYNTHETIC FILTER DISKS - Check a local chemical supply. The filter disks are made from PFTE and usually filter down to less than 1 micron. 90mm is a standard size. You might be able to find them from a local, non-mycology related source.

SYNTHETIC FILTER DISKS - You can't beat synthetic filter disks though. They're ten times thicker than tyvek and last a lifetime. I have some that have been through hundreds, perhaps thousands of cycles.

SYNTHETIC FILTER DISKS - Do NOT inject through a filter disk. If you use synthetic filter disks, you'll need to lift the filter up to squirt under it. Do this in a glove box, or in front of a flow hood.

SYNTHETIC FILTER DISKS - Synthetic filter disks are my favorite. I have some from the first batch I ever bought, ten years ago. I still use them after hundreds, if not thousands of times.

SYNTHETIC FILTER DISKS - They all work. My preference is synthetic filter disks because they can be used hundreds or even thousands of times.

SYNTHETIC FILTER DISKS - You need to use the lid under the disk. If you only use a filter disk, the grains will dry out before full colonization.

SYNTHETIC FILTER DISKS - Synthetic filter disks work great for LC, but as with all filters, be sure to keep it dry.

TYVEK - A single layer of good tyvek should be enough. Don't put cotton in the middle of a tyvek sandwich or it will get damp and ruin your day. Use kite tyvek or tyvek from a set of coveralls. Don't use three layers unless you have a lot of holes in the lid. You'll cut off the gas exchange. I drill four 1/8" holes, and use two layers of tyvek, both on the outside of the lid so they stay dry.

TYVEK GRAIN JARS - I've used tyvek coveralls for filter material many times. I doubt that's your problem. Tyvek is used for safety coveralls because it allows the person's sweat vapor to escape, while still providing protection from the toxins.

TYVEK - Don't use post office tyvek for anything but mailing. It's a violation of federal law. Go to your local home mega center, and in the paint department, they'll have tyvek coveralls for five or six bucks. Get a few of those to cut up.

TYVEK GRAIN JARS - Actually, the tyvek goes over the lid, not under it. You want the tyvek on the outside so it stays dry. Put down the lid with small holes in it first, the tyvek second, and lastly the ring to hold it all in place.

TYVEK LIDS - Not only will they dry out that way, they'll cause premature pinning by providing air exchange, as opposed to just gas exchange. You need to at least tape over 90% of the tyvek with duct or shipping tape.

TYVEK - Go to your local home mega center and get tyvek coveralls from the paint department to cut up and use as filters. Post office tyvek is not only illegal to use but subpar as far as performance goes.

TYVEK - Post office tyvek is thinner and not as effective at stopping contaminants as the multi-ply, much thicker tyvek used in wrist sleeves and coveralls.

TYVEK - The tyvek should be OUTside the lids. If you put the tyvek inside the jar, you'll have a much higher contamination ratio.

TYVEK - Tyvek coveralls, wrists leaves are washing machine safe.

KITE SUPPLY STORE. TYVEK - http://www.intothewind.com/search.

COLONIZING JARS/BAGS - I've scanned my crops and colonizing jars and substrate bags with an IR camera and noticed up to five degree F increase in quart jars of rye, and up to a 15F degree increase over ambient when shooting at large gusseted spawn bags, but that was 15F over ambient at the edge of the bag. I'm sure the center was hotter. I usually have up to 200 spawn bags colonizing at any given time on shelves in my grow room, and I never heat it, even in the coldest months of winter. The temperature in the room rarely drops below 75F, even when it's freezing outdoors. We use minimal heat in the rest of the condo as well, simply leaving the grow room door open is enough to supply most of the heat we use.

FLIPPING JARS PF/GRAINS - Don't flip jars. As prisoner said, it screws up the vermiculite filter. CO_2 doesn't need to 'drain' out by flipping the jar upside down. That's a bit of disinformation that once typed refuses to die. The reason is the heat produced by the mycelium causes circulation that takes care of the gas exchange.

FLIPPING JARS PF/GRAINS - When you examine them, don't turn them upside down. That can cause the vermiculite barrier to shift. You can expect there to be contaminant spores near the air/inoculation holes, and if you shift the jar around, those mold spores can be shifted down and into the substrate, contaminating it.

COLONIZING JARS - Bear in mind, a substrate on the dry side will colonize faster than an overly wet one, so if your jars didn't colonize, something else might be wrong. It's also a good idea in a dry climate to run a humidifier in the room your grow is located to raise the ambient humidity.

COLONIZATION/INCUBATING GRAIN JARS - The moisture comes from condensation on the lid of the pressure cooker that constantly rains down on the jars below. That's the reason for the foil. I'd start over and get it right. Don't waste spores getting off on the wrong foot.

PF CAKES - Cakes often pin on the bottom because that's where the moisture runs to by gravity and also it's closer to the perlite, thus the humidity is higher and stimulates pinning.

COLONIZATION - Grains colonize much faster when prepared on the dry side. I do it that way by design. If you see visible moisture on the surface of the grains, they're too wet.

GRAINS/SUBSTRATE - Most often, if a cased substrate smells of alcohol. Some fermentation has, or is taking place.

COLONIZING JARS - If the mycelium runs out of O_2, it will stall and die.

G2G TRANSFERS - One should never use a jar that isn't at least 100% colonized for a grain-to-grain transfer. The biggest reason is that since sterilization is a relative term, it's never complete. You have a window of opportunity to get your grains colonized before the contaminants that survived pressure-cooking come back to haunt you. If you grain to grain with uncolonized grains, you add their age to the age of all the grains in the receiving jar, possibly contaminating them all. The difference between 100% colonization and 80% colonization should be no more than two days, so don't risk failure for a measly 48 hours.

SPAWNING G2G - Bang the colonized jar against a tire or phone book to separate the kernels. Next, open each freshly sterilized rye jar one at a time, and pour and twist from the grain master to deliver a small amount into each receiving jar. Try to have the receiving jars open for no more than five seconds, so plan ahead and work fast. Clean all jars with alcohol before opening. Wear latex gloves and wash them with alcohol after putting them on. As said above, use a glove box, or even better of course is a laminar flow hood. Good luck.

G2G GENERATIONS - It was ANNO that pointed out - young vigorous mycelium does better than old. However, I have gone out 5 G2G transfer generations - without ill effect. Genetics plays a part in it. In nature - mycelium is designed to grow out & fruit in one season. You can FOOL with Mother Nature - but extending it to far out - usually brings on some mutation.

G2G TRANSFERS - When you do a g2g, unscrew the ring, then with your thumb and forefinger, squeeze the ring so you capture the lid and the filter and lift all three as one unit. Pour from the donor jar to the open receiving jar, and then replace the lid as one unit. Have the receiving jar open for no more than a few seconds when doing this.

G2G TRANSFERS - I shake the master jar to loosen the kernels, and then do the g2g right away. After the transfer, gently shake the receiving jar, and then shake again at 20 to 30 percent colonization. I never wait for the grains to recover before shaking or g2g. They'll recover right into the fresh grains of the receiving jar. Good luck.

G2G TRANSFERS - Four grain-to-grain transfers should be considered the outside limit, but chances are you'll see growth slow before then anyway. Cloning from the third would make it the fourth, and wouldn't help. Go back to spores. A given cell line can only divide so many times before loss of vigor sets in.

G2G TRANSFERS - Never use a jar that pins early for grain-to-grain transfers. Usually, something is the trigger for early pinning, such as bacterial contamination. I know you don't g2g brf jars, but had it been a grain jar, you wouldn't want to use if for transfers.

G2G TRANSFERS - You can generally use a fully colonized grain jar to inoculate up to ten times that amount of sterilized grains. How many bags per jar simply depends on what size spawn bag you used, and what size jars your grains are in.

LC > G2G - Fastest colonization I ever had is with G2G.

SHAKING GRAIN JARS - I disagree with more than one shake during colonization. A shake at 20% to 40% will spread those kernels around, ensuring the rest is colonized within a few days. After shaking, there's a 24 to 48 hour period where the mycelium is merely trying to recover from damage, but isn't growing into the new grains. If you shake more than once, you force the mycelium to waste needless energy re-knitting, when it could be aggressively growing. The same applies at the end. Shake to loosen the grains, and then spawn them to your tray of manure or straw, etc. Let them recover directly into the manure or casing layer. If you shake, then allow to recover, they're damaged again by spawning, so must recover yet again. My point is that shaking is abusive, but a necessary abuse. Simply keep it to a minimum.

SHAKING GRAIN JARS - From my tests, it actually slows down colonization, by forcing monokaryons to reach out farther before finding a compatible mate. Dikaryons colonize and feed much faster than monokaryons. By shaking, you disperse the ungerminated spores over a larger area. I prefer to inject, and then let the jars or bags sit for several days until you see germination, or if you inoculate with an agar wedge, wait until the mycelium has moved off the wedge and into the grains before shaking. If you do the above, only one shake is required during the whole process.

SHAKING GRAIN JARS - When you shake a jar, it will 'look' uncolonized for a few days until it recovers. You only need to shake once at 20% to 30% colonization. Your second and fourth jar above look about done. Give them a few days past full colonization before spawning to bulk. The third jar needs a few days. They'll all look like the first jar after shaking. That's normal. Shake just before spawning by banging the jar against a tire, and then layer into your manure or whatever you're using as bulk. The mycelium on the grains will recover right into the substrate.

SHAKING GRAIN JARS - You need to break it up at 20% to spread the mycelium around so it can inoculate the rest of the rye. It will speed colonization up. If the mycelium fails to recover after breaking it up, it means the grains were contaminated anyway. Read up on 'shaking'. That's what we do with rye grain jars. I use a bicycle tire to bang the jar against to break it up. With bags, simply massage the bag between your fingers to break up the clumps and spread them around the bag.

SHAKING GRAIN JARS - If you shook right after inoculation, it will be fuzzy at first. I suggest inoculating and NOT shaking for at least a week. By shaking, you spread the spores around, forcing monokaryotic mycelium to hunt for a mate. If you let the spores germinate right next to each other, they form bonds and become dikaryotic in the first few days after germination, and then grow with the thicker, rhizomorphic mycelium.

SHAKING GRAIN JARS - Shaking right after inoculation is a mistake. You should allow the spores to germinate in close proximity to each other so they can pair up and become dikaryotic. Monokaryotic mycelium is thinner and much slower growing than dikaryotic mycelium. By shaking the jar, you required it to colonize with the slower growing monokaryons.

SHAKING GRAIN JARS - The best way to break up a grain jar is to beat the hell out of it against a fully inflated tire. I use a bicycle tire and air it up nice and hard before use. Half a dozen bangs usually separates every kernel from every other kernel. If not, it's a good sign your jar was contaminated with bacteria, which makes the kernels stick together like rubber.

SHAKING GRAIN JARS - Grains should NOT be shaked after inoculation with spores. Monokaryotic mycelium grows far slower than dikaryotic mycelium. It's best to inject the spores and leave them to pair up in close proximity to each other. Once they pair up and become dikaryotic, shake once to distribute the grains, which speeds up colonization.

SHAKING GRAINS - Grains should only be shaken once during colonization. More than that slows down progress. Shake at anywhere from 15% to 30%. The grains will begin to show recovery by 24 hours, and by 48 hours, things should be growing rapidly again. You'll have to shake again after full colonization to remove the grains.

SHAKING GRAIN JARS - If the grains don't break up easily when banged against a tire, it's a good sign that they're contaminated with bacteria. It is even more likely since you're using an incubator. Grain jars; especially quarts should never be placed in an incubator, but rather allowed to colonize at normal room temperature.

SHAKING COLONIZED GRAIN JARS - Colonized grain jars break apart very easily by banging against a fully inflated bike tire, and you NEVER want to scoop out grains. It damages the kernels, leaving them open for bacteria, and adds an additional vector of contamination to the process.

SHAKING - Never hold a jar in one hand while holding a camera in the other. That doubles the amount of shaking going on, screwing up the picture. Put the jar down. Rest the camera on a chair, book, or something else if you don't have a tripod.

SHAKING - Shaking always makes them look 'uncolonized' because it beats the mycelium on the surface of the grain. After a few days, as you found out, they recover. You should only shake a grain jar once at 25 to 35 percent colonized.

SHAKING GRAINS COLONIZING - There is no need to shake more than once. Three times is mycelium abuse. Please continue the same thread for ideas along the same lines. Don't start a new thread with each question.

SHAKING GRAIN JARS - Shake at about the 25% stage. Shaking prior to that only batters the myc & then it takes time to heal & start growing again. You ever hand a black eye? How long did it take to heal?

SHAKING GRAIN JARS - Grain jars shouldn't be filled more than 2/3 to 3/4 full to allow room for shaking. If you'll bang the jars against a fully inflated bicycle tire, the kernels will separate easily.

SHAKING - A quart jar of healthy mycelium on rye that is shaken at 25% will be completely colonized three to four days later. If not, something is wrong.

SHAKING GRAIN JARS - Shake jars well at 20% to 30% colonized to spread the grains around. They're usually fully colonized four to five days later.

SHAKING GRAINS - Remember, when things look fine until you shake, then don't recover, it's almost always bacteria.

SHAKING GRAIN JARS - Shake, and if it recovers it's fine. If not, it was contaminated.

SPAWN BAGS - I really hate to disagree, but it's best to not shake at all just after inoculation. Leave the spore solution all in one spot so the monokaryons can find compatible hyphae nearby and do the sex thing. Once you have solid white mycelium growing, those are the dikaryons and they grow much faster than the wispy, grayish monokaryons that emerge from the spores. Many new growers mistake these for cobweb mold and toss out perfectly good projects because they shake at inoculation. If you shake the bag or jar early, you force the slow growing monokaryons to colonize much more of the substrate before finding a mate, thus slowing down the progress. I'd recommend giving the first and only shake at 30% colonization.

STORING GRAINS/PETRIS - Actually, grains have been found better for mycelium storage than agar slants, but unfortunately take way too much room in the refrigerator. However, I've used jars that have been stored fully colonized in the refrigerator for several years. Put them in the refrigerator at full colonization, and then when you remove from the refrigerator, allow three to five days at room temperature before spawning.

STALLED GRAIN JARS - In the overwhelming majority of cases when a jar stalls, it's due to lack of gas exchange. Make sure the holes are open on the lids. If you have a vermiculite barrier, you can loosen the lids or even remove them for a time. Jars rarely dry out.

GRAINS STORING - You can store colonized grains in the refrigerator, or use them for grain-to-grain transfers to expand your mycelium. Correct, removing jars from the refrigerator requires a couple of days of warm up before they start growing again.

SPAWNING - Make thin layers so they fill in the gaps quickly. I've found this has less of a chance of breaking kernels of grain spawn, which can allow contaminants to get a foothold in the uncolonized part in the middle.

STALLING JARS - They don't 'stall' without a reason. Either it ran out of air due to no holes for gas exchange, or it's contaminated with bacteria. You can't spawn uncolonized grains or the bulk is sure to contaminate.

SPAWN BAGS - Unless it's a HUGE bag, don't use over three to five ml of spore solution or liquid. More than that will be too much and throw off your moisture content.

STORING GRAIN JARS - They can sit for a couple of weeks at normal room temperature after full colonization without harm.

RYE GRASS SEED - Use twice as much grass seed by volume as water. For a 1-quart jar, use 1 1/4-cup rye grass seed, and 5/8-cup water. Add a pinch of gypsum between your thumb and forefinger per jar. Put a solid lid on the jar and shake well. Allow to sit for an hour or two, and then shake again. Replace the solid lid with a filtered lid, and PC for an hour at 15 psi. Rye grass seed makes an excellent grain master, because you can easily do a grain-to-grain transfer into 20 jars. I won't go over ten jars with rye berries. It's also a great spawn to bulk substrates, because of all the inoculation points. It also seems less susceptible to trichoderma then the larger rye berries. We usually don't recommend it to new growers because it often takes quite a few tries to get the moisture right. If it's too wet, the mycelium can't colonize. Ditto if it's too dry. The above plan should work out for you though.

RYE GRASS SEED - Rye grass seed needs to be mixed with half as much water by volume as you have grass seed. For a quart jar, I use 1 1/4 cup of grass seed, and 5/8 cup of water. Add a pinch of gypsum between your thumb and forefinger per jar. Half the amount of water can be substituted with brewed coffee. I put a solid lid on the jar after mixing and shake well. Allow to sit over night, and then shake again. Replace the solid lid with a filtered lid and PC for an hour at 15psi.

PREARING RYE - It's irrelevant. I bring rye to a raging boil after the 24-hour soak, with the stove on 'high', and have ZERO busted kernels. As shown in the video, rinse grains very well with hot tap water before the soak. Fill the kettle with hot tap water to begin the soak. Add gypsum. After 24 hours, bring to a raging boil for five to ten minutes, then drain and shake. I've never seen more than one kernel in a thousand busted when following the above.

RYE GRAIN - After a 24-hour soak, I once accidentally left the water in a rapid boil for nearly an hour. There were no burst kernels and they weren't any fatter than they'd have been after a ten-minute boil. I used them and they were fine. The secret against cracked kernels is to soak the grains first, and then to heat the water and grains together slowly.

RYE GRASS SEED - Rye grass seed is also excellent for spawning to bulk, and very cheap too. It's a bit trickier to prepare, but goes a long way when used for grain to grain transfers or for spawning to bulk substrates.

RYE GRASS SEED VS RYE BERRIES - I doubt you can get grass seed to fruit, although it makes excellent spawn. You want rye grain. Copes need the grains to be spawned into manure.

WBS - I gave up on wbs due to the inconsistent types of seed in it. It works, but rye is much better and only costs about 5 cents per quart jar if you buy it in 25 pound bags.

RYE GRASS SEED - If you simmer rye grass seed, you will ruin it. Soak only.

FLIPPING JARS - If the bottoms didn't colonize due to bacterial contamination, it will have no effect. If the jars didn't colonize due to excessive moisture that ran to the bottom, it will help, by draining it to the other end of the jar. Some growers think flipping upside down is to release CO_2, but this is incorrect. The heat produced by the mycelium produces circulation that does that job. I've never yet had a jar that wouldn't colonize the bottom, provided it was made correctly to begin with, using the proper amount of water AND the correct jars, which you don't have. BRF cakes do best in short fat jars, such as wide mouth half-pints.

PF TEK JARS - The biggest cause of failure with pf tek is not following proper sterile procedure. You the cultivator are the biggest single source of contamination, so be very careful. Thousands of bacteria are exhaled from your mouth with every breath, so wear a surgical mask. Millions of bacteria reside under your fingernails, so wear gloves, and wash them with alcohol before use. Use a glove box, and flame the needle of your syringe red hot before use. Alcohol might clean the outside of the needle, but contaminants can enter into the center of the needle and not be touched by the alcohol.

LIDS GRAINS - In addition, your order of assembling the lids is incorrect. You want the metal lid with holes first (make the holes no more than 1/8"), followed by the filter material, then the ring. This keeps your filter on the outside of the jar where condensation doesn't get it wet. Remember, if your filter gets wet, you're screwed. Bacteria in the air will colonize right through the material as if it wasn't even there. The reason for making the holes in the lid small is so that when you shake, the wet grains don't contact your filter material. A wet, nutrient saturated filter is sure to contaminate.

GRAIN JARS - Actually, half a teaspoon of bleach in a gallon of water will kill bacteria, but it throws the pH way off, so I don't recommend it at all, especially in grain jars, which prefer an acidic pH. I wouldn't inject water into a grain jar. If they're drying out, chances are, your gas exchange holes are too big. You don't want more than four 1/8" (3mm) holes. You could even get by with smaller holes. I use four 3/32" (2.4mm) holes for both 1/2-pint pf cakes and full quart grain jars. Larger holes can dry out the material and encourage invitro pinning.

GRAIN JAR SIZES - Quart jars are best suited for grains in my experience. Anything less, and there just isn't enough spawn for your bulk substrate. Due to the requirement to leave shaking room, a pint jar can hold more grains than two 1/2 pint jars, and a quart jar can hold more grains than two pint jars. Half-gallon jars are nice, but they really should be colonized at a 45-degree angle to help with gas exchange. I've had a lot of trouble with CO_2 concentrations when leaving 1/2-gallon jars standing upright.

GRAIN JAR LID - If you'll drill two or three small, 1/16" holes in the metal lid, the grains will never touch the filter when you shake. A fully inflated bicycle tire works great for banging jars against to break them up. Just make sure you have the tire pumped up nice and hard.

GRAIN JAR LIDS - I recommend using four 1/8" holes for gas exchange. If you use more than that, you run a risk of drying out your grains and/or stimulating pinning inside the jar due to having too much air exchange, as opposed to a small amount of gas exchange.

GRAIN JARS - As said, you soak for bacteria, not molds. If it turned green without opening, then plain and simple, your filter is not doing its job. Look for tears. Is it post office tyvek? If so, that could be the problem. I don't consider it suitable for mycology.

GRAIN JARS - A 1/2" hole in the lid is way too much for a small jar. In fact, with quart jars, I only use three to four 1/16" holes for gas exchange. A large hole will not only dry out your grains, but can lead to pinning before full colonization.

HALF-GALLON MASON JARS - My experience with half gallon and larger jars is they need to be incubated at an angle of 45 degrees to allow for gas exchange. They get stagnant standing upright with the lid/filter only on top.

RUSTY LIDS - Rusty Lids: It's harmless to the mushrooms and to you if eaten. Just don't cut your finger on the rusty lid. Lockjaw sucks.

PF CAKE JAR - Use 1 ml total for a 1/2-pint cake.

SIMMER OR NOT TO SIMMER - The above posts prove there are many ways to skin the proverbial cat. The important thing is to have the grains at twice their original dry size, with no burst kernels and no excess moisture in the jars.
After a 24-hour soak, the grains are fully hydrated, but personally, I boil for a few minutes after the soak for one reason-It allows the grains to steam off the excess moisture from the surface as the rest of the water drains in the colander. By shaking the colander, the grains release the excess moisture as steam.
Experienced growers are all successful and most have evolved their own tek for preparing the grains. As long as your grains seem dry on the outside, and are twice the original size without burst kernels, they are ready for the pressure cooker, regardless of how one goes about reaching that point. Some growers even dry the grains off with a towel.
I would say to any new grower to read the way the experienced cultivators do things and try a few ways. After you pressure cook your product, don't hesitate to toss it out without inoculating if things don't look right, and start over. Try, and then try again until you get it right. Once you find a method that works for you, stick with it.
Good luck.

JARS PRESSURE COOKER - It's really not about jars breaking, although sometimes they will. Here is the reason: At 15psi, the temperature in your PC and inside the jars is 250F. If you quick cool the PC, the substrate or whatever is in your jars is still at 250F, but now the pressure is gone. As we all know, water boils at 212f at sea level pressure. That means that the moisture in your jars will boil off. It will continue to boil off until the temperature of the substrate cools below 212F. There's an excellent chance that you will have destroyed the moisture content you worked hard to get right before sterilization. If you quick cool with bags, the filter won't expel the steam fast enough, so the bags inflate and burst, spilling whatever is in them. When the instructions say you can quick cool, you must bear in mind they don't build PC's for mushroom growers. They build them for kitchen food use.

PCING GRAIN JARS - Lids tight. If they're loose, there's a chance that contaminants will be drawn into the jar as the PC cools at the end of the cycle. Air in the jar won't expand and need to escape because the air in the pressure cooker is under the same pressure, thus it's equalized. It's best to let steam escape for a few minutes before placing the weight on or closing the toggle if it's a sterilizer, but don't let it go too long. Anytime steam is escaping from the PC, it's also letting moisture escape from your jars. If the PC is blowing steam wildly, it's also blowing steam wildly from your jars, possibly blowing the filter material and/or drying out your grains. This is the reason you never want to pop the weight off at the end of the cycle to let the steam out.

RELEASING PRESSURE PC GRAINS - One should never release pressure immediately after the cycle. The very rapid cool down from 250F to 212F while the grains or other substrate inside of the jars is still 250F will cause many jars to break. Furthermore, water at 250F must be under pressure to exist in the liquid state. Therefore, when you release pressure, you also release moisture from the substrate. That is a fact of physics. It can be made up for by adding more water to begin with, but now you're forced to figure out how much is going to be lost. That is beyond the reach of the new folks trying to learn so many other facets of the hobby. It's far better to tell them to NOT release pressure early to remove one more variable from the equation.

PRESSURE COOKING JARS - Jars should be inoculated as soon as possible after sterilization. I wish people would quit saying the jars need to cool past the point when they're cool to the touch. They do NOT stay warm on the inside of the jar longer than the outside by more than a few minutes at most. The water permeates every part of a grain or brf jar, and water is an excellent heat transferrer. If the jar itself is cool to the touch, then the insides will be also, and that includes the middle. Think about it. If you have a cup of coffee get cold from sitting out too long, it isn't still hot in the center.

NO NEED TO SIMMER - LOL the soak / simmer thing is something we all go through. My experience with "simmering" grains almost always led to mushy - sticky grains & on occasion - wet spot contamination - in jars. I prefer WBS because of its low cost & availability - everywhere. No simmer is necessary with WBS. Just experimenting around, I have supplemented WBS spawn with rye (5 % per batch), rape seed (5%) & cracked corn (5%) & had great results.

PCING GRAINS - PC'ing does not remove water from the grains unless you screw up and pop the weight off at the end of the cycle to let steam out. In addition, grains prepared on the dry side will colonize much faster than wet grains.

BURSTED KERNALS - Attempting to make your mycelium colonize busted kernels is like trying to get your car to drive cross-country on two flat tires-possible, but not recommended for good performance and speed.

STERILIZING GRAINS - I recommend 120 minutes for quart jars of grains to take care of bacteria.

SOAKING GRAINS - If you soak overnight, with the soak beginning in hot tap water, you can boil the grains for an hour or two and the kernels won't bust. They also won't take on any more water. Once the kernel is saturated, it doesn't absorb any more, no matter how long you boil. After the soak, add hot tap water to the soak water if necessary to fill the kettle as full as you can before placing on the stove. Heat to boiling, and then after several minutes, pour the water off. Shake the colanders so the steam can evaporate off the kernels, drying them. That's the main purpose of the boil, besides killing the germinated bacteria before pouring it down the drain. It also gives the grains sort of a pre-sterilization prior to the PC cycle. Don't skip the gypsum. It's worth a trip to the nursery.

SOAKING GRAINS - I soak anywhere from 4 to 24 hours. It really doesn't make much difference. The grains are only going to absorb so much, so you'll never over-hydrate by boiling. After a few hours to overnight soak, I let the pot boil for five to ten minutes, then drain into the colander. The steam that evaporates off the grains will dry the outside while the water runs down the drain. If you'll toss the colander around with the grains a few times to make them steam off, they're ready to load in twenty minutes. Gypsum serves two purposes. It adds calcium and sulfur, both essential mushroom nutrients, and helps prevent the grains from sticking and clumping up.

SOAKING GRAINS - 18 / 24 hour soak is a must do thing. Long a soak as possible, so long as WBS doesn't ferment (smell very badly), sprout, or rot is best. No simmer needed. If you have some aged / leached / steer / horse manure around, either brew some into tea, or add softball size handful into a nylon stocking (doubled up - several times) & add cup of strained tea, or use nylon stocking bag - like tea bag & leave it in the soak & stir halfway through soak. Adds significant N to soak water, which WBS absorbs & myc loves. You will get bigger better - everything.

GRAINS COFFEE SOAK - Use weak liquid coffee to soak your grains AFTER rinsing them in hot tap water. Rinse before the soak, not after. Once you've soaked in water or weak coffee, bring the soak water to a boil with the rye in it. It's all described in the tek posted above, and also on the video. I've used coffee grinds in grains, but there's little benefit. It's better as a substrate ingredient.

GRAIN SOAK PEROXIDE - It would be a waste to use peroxide in the soak water for two reasons. One, you want the bacterial endospores to germinate and grow during the soak, so the pressure cooker can kill them. Two, peroxide breaks down very fast in the presence of organic materials, so it would likely do nothing at all anyway. It would be long gone by the time you boil.

GRAINS SOAKING - I suggest a bit of hydrated lime if you're soaking in weak coffee, due to the acidity of the coffee. Use no more than a teaspoon for 2 gallons of soak water. If you're soaking in plain water, skip the lime.

Use one tablespoon of gypsum per gallon of soak water, regardless of how much grains are in it.

COFFEE SOAKING GRAINS - Yes. Mix it weak. About half or less the normal drinking strength. Add it hot. Use hot water for the rinse and add hot coffee later. The heat prevents the grains from germinating during the soak.

GRAINS SOAKING - As I said above, it isn't necessary to use long soak times with rye or wbs. If rye is used/PC'd before it starts to ferment, I actually like the scent.

COFFEE SOAK - Yes. I add coffee to grains, partly to lower the pH. Mushroom mycelium grows fastest at pH about 5.5 to 6.5.

COFFEE SOAK - If you use too much coffee, it will actually slow down growth.

FUNGICIDES FOR GRAINS/CASINGS - I found no problems when using banrot, and the fruits came out normal. It seems I used 1 tablespoon of Banrot 40WP per five gallons of soak water, but that could probably be reduced. Banrot will prevent fungi spores from germinating, but doesn't affect mycelium. It also seems to prevent bacteria. I once left a freshly sterilized jar of rye berries exposed to the open air for half an hour or so, then closed it up and a month later, it was still contaminant free. However, good sterile procedure renders it unnecessary for grains, and while soaking casing material in it will prevent trich and cobweb, proper pasteurization and good air exchange will also prevent mold on casing layers. I prefer growing without chemicals and am generally an organic gardener. The Banrot experiments were simply experiments. Dried and crushed Rhododendron leaves will also help prevent trichoderma and cobweb in casing layers.

GRAINS - You boiled the rye, but not the millet? Then mixed the two? That gives you two different grains with different levels of hydration. Draining for an hour does nothing. All the water that will drain out from a batch of rye does so within 1 minute. The water that is stuck to the surface of the grains, will make them too wet later. You need to drain after the simmer while the grains are still boiling hot, so you can let the steam dry on the surface. Avoid busted kernels at all costs. None is best. If you have more than just a few, do the batch over. If you've soaked, beginning in HOT tap water, there should be no busted kernels after boiling because they will have softened up. Did you leave the stove on high during the process? If so, your jars probably puked out all the moisture that was in the grains. You're supposed to turn down the stove as soon as the weight rattles. Turn it down so the weight either doesn't rattle at all, or rattles once every few minutes at most. Every time the weight rattles, moisture leaves the PC, and a corresponding amount of moisture leaves each jar of grains. That is basic physics.

GRAINS PREPARATION - One of the secrets of grain preparation, regardless of which grain, is to rinse the kernels very well before continuing with whatever preparation tek you're going to use. All grains get packaged with a lot of chaff and grain dust that if not rinsed out will cause the grains to stick together later and cause that sticky goo. Put your dry grains in a large kettle and fill with water as you stir it around. You'll see all the dust and other crap come floating up. Slowly dump out the water to get rid of the junk and repeat two more times or until the water pours off clear. Adding gypsum is also a great idea. It will take anyone a few tries to get the moisture content right, regardless of which grain or which tek you follow. If it's too wet this time, make adjustments next time, and so on until you work out your system.

GRAINS - The biggest reason for clumped up grains is the failure to rinse properly BEFORE soaking/simmering/sterilization. Rinse the dry grains so the dry chaff and dust and other debris can rise to the top and be poured off. Give two or three rinses and your grains will be clean and free of the dust that behaves like glue later. The second biggest reason for clumping is failure to use gypsum. If the grains are properly rinsed, and gypsum is added, they will NOT stick together later, even if you let them sit in the pc until they reach room temperature.

GRAINS - I strongly disagree with mixing vermiculite in grain jars. If you have excess moisture, it will soak it up. If you have the correct moisture, it will screw it up by making the grains too dry. The trick is to learn to get the right moisture content. Grains should be totally dry on the surface before loading jars. That's all. It's simple. The moisture inside the grains is what you want. Either use a towel to dry after draining, or drain the grains after a simmer, and toss them around in the strainer so the steam can dry the surface.

GRAINS - Make sure if you get rye from a feed store that it hasn't been treated with fungicides if you plan direct inoculation with spores. Many times, feed grain is treated with fungicides to prolong storage life in damp barns. If you inoculate with agar wedges or LC, the fungicides won't hurt because they only stop spores from germinating. Personally, I only use certified organic rye berries, obtained from a health food bulk supplier. It costs me $8.75 for a 25-pound bag, but it's worth the extra cost, imo.

GRAINS PREPERATION - As said above, prepare you rye properly and don't dilute it with vermiculite. That's a bogus tek to help beginners get away with being sloppy. In addition, because the vermiculite soaks up the excess water, you never learn to prepare grains properly. It's sort of like never taking the training wheels off your bike. They'd look pretty silly on a Harley someday.

GRAINS - 99% is not 100%, and you have no idea if the center of the jars was colonized or not. Uncolonized grains exposed to air = contamination. They should not smell earthy; they should smell like fresh mushrooms. The earthy smell in grains indicates trichoderma or other molds, so there's always the possibility they were already contaminated.

GRAIN WATER CONTENT - It's because fungus grows better on damp things than on wet things. The grains aren't really dry when properly prepared, they just 'look' dry. That allows the most amount of air in the spaces around the grains, thus favoring the mushroom mycelium over bacteria, which prefer a wetter, more anaerobic environment.

GRAINS - It's normal to see what appears to be uncolonized grains where they are pushed up tight against the glass. If that's all it is, they're good to go. Also, sometimes there's foreign material in the grains, so you might even be looking at a small rock or something.

PREPARING GRAIN - I boil in the water they soak in. The main reason for that is to kill off the live bacteria in the soak water before you pour it down your drain. The soak water can make for a pretty stinky kitchen sink drain if you don't boil it before pouring off.

GRAINS - Also, dumping grains into already boiling water as shown there is a mistake that often leads to burst kernels. Grains should be placed in cold water and slowly brought to a boil, or preferably soaked 24 hours to hydrate.

GRAINS - What causes spores to clump up is all that grit, dirt, and dust in their if you don't soak.

CASING/FC/CO2/HUMIDITY/CAKES/OUTDOOR/SOAKING/MISTING

CASING - A casing should be a non-nutritious top layer that is placed over a colonized substrate to help induce pinning and to supply moisture to the substrate and the developing fruits. You can use others with nutrition but it's best not to as this will cause overlay if your not careful. A casing of 50% Peat Moss, 40% Vermiculite, 10% Coco Coir is something called CAC' which some commercial growers use. This is fine but once again you have to watch it or it can colonize the casing for being nutrition and what's the point of a casing if it fully colonizes? With uncased substrate, wait for full colonization, and then place in the fruiting chamber. Try to keep humidity at 99%, since uncased substrates should be treated as cakes. Remember, when using a casing layer, we keep the humidity a bit lower to allow some evaporation from the casing, which is replaced by daily misting. A piece of wax paper layed loosely over the uncased substrate will help produce a micro-climate conducive to fruiting, but remember that even though it helps, wax paper is no substitute for a genuine casing layer. Incubate until you see mycelium coming up through about 20 to 30 percent of the casing layer. Sprinkle fresh casing material over that mycelium which is showing (That's what we call patching) and place in the FC. The best casing mix is 50% Peat, 50% Vermiculite, 10% gypsum, Teaspoon per cup of peat of Hydrated Lime. Mix the dry ingredients very well, then slowly bring to field moisture level and pasteurize. Also you can use jiffy mix as all it is Peat/Vermiculite/Lime treated but I see it less valuable as just making your own buying a block of peat moss/vermiculite/hydrated lime/gypsum and not having to deal with other shit or pasteurize. Sunshine Mix #3 also works though. The reason we use lime is to raise the pH and to make the casing layer inhospitable to competitor fungi, which are less tolerant of a high pH than established mushroom mycelium. Gypsum is not used to change pH. Gypsum contains both calcium carbonate and sulfur, thus it tends to keep the pH near neutral, preventing swings as the metabolites try to push the pH down. Calcium carbonate or hydrated lime is not used to counter the effect of the metabolites. As said above, that's what the gypsum does. Use gypsum on substrates such as compost or horse manure, but don't use lime. Save the lime for the casing mix, where you should use gypsum and lime together. Gypsum is added to help keep the kernels separated after sterilization and to provide calcium and sulfur, basic elements promoting mushroom metabolism. Using both these will keep contaminants at bay. What you want is a short term (Hydrated Lime) because the life of a casing is measured in weeks instead of months or years. Use hydrated lime to get the ph right at the start, and use gypsum at a rate of ten percent to the peat in your casing to prevent ph swings later. Pickling lime is hydrated lime. It's my favorite, and many commercial grow operations DO use it. Don't use limestone; limestone is for long-term use, such as in a garden. Casings, which flush for a month or so, do not need long-term ph adjustment. They need short term, therefore hydrated lime is what you would want to use. The most critical time for contaminants to enter a casing is during the initial colonization and first flush stages. Once the layer is fully colonized, it's very contaminant resistant. This is why we use Lime/Gypsum. A common contaminant that occurs in casings is the 'Cobweb Mold' which isn't toxic just very annoying that thrives in old stale air. You can melt this using 3% peroxide over the casing. It will not hurt the casing one bit; it's just annoying because you have to keep on it. Don't go easy spray as much as you can. Not in the one spot! Spray the entire casing. Bacteria in a bulk substrate are not a contaminant. Commercial mushroom farms toss out any fruits that have bacterial blotch growing on the fruits themselves. However, having bacteria present in the substrate is not a cause for concern, and in fact many agaricus species won't fruit at all from sterilized substrates. Casing layers are not pasteurized in commercial mushroom production in order for the casing to have a high microbe count. NEVER keep a terrarium or other grow tub sitting on the floor. Get a table or shelf to put it on. Over 90% of the contaminants in a room are within a foot (1/3 meter) of the floor. You can tell when your casing needs a mist by looking carefully at the cakes or casing layer. Allow them to dry slightly, then mist lightly. After a few grows, you'll be able to instantly tell when a project needs to be misted. You don't want them to dry completely out, or get waterlogged. Rhizos on top are a good sign. Let them grow. Knots form later. We using 'Perlite' in our casings because perlite works not by holding water, but by preventing clumping and providing lots of air pockets in the layer itself, which stimulates primordia. By mixing perlite with vermiculite, you get the best of both worlds... moisture retention in the vermiculite, and air retention in the perlite. Ph balancing isn't necessary unless you add peat, which isn't absolutely required for cubes. Just don't try to grow agaricus or other edibles without peat in the mix, because they won't pin. If you're going to case substrates, you want the humidity no more than 90%, with 80% being ideal. Too high a humidity is a major cause of weak or no pinsets on cased substrates.

CASING - You don't need alcohol, peroxide, heat treatment, bleach or anything else on the perlite. Just rinse, and then drain well. Leave no standing water. There is nothing sterile about a fruiting chamber. FC

Having a slightly acidic casing layer PH will not cause side pinning. Sure, you can mist with a bit of baking soda or hydrated lime in the water if you failed to balance the casing layer PH first, but as I said, that isn't the problem. An acidic casing layer will favor trichoderma and other molds, while mushroom mycelium is more tolerant of basic PH. This is the reason we use lime. As the mycelium colonizes the substrate, the metabolic byproducts produced begin to swing the PH lower. By the time pinning starts, you have a near neutral substrate, which is what you want.

Casing layers pin on the sides for several reasons, but most important to remember, they pin there when that's the best environment for them to form primordia. The crease between substrate and tray is a perfect microclimate. It's nice and humid down there and there is plenty of moisture for the substrate to work with. It's also protected from the spray from the mister, which will damage developing primordia if they get sprayed and are allowed to remain wet. When the mycelium is actively reaching/colonizing the top of the casing layer, back off on misting. A sheet of wax paper can be layed on top to hold in the microclimate you're looking for. It helps to wrinkle it up into a ball, and then spread it out again before laying on top of the casing. These wrinkles will ensure there is plenty of air circulating under the wax paper, while at the same time holding a high humidity level in your mini-environment under the wax paper.

It's normal for the substrate to shrink. It's more than loss of water because the mycelium is actually eating the substrate; therefore it naturally gets smaller over time.

At this point, I do not recommend liming the casing layer. You're trying to make it pin, not suppress trichoderma or other molds. If it only pins on the sides, you can be assured they'll grow into monsters. I doubt your total yield will be very much less, although it doesn't look as cool as a wild flush that hides the entire casing layer beneath a forest of mushrooms.

CASING - Exactly. Peat based casing layers should be pasteurized, not sterilized. It does no good to say something doesn't perform well if you don't follow proper procedure in making it. As I've said many times, the commercial growers have invested millions of dollars into research on ways to maximize crops. We can learn a great deal from them, and then expand on that knowledge. Edible and medicinal mushrooms with few exceptions are exponentially harder to grow then cubensis, so learn from those who are already at the next level. Growing cubes can be looked at as a way to learn mycology and then move on, or it can be looked at as a way to get some cheap drugs. Those who follow the latter are here today, freaked out by a trip and gone tomorrow. That's why there is such a huge turnover on this and other boards. Look at growing cubes as a way to 'learn the ropes' and then move to harder and more rewarding species. When you do that, the small things such as casing layer composition become much more important to get just right. Many species won't even fruit at all on a sterilized casing layer. Cubes will fruit, but poorly compared to how they fruit on a properly balanced, pasteurized casing layer, applied over a properly balanced, pasteurized bulk substrate.

FUNGICIDES FOR GRAINS/CASINGS - I found no problems when using banrot, and the fruits came out normal. It seems I used 1 tablespoon of Banrot 40WP per five gallons of soak water, but that could probably be reduced. Banrot will prevent fungi spores from germinating, but doesn't affect mycelium. It also seems to prevent bacteria. I once left a freshly sterilized jar of rye berries exposed to the open air for half an hour or so, then closed it up and a month later, it was still contaminant free. However, good sterile procedure renders it unnecessary for grains, and while soaking casing material in it will prevent trich and cobweb, proper pasteurization and good air exchange will also prevent mold on casing layers. I prefer growing without chemicals and am generally an organic gardener. The Banrot experiments were simply experiments. Dried and crushed Rhododendron leaves will also help prevent trichoderma and cobweb in casing layers.

PEAT MOSS CASING - You seriously need to read and study and not start a thread for every single question that pops into your head. The members can help answer what you don't understand AFTER study, but this isn't a place to learn everything. Commercial growers use buffered peat and NO vermiculite as casing. Their income depends on growing as many mushrooms as they can for the money they spend to grow them. Do you really think a multi-billion dollar industry is just throwing money away? Read, search and study. ALL the questions you're starting these threads lately for are already answered in detail, and available by a simple search, which is faster than typing a question. Those who know these answers are sick and tired of typing the same stuff hundreds of times, over and over again, and aren't going to do it anymore. Those who don't know the answer will make something up just to take a wild guess, and the disinformation continues...

BULK SUBSTRATES CASING - Thicker substrates cause a lot of problems. Layering will give faster colonization with less damage to your spawn than mixing. You'll have more success with thinner substrate layers. Don't even attempt a six or seven inch thick horse manure substrate. They will heat up, and also have the tendency to go anaerobic in the core, leading to contamination. You'll get far more bang for the buck with two trays of 3 inch substrate layers than one tray with 6 inches. Horse manure fruits very well uncased. A properly made peat/vermiculite casing layer will increase yields, but is by no means necessary.

UNCASED/CASED FC - With uncased substrate, wait for full colonization, and then place in the fruiting chamber. Try to keep humidity at 99%, since uncased substrates should be treated as cakes. Remember, when using a casing layer, we keep the humidity a bit lower to allow some evaporation from the casing, which is replaced by daily mistings. A piece of wax paper layed loosely over the uncased substrate will help produce a micro-climate conducive to fruiting, but remember that even though it helps, wax paper is no substitute for a genuine casing layer.

CASINGS - Primordia form in 99% humidity, and rarely in less. A casing layer can help to keep humidity at the surface of the substrate at 99%, even though the air in the fruiting chamber might be lower, therefore they allow for more sloppy technique. However, with less than upper 90's percent humidity, the casing layer dries out fast at the recommended level of air exchanges, defeating the purpose unless you mist heavily a few times daily. That's why I recommend 99% humidity for all growing, regardless of whether one cases his substrate or not.

LYSOL MUTATIONS - I want to scream every time I hear that. It's wrong. Lysol doesn't cause mutations. I can only catch it so many times, and this Lysol/mutant myth is spreading like a damn virus. Your new homework assignment is to spray Lysol near (not on) one of your fruiting cakes and report the results. Lysol is mostly alcohol and isn't good for mushrooms, but using it in the room isn't going to cause mutations. I spray the face of my flow hood with Lysol prior to transfers, so it's always blowing on something.

CASING - Mycelium needs light for much more than for the mushrooms to 'know which way is up'. Upon full colonization and a reduction in CO_2 levels brought about by increased FAE, light becomes an important pinning trigger, and must be bright enough to penetrate the casing layer so that hyphal knots can form from deep within the casing instead of just on top. Dim light will produce 'some' pins, but if you want one of those wall-to-wall flushes, use bright light. I hope this helps clear up any confusion.

CASING - Agaricus farmers use peat without the vermiculite, while people growing cubes tend to mix peat and vermiculite. There's a reason for this. Agaricus fruits at ten to twenty degrees cooler than cubensis in very low light. There is far less evaporation of moisture from the casing layer at lower temperatures, thus the reservoir effect of vermiculite is not as necessary. For a given volume, vermiculite holds more moisture than peat, thus combining the two results in a compromise that favors fruiting in warmer conditions.

CASING/CAKES - You pick the fruits that are ready to pick and leave the pins. The easiest way to re-hydrate a bulk substrate that is dry is to pour water around the edges of the tray so that the substrate floats a bit. Leave it overnight and pour off the excess water. Mist the casing layer well. Never pick the pins because it's common with many species to set pins for the first few flushes at the time of first flush. These pins remain dormant until their turn comes. If you pick them, you ruin future harvests.

CASING PERLITE - Perlite works not by holding water, but by preventing clumping and providing lots of air pockets in the layer itself, which stimulates primordia. By mixing perlite with vermiculite, you get the best of both worlds …moisture retention in the vermiculite, and air retention in the perlite. Ph balancing isn't necessary unless you add peat, which isn't absolutely required for cubes. Just don't try to grow agaricus or other edibles without peat in the mix, because they won't pin.

CASING LAYER - A casing layer allows us to be a bit sloppier on conditions. For example, if you have to leave for work every day for 10 hours or more, a casing layer will protect your substrate while you can't be there to mist. If you can hang around and babysit your crop, it makes little to no difference. Note this applies to cubes only. Other species fruit poorly or not at all without a casing layer, and many edibles won't even fruit on a pasteurized casing, it must be untreated.

SPORE DEPOSITS ON CASING - Heavy spore deposits do tend to hinder future flushes to some extent, but not to the point they describe. You don't need to leave them attached to the casing until you have a black mess everywhere in order to make prints. Pick them as the caps flatten out, but before they go crazy dropping spores. I have several totally sporeless strains. They're the way to go. Culture slants last for years in the refrigerator, making prints unnecessary.

LAYERING VS MIXING CASING - It seems to make sense that mixing would give faster colonization, but my experience is the opposite. By layering, the mycelium on the grains recovers and knits together, and then rapidly takes off and colonizes the rest of the substrate. In addition, since mixing 'can' damage the kernels, and a broken kernel is a prime site for contaminant spores to germinate, layering has the added benefit of less trauma to the spawn medium.

CASING - Bacteria in a bulk substrate is not a contaminant. Commercial mushroom farms toss out any fruits that have bacterial blotch growing on the fruits themselves. However, having bacteria present in the substrate is not a cause for concern, and in fact many agaricus species won't fruit at all from sterilized substrates. Casing layers are not pasteurized in commercial mushroom production in order for the casing to have a high microbe count.

CASING CONTAMINANT COBWEB - The most common contaminant during the fruiting stage is cobweb mold, but it's caused by lack of air circulation and exchange. The more you lift that lid and fan the better. There should be no dust. Wipe it off the top first, and of course, NEVER keep a terrarium or other grow tub sitting on the floor. Get a table or shelf to put it on. Over 90% of the contaminants in a room are within a foot (1/3 meter) of the floor.

MUTANTS - Mutants are pretty common. It wouldn't be from mixing B+ and TC. The mycelium only cares about A and B mating types, not the name somebody wrote on the syringe or print. You may end up with separate zones of each 'strain' or you may end up with a cross, or somewhere in between, but it won't be a hybrid since they're the same species anyway. Either way, it looks like not a half bad pinset you have started there...

CASING - A 'casing' is simply a non-nutritious top layer that is applied over a substrate in order to supply moisture and an environment that is conducive to primordia formation. It should not be used as a synonym for a tray, substrate, or total project. The purpose of a casing soil is to provide moisture and also to provide lots of little air pockets with high humidity to stimulate primordia formation.

FLUSHES BULK SUBSTRATES - True, but in that same time you could have replaced that with a fresh one and got started on another 80% of either 100 or 250, increasing your total yield considerably. It really doesn't matter with hobby grows anyway, but in the commercial field where yield per square foot makes the difference between profit and going out of business, it counts.

LAYERING CASING - I strongly recommend against leaving any grains on top of a substrate, exposed to air. If the grains dry out and the mushroom mycelium weakens, they become the perfect place for molds to start. Many growers get away with it, but the contamination rate will be higher over time. Grains should be covered with at least a very light layer of substrate, imo.

PERLITE CASING - Actually, perlite works very well in casing layers. It can't be used well in pf cakes, but in casing layers it helps to break up the peat and provide lots of O_2 in casing layer, which stimulates pins. Of course, peat moss can be used without any vermiculite or perlite at all. Just lime to balance Ph, and use gypsum at ten percent by volume of the amount of peat.

CASINGS FC - A layer of vermiculite under the substrate is counterproductive. I recommend against it. Some beginning growers do it so that if they over mist, the vermiculite soaks it up. However, if you fail to overwater, the vermiculite draws moisture from your substrate. The vermiculite on bottom can also cause the mycelium to pin there instead of on the top where you want it to.

CASING - It's very common for the mycelium to try to colonize the sides of the tray above the substrate line, especially if condensation is present, which I'm sure it is with your heater. Your fruiting chamber should be kept at normal room temperature, not heated. If it's too cold in your house, run a small space heater in the room, not the terrarium itself.

OVERLAY CASING - Overlay is matted, nearly dead mycelium. Full colonization, even if 100%. Overlay is matted, overgrown mycelium that makes the casing layer impervious to water absorption. A bit of rhizomorphic mycelium on the surface is ok. It's what produces primordia. Patch if you want to, but if you have primordia showing, don't.

OVERLAY CASING - Overlay is the condition that results when mycelium has been allowed to completely cover the casing surface. It is caused by prolonged vegetative growth temperatures, high CO_2 levels, and excessive humidity. If overwatered, the overlay will become matted, or, will form a dense, dead layer of cells on the casing surface.

CASING - I've been saying unpasteurized casing material works better for years, but it's heresy around the OMC where half the growers PC their casing material. Chances of Dactylium mold contamination are higher with an untreated casing layer, but if one can manage proper air exchange, results are superior, ESPECIALLY with cubensis.

CASING - Use gypsum at up to ten percent of the peat. Don't count the perlite and/or vermiculite. Test it with pH strips, and adjust with hydrated lime as necessary to get a starting pH of 8. When they say it has lime added, it means to make it right for plants, which generally like about 6.5 pH, which also happens to favor trichoderma.

CASING - You apply it to your fully colonized substrate and cover it up. You then place it on a shelf out of the way, at normal room temperature for a few days. When the mycelium pokes through a few days later, introduce to fruiting conditions. Read up on patching. It's optional, but does increase yield and pinset.

COLONIZING HIGH CO_2 - One benefit of a high CO_2 level during colonization is that less of the actual carbon in the substrate is converted to CO_2 gas. In other words, if you allowed too much fresh air during colonization, more of the substrate would be 'consumed' by the time the mycelium got to the fruiting stage.

CASING - I would look for a mix without fertilizer if possible. It really won't hurt your fungus, but it could stimulate algae. The chemical plant food won't feed the mushroom mycelium or contaminant molds, but for my grows, I'd prefer to keep it away. I don't even use that stuff on plants.

CASING/JARS - Bear in mind, a substrate on the dry side will colonize faster than an overly wet one, so if your jars didn't colonize, something else might be wrong. It's also a good idea in a dry climate to run a humidifier in the room your grow is located to raise the ambient humidity.

VERMICULITE CASING - Actually, vermiculite can provide moisture to support a flush, but it doesn't fit the definition of 'casing', a term which is tossed around and abused fairly loosely. Furthermore, cobweb mold LOVES plain vermiculite, which lacks the beneficial organisms to fight it off.

COLONIZING MANURE - Leave the substrate loose and airy. I like to add a touch of vermiculite to manure for that purpose as well. A slightly dry substrate will actually colonize faster, so I don't think that's the problem. I make mine dry on purpose, and then dunk before first flush.

COLONIZATION SPEED - Nobody can answer that. There are too many factors besides strain that go into pinning. Also, there's no 'strains' that just colonize slower. Colonization speed is related to substrate moisture level, preparation, gas exchange, amount of inoculants, etc.

CASING - What you want is a short term (Hydrated Lime) because the life of a casing is measured in weeks instead of months or years. Use hydrated lime to get the ph right at the start, and use gypsum at a rate of ten percent to the peat in your casing to prevent ph swings later.

CASING - You don't finely grind up casing layer ingredients. The courser it is the better. It's important for air to be able to penetrate the entire casing layer. A few small pieces of debris in the peat doesn't hurt a thing. I never remove them. That's the reason we pasteurize.

CASING - You want upper ninety to near 100% humidity with lots of air exchange. Misting is required. Even at 99% humidity, the proper amount of air exchange will dry your casing layer (which is a pinning trigger), thus you need to mist to replenish the moisture.

COLONIZING - In addition, colonizing mycelium as agar pointed out, generates its own heat. The process is called thermogenesis. I've seen up to a fifteen degree F increase in substrate temperature over ambient air temperature with manure-based substrates.

CASING - It sounds like the substrate and/or casing layer might be too wet. After awhile, you can get a feel for when a bulk sub needs water by picking it up and judging the weight. You can actually develop a very accurate feel for moisture content this way.

CASING - It looks fine to me. The substrate is supposed to shrink. It's being eaten. It will pin in a few more days, and it's ok to keep the humidity up. You don't need to reduce it until after the pins turn into small mushrooms. Until then, 99% won't hurt a thing.

SLOW COLONIZATION - The biggest causes of slow mycelium growth are a too wet substrate, and not enough gas exchange. Make sure the holes on your jars are open. If your substrate is too wet, there's not much you can do except fix it on the next batch.

WHY CO_2 LOW AND HIGH FC AND COLONIZING - If the CO_2 levels are too low during colonization, the mycelium will consume more of the substrate. By keeping the CO_2 levels high during colonization, we save the mass of our substrate to support the flush.

CASING VERMICULITE - Contaminants will easily germinate on damp vermiculite, and then spread their mycelium to your substrate below. The vermiculite barrier works in pf jars because it's dry. In addition, nothing 'wicks' contaminants, vermiculite or no vermiculite.

CASING - A 'casing' is a non-nutritious top layer that is applied over the fully colonized horse manure in order to supply moisture to the substrate below and to provide an environment suitable for pinning. A casing layer is optional with cubes.

MIXING - Often, they'll combine into one strain, but you'll never know, because there's very little difference between the various strains anyway, PE and the albinos excepted. It would be a 'cross' not a hybrid, which is an interspecies mating.

SUBSTRATE DEPTH FC - Two feet of substrate would go anaerobic in the core due to no air getting in, and rot. 8" seems to be about the maximum you can go with consistent success, but it better be loose and airy if you're going that deep.

FC. CASING FC - Incubate until you see mycelium coming up through about 20 to 30 percent of the casing layer. Sprinkle fresh casing material over that mycelium which is showing (That's what we call patching) and place in the

CLUSTERS - Clusters vs. single fruits are strain related. Often when multispore inoculation was used, you'll see one on first flush, and the other(s) on second and later flushes. The reason is that different strains are flushing.

CASINGS - Mycelium on the caps is not an indication of too much humidity. It's a combination of two types of mycelium on the fruiting body. It's more genetic in nature, occurring in some substrains more than others.

CASING/CAKES - However, it's normal for the substrate to shrink. It's not just from drying, but from the mycelium actually eating the substrate, so it naturally gets smaller over time even if you dunk it.

CASING WHAT IT'S USED FOR - The CASING is the non-nutritious top layer that is placed over a substrate to help induce pinning and to supply moisture to the substrate and the developing fruits.

CASINGS - They do shrink, but not typically on first flush. If this is first, they could be dry. Pour some water around the edges, then after a few hours, dump out any water that hasn't been absorbed.

CASING - However, it's normal for the substrate to shrink. It's not just from drying, but from the mycelium actually eating the substrate, so it naturally gets smaller over time even if you dunk it.

LATE CASING - Never add a casing layer after pinning starts. It leads to contamination under the casing layer, and also causes the pins that have formed to abort in many cases.

BETTER LAYERING BULK - If you spawn in layers, the spawn layer recovers very fast which then makes it resistant to contaminants as it colonizes the layers of manure.

CASING/SPAWNING - Contamination prior to first flush indicates your spawn was contaminated. Mold mycelium is white, thus you didn't notice it until sporulation.

CASING - It works great. It's just a bit spendier than buying a block of peat and a big bag of vermiculite. Sunshine mix #3 also works well. Don't forget to pasteurize.

CASING - Flush - It can either pin at will or once you see that the flushes are giving off continual harvests and the mushrooms look more haggard, it's done.

CASING RATIO - You can leave it uncased. I wouldn't go 1:4 with that. Stick to 1:2 or 1:3. Horse manure does fine at 1:4 and straw can be done at 1:10.

FREEZING CASING - No. Freezing will squeeze the moisture content out. Pasteurize tonight, then use tomorrow without freezing or nuking.

SPORES/CASING - Spores won't germinate on a fully colonized substrate. Harvest just before spore drop for best quality fruits though.

CASING - If it's waterlogged, the fruits will be small and rotten. If it's too dry, the fruits will be dry, cracked, and hard, plus small.

CASING - Vermiculite by itself is the poorest choice of a casing material. It's barely better than no casing at all.

CASING - If you wait until the mycelium is all over the top of the casing, then what is the use of the casing?

COBWEB ATTACK - 3% peroxide straight from the bottle in your mister will melt cobweb mold on contact.

CASING - Add 10% coir to your casing mix. That is somewhat like CAC'ing that some edible growers do.

CASING - Most often, if a cased substrate smells of alcohol. Some fermentation has, or is taking place.

CASING - Casing layer moisture content is critical; so don't leave it to a machine to figure out.

SUBSTRATE CASING - Substrate = Layer in which mushroom MYC feeds from.

CASING - Rhizos on top are a good sign. Let them grow. Knots form later.

WHY OVERLAY CASING - A dry casing layer causes overlay.

CASING - Casing layer = Layer on top, holds moisture.

PF TEK FC - Fine vermiculite holds more moisture per volume of measurement than course vermiculite; due to they're being more of it. The basic formula of 2-1-1 works great with fine or medium vermiculite, but if you're using course vermiculite, you might want to cut down a bit on the water. I've found that cakes as well as grains, and even bulk substrates colonize a bit better and faster if made up on the dry side. With cakes, it's easy to adjust the water down, and then simply do a dunk and roll at birthing to put the moisture in for the flush at that time. If the first batch comes out a bit too wet, simply reduce moisture by 10% to 20% on the next batch until you find the sweet spot. I'd still recommend the occasional fanning. You simply can't have too much air exchange, and the turbulence from fanning helps prevent trich from getting a foothold on your projects. Good luck!

PF CAKES - It's up to you if you want to roll in vermiculite after the second flush. If there's still vermiculite stuck to the cake, then it can do its job of absorbing water and supplying it slowly to the mycelium over time. If the mycelium has fully colonized the first batch of vermiculite you rolled in, then go ahead and roll after the second dunk. The idea is to have some uncolonized vermiculite on the sides and top of the cake to absorb water and act as a reservoir for the mycelium. 24 to 36 hours if fine for dunking depending on how much moisture the cake needs to absorb. If they're really lightweight, meaning they've dried out, then dunk longer. If they feel heavy, then they don't need to dunk as long. You don't have to worry about drowning them. They could survive weeks under water if they're in the refrigerator.

HYDRATING A CAKE - There's lots of ways to hydrate a cake. Dunk and roll is my favorite method. You're actually hydrating the individual mycelium cells, so it's a good idea to push the cakes a few inches under water so there's a bit of water pressure on them. Remove after 24 to 36 hours and roll in dry vermiculite, which is then heavily misted after being placed into the FC. Another method is to pile up vermiculite as deep as you can on top of the cake and keep that saturated. Another is to set the cake in a saucer of water. The straw method also works. These last methods are fine during a flush. Between flushes or prior to the first, I'd still suggest a dunk and roll. Mushroom farmers have been soaking substrates in water to rehydrate them for at least a thousand years. It's the time-proven method.

REHYDRATING A CAKE - You can also simply use your finger or a sharpie and make a small hole in the cake when you originally mix it and fill that with vermiculite. Then, simply pour water into the reservoir when the cake starts to dry out. Either way, don't keep the cake wet all the time or it will waterlog. Hydrate it, and then allow it to dry out a bit before wetting it again. If you dunk and roll prior to first flush, and then dunk between flushes, the straw tek isn't necessary.

SOAKING CAKES - I've seen pf type cakes survive two-week dunks in the refrigerator. I've also seen master slants under water survive two or three years in the refrigerator. You shouldn't dunk in the jars. It takes pressure to hydrate the mycelium. Dunking isn't hydrating the substrate, which is fully colonized. Dunking is to hydrate the individual mycelium cells, which takes time and a higher pressure outside the cell wall than inside (osmosis) for hydration to occur. Dunk in a large kettle or bucket, etc., so the cake can be pushed completely under water, thus providing the pressure required. Soak the cakes in this manner for 24 hours.

CASING/CAKES - Allowing a substrate to consolidate its hold on the substrate before introducing to fruiting conditions is good practice. By digesting more food before fruiting, better quality fruits are produced. Other than that, there are no known ways to readily increase potency in substrates. There's lots of talk about tryptamines, etc., but the claims of increased potency can't be independently repeated. I believe from my many experiments with hundreds of substrates and additives that potency is genetic. If your mycelium has enough food to produce mushrooms, it has enough food to produce the active ingredients as well.

PF CAKE FC - Place the cakes in the terrarium so that what was the top of the jar is now the bottom. The reason is the bottom of the jar is concave, thus it leaves an indentation on the bottom of the cake. This makes a nice 'bowl' to hold moisture later when it becomes the top and is filled with vermiculite. You can actually pour water directly on top of the cake, saturating the vermiculite in this 'bowl' and it will slowly hydrate the cake, supplying moisture for the flush. It's OK if mushrooms grow from the bottom of the cake. Just let them grow. They pick their own favorite place to pin, so don't mess with them.

PF CAKES - Stamets also explains the idea of consolidation in his books. It's not necessary with grains if you're going to be spawning to bulk or using for grain-to-grain transfers, but you do need to wait for full colonization. However, with pf cakes and other bulk substrates, it helps to wait some time after full colonization before initiating fruiting conditions. Doing so results in more prolific flushes. Failure to do so with some of the harder to grow edibles such as P. nameko and Shiitake sometimes results in no flush at all.

CONSOLIDATION PF CAKES - It isn't really necessary to wait for primordia to birth, but the idea is to give about a week after full colonization for the mycelium to digest some of the food it has just colonized. We call this process 'consolidation' and it makes for a much better pinset. Consolidation allows the mycelium to perform this process while still in the jars so they don't dry out before the flush. Those who birth right at full colonization often ends up with dry cakes by the time they flush, which reduces yields.

CASING/CAKES - You pick the fruits that are ready to pick and leave the pins. The easiest way to re-hydrate a bulk substrate that is dry is to pour water around the edges of the tray so that the substrate floats a bit. Leave it overnight and pour off the excess water. Mist the casing layer well. Never pick the pins because it's common with many species to set pins for the first few flushes at the time of first flush. These pins remain dormant until their turn comes. If you pick them, you ruin future harvests.

FC PF - The reason for waiting a week after full colonization is to allow the mycelium to consolidate its hold on the substrate. Until the mycelium digests some of the substrate it has colonized, it will not fruit. If you birth the day of full colonization, the week spent consolidating the hold, will be a week spent drying out the cake, thus making pinning harder and yields weak. If you wait a week after full colonization, pins often form within 48 hours of birthing/dunk and roll.

CAKES - Don't use distilled water for cakes, for all the same reasons you shouldn't drink it. Google it if you don't know what I mean. They contaminate much easier. Tap water is fine. For crying out loud, we've had lots of threads where people have dunked cakes in ten percent bleach, so the very small amount in tap water isn't going to hurt anything. Use tap, river, lake, spring, etc., but not distilled. Save your distilled water for making agar.

CAKES - A cake can only support a few mushrooms at a time, due to the size of the cake (substrate). If you get an awesome pinset on a cake, expect 80% of them to abort. Pick off the aborts when you pick the flush, but don't pick any pins that aren't black. Often, pins for the first two or three flushes set at the same time as pins set for the first flush. Once you pick the first flush off and dunk, they'll take off and grow.

HUMIDITY CAKES - My terrariums have a dozen or more holes drilled into the bottom. The natural air currents, since air is drawn from cold to warm, cause air to enter the bottom of the terrarium, work up through the perlite while being humidified along the way, then into the terrarium and back out the holes above the substrate. This provides FAE without fanning, and 95% to 100% humidity.

PF CAKES FRUITING FROM BOTTOM - I'd leave them. They'll push out from the bottom. Often, water drains by gravity to the bottom of a cake. They pin there because that's the best environment, thus they took advantage. If you flip the cake, it might work or they might abort. If you do decide to flip the cake, place it in a saucer of water overnight and allow the cake to soak up some moisture.

PF CAKES - Any cake that hasn't pinned after two weeks should be dunked and rolled again. Keep them at 99% humidity and normal room temperature. Inoculate a few cakes with oysters and cook them up for the family in an omelet. Then you won't have to worry about kids. In my opinion, mom and dads bedroom should be off limits to kids anyway. At least, that's how I raised mine.

PF CAKES - I'd recommend removing the trays, and then raking your fingers through the perlite to fluff it back up. Set small blocks or pieces of pvc on the perlite to hold the trays elevated. You could also build a wire rack for the trays to sit on. However, keep up plenty of air exchange even with the holes, as normally the substrate trays evaporate enough to maintain pretty good humidity.

PF CAKES - I didn't notice that the first time. You should wait one full week after full colonization before birthing. This allows the mycelium to consolidate its hold on the mycelium. They will rarely pin during that first week anyway, so keeping them in the jars keeps them in the high CO_2 environment, where they also lose less moisture to evaporation.

FC PF TEK - Most jars are concave on the bottom so there's a small well in the bottom of the cake. Put it into the fc where what was once at the bottom of the jar is now the top of the cake. This little divot can be filled up with vermiculite, and then you can pour water onto it every day to keep the cake fully hydrated. That's the key to good performance.

PF CAKES - We wait one week after full colonization to allow the mycelium to digest a bit more of the food it has colonized, thus allowing it to consolidate its hold on the substrate. It won't fruit before this week passes anyway, so it's best to leave in the jars. After a week, birth the jars, dunk and roll, and then place into fruiting conditions.

HUMIDITY - Condensation on the sides is in no way an indication of high humidity. In fact, it's an indication that you have low humidity because your humidity has been stolen from the air to be deposited on the surface of the terrarium. What it indicates is a temperature differential between inside and outside the terrarium. Nothing else.

PF CAKES - After rolling in dry vermiculite, I hope you misted several times over the next few hours to fully hydrate the vermiculite. Don't mist the sides of the terrarium, as it does no good. Aim the mist up into the air and let it fall directly on the cakes. In fact, after the dunk and roll, aim the mister right at the cakes and soak them well.

FLOODING CAKES FC - What WILL flood your cakes is pumping from a humidifier AFTER the air is already at 100%. That's why I recommend three to five inches of well-drained perlite for a terrarium, and no mechanical humidifier. This way, if your humidity reads less than 95%, it means you need to calibrate your hygrometer.

FC PF - There should be ZERO standing water in the perlite. Having standing water relegates that perlite that is underwater useless. Rinse the perlite; drain well, and then place into the terrarium. Three to five inches of well-drained perlite will deliver 95% humidity, provided you've drilled those small holes into all six sides.

CAKES FC PERLITE - You're not supposed to let them sit on the perlite. It causes them to wick up water from below, and also to attempt to grow into the perlite. Put down a jar lid or something to separate them from sitting right on the perlite so they won't become waterlogged. If they do, they won't fruit.

PF - You should NOT see condensation on the sides of the terrarium, especially with holes in the sides for air exchange. Condensation indicates one thing and one thing only: A temperature differential between inside and outside the FC. It does not indicate humidity in any way, shape, or form.

CAKES - This gives you a place to fill with vermiculite, which you can then pour water into in order to keep the cake hydrated during the flush. They'll fruit either way, but divot side up gives a nice moisture reservoir, to counter the small size of the cakes which often limits fruit size.

PF CAKES - If you used the dry vermiculite filter per the pf tek, you can loosen the lids with no problem. Don't move the jars around or turn them upside down or anything silly like that because it can cause the vermiculite filter to shift, allowing contaminants to reach the rice flour below.

PF CAKES - Moisture in a pf cake often drains to the bottom of the cake from gravity, thus pinning starts there. In addition, right against the perlite is the most humid microclimate, thus it encourages pinning. It's also the area that any perlite will stick to the cake simply by geography.

CAKES - Often, the mycelium will set way more pins than it can support. Since there's no way a pf cake can support 48 mature mushrooms, expect the majority to abort. Start really giving it a lot of water. You can put a pile of vermiculite on top of the cake and then keep it wet.

SOAKING CAKE - A member recently dunked his cakes for two weeks, thinking that putting them in water and then refrigerating was the best way to store them. Guess what? They survived and did just fine. I'd still recommend 24 to 36 hours max though.

CASING CAKES - Mushrooms depend on a LOSS of moisture from the substrate to fruit. If you saturate them, or keep a steady moisture level, they fruit poorly if at all. Mushrooms are not plants, which benefit from steady moisture levels.

CAKES/FC/HUMIDITY/PINNING - It should rise and fall. FAE will lower the humidity, and then you mist to replenish it. That's what you want. Evaporation of moisture from the casing layer or substrate is a major pinning trigger.

CAKES - Try to keep normal room temperature, and near 100% humidity. Mist as required keeping the vermiculite on the outside of the cake moist. Three or four light mistings per day are superior to one soaking.

CASING - Scratching seems to have benefits with button mushrooms, but in my experience, it does little to no good with cubensis. I tried it many times, and it seemed to set back progress every time.

PF CAKE - That slime is the reason I recommend to rinse the cakes well both before and after the dunk. Rinsing before the dunk helps prevent it, and rinsing after the dunk removes any that has formed.

CAKES DUNK AND ROLL - You're supposed to mist after the roll in dry vermiculite to get the vermiculite that stuck to the cake moist. Otherwise, the vermiculite will suck moisture from your cake. Yes, mist it now.

PF CAKES - Cakes often pin on the bottom because that's where the moisture runs to by gravity and also it's closer to the perlite, thus the humidity is higher and stimulates pinning.

CASINGS/CAKES - Since hyphal knots to primordia to pins takes at least two to three days, those pins formed because of what you were doing before you made the changes.

PF CAKES - I always add a tablespoon of gypsum to each multiple of the basic recipe of 2 cups vermiculite, 1 cup each of brf and water.

CAKES - People need to realize that a greenhouse isn't appropriate for pf style cakes because they require a very high humidity.

BRF CAKES - No water should squeeze out of BRF mix, no matter how hard you squeeze. Follow the recipe next time.

CAKES - After each flush, allow the cakes to sit for a few days to rest, and then dunk for 24 to 36 hours again.

CAKE FC - With lots of pins without the correct moisture the excessive pins can drain a cake in no time.

GYPSUM PF TEK - In fact, I add a tablespoon of gypsum to the basic 1,1,2 pf recipe.

CO_2 - CO_2 will build up in a terrarium, whether or not holes are drilled into all six sides. The levels will be lower than they would be without holes drilled and/or fanning regularly, but will still be above normal ambient. With oyster mushrooms and lion's mane to name two species that are very CO_2 intolerant, you need to fan a few times per day, even when using my terrarium design. The point above is that even with 100 holes in the floor of the fruiting chamber/terrarium, CO_2 levels will still be elevated. The holes help, but don't make for maintenance free fruiting. In other words, gravity won't 'drain' the CO_2. I hope this clears up any lingering confusion. In addition, CO_2 is not the only reason we provide air exchange. The other important reason is that contaminants prefer stale air, while mushroom mycelium prefers fresh, moving air.

CO_2 - CO_2 doesn't 'sink to the bottom' or 'pour out like water'. It mixes with the air and raises the CO_2 content. CO_2 can be measured in the upper reaches of the atmosphere. If it all settled to the bottom (ground) it would snuff out life on earth. Therefore, you can't drain CO_2 out of your terrarium by holes on the bottom. Fans in a small terrarium will dry out the air. That's why your current cakes are blue. They're dry and stressing. You want natural circulation in your FC, near 100% humidity, and enough holes or fanning by hand to get the CO_2 out.

CO_2 - If CO_2 was heavier enough than air that it settled to the bottom, we'd all be dead from CO_2 poisoning on the surface of the planet. CO_2 mixes with the air. To get rid of it, you exchange the air in the terrarium. You can't simply drill a hole in the bottom and expect it to run out like water. CO_2 is found high in the atmosphere, not just at the surface. It's the same in your terrarium. In a completely airtight container, the CO_2 would sink to the bottom. Such is not the case with our growing containers.

CO_2 - CO_2 won't run out of holes in the bottom. It's widely misunderstood that CO_2 is heavier than air, and many growers think it will run out like water if only there's holes in the bottom. The fact is, the CO_2 mixes with the air inside the tub and raises its CO_2 content. You have to exchange ALL the air in the tub to get rid of it. I simply drill lots of holes in the fruiting chamber, and let nature take care of it.

COLONIZING CASING CO_2 - The 5K to 10K ppm levels of CO_2 are during colonization. The fungus naturally produces the CO_2 just as humans also produce it. The 300 ppm levels are what is optimum for fruiting, and you'll have to ventilate to get it that low. We don't supplement with CO_2, but rather have different strategies for getting rid of it, depending on the part of the cycle we're in.

CO_2 CASING - You want holes all around to create circulation. It's a myth that CO_2 settles to the bottom and needs to be 'drained' out. If that were the case, we'd all be dead from the CO_2 from the power plants, car exhaust, etc. sinking to the surface of the earth, but the fact is, CO_2 can be measured in the highest reaches of the upper atmosphere. It simply mixes in with the air and goes where the air goes.

CASING CO_2 - High CO_2 levels are beneficial during colonization. It prevents most of your substrate from being turned into CO_2. Without proper covering, up to 50% or more of the carbon in your substrate will be released as CO_2 gas by the mycelium. In addition, many competitor fungi can't thrive in the high CO_2 environment, thus it helps favor for mushroom mycelium.

CO_2 FRUITING - High CO_2 levels are another thing that causes pins to abort. Mycelium can form primordia in conditions that can't sustain a flush, so lots of air exchange is very important throughout the fruiting process.

CO_2 FC - 'Drainage' holes drain the CO_2, and you want the CO_2 high in the substrate and low on top of the casing layer because that stimulates pinning where you want it to happen.

CO_2 - Drill holes as described. CO_2 isn't enough heavier that it will 'drain' out holes in the bottom. You want lots of holes so there can be constant fresh air.

HIGH CO_2 - High CO_2 will give long stems, but not huge caps. However, if you don't give any air exchanges, you'll grow nothing but green molds.

MUSHROOMS CO_2 - Tall, skinny mushrooms are indeed a sign of insufficient air exchange. Lack of light will also cause that.

HIGH CO_2 - Long, spindly stems are a sign of too high a CO_2 level, and green molds are a sign of insufficient air exchange.

HIGH CO_2 - Increase air exchange. High CO_2 levels cause stem elongation and small caps.

HOLES IN FC AND WHY - The holes in the bottom increase humidity. How? It's a development from something I learned working on the Alaska Pipeline project in the 1970's, helping to engineer the supports that are actually self contained refrigeration units that keep the tundra frozen even in summer so they don't shift, thus preventing the pipeline from rupturing. The supports require no electricity to operate.
The methodology is this: Air currents travel from high pressure to low. Heat expands the air, thus causing low pressure. Cold compresses the air, thus causing high pressure. The damp perlite is cold, so the air surrounding the perlite is our 'high' pressure. The substrates within a terrarium produce heat, as does the lights shining through the sides or top, thus the air in upper terrarium becomes 'low' pressure. This causes air to want to flow through the perlite and into the terrarium, but only if there is an entry point at the bottom for the air to be drawn in. The air, by natural convection passes through the perlite, absorbing moisture as it does. It then enters the terrarium, and is expelled through the holes above. This natural circulation provides FAE without fanning, while keeping the humidity higher than it would otherwise be.
I developed this over the last year, but am just now releasing it after a full year of testing; so don't look for anyone else beside myself to have used this system yet. It works. Oyster mushrooms still should be fanned a time or two per day, but every other species has done very well with this system with no fanning, and humidity maintains between 95% and 98% provided four to five inches of damp perlite are used. Smaller depths may work with smaller terrariums, but with the 106-liter terrarium I've posted pictures of, four to five inches is best.

DIFFERENCE BETWEEN AIR EXCHANGE AND GAS EXCHANGE - Gas exchange is when the gasses must percolate up through a vermiculite barrier or other filter to three or four small holes in the lid. The small filter on spawn bags allows for gas exchange. The very limited exchange that takes place allows the excess CO_2 to get out of the jars and be replaced by very small amounts of filtered room air. Air exchange is when we remove the lid on a fruiting chamber or run a fan in a greenhouse to forcefully fan the contents in order to blow out the stale air and replace it with large amounts of unfiltered room air.

FC/HUMIDITY/HOLES - I drill dozens of holes all over my terrariums, including the very bottom. The holes on the bottom actually increase humidity, while letting the CO_2 drain. The reason the holes on bottom increase humidity is because air currents travel from cold to warm, due to the pressure difference caused by the molecules being farther apart in warm air. The warm air in the terrarium causes air to percolate up through the perlite, wicking moisture as it passes through.

AIR EXCHANGE FC - Sure looks like too much substrate and mycelium for such a small container. I'd imagine the gasses build up in no time in something that small. You need three to five air exchanges per HOUR, not two per day. That's why I recommend drilling holes into all six sides of the terrarium. If you mist, and then close that thing up with the fruits wet, it's just one more example of the proof that doing so causes aborts.

FAE CONTAMINATES - The fact of the matter is, green molds can't survive in a fresh, turbulent air environment. They require stale, still air. That makes green molds fairly easy to control. All the sterile procedure in the world won't help once your project is in fruiting conditions. At that point, give fresh air and keep it moving. Green molds will still pop up from time to time, but they won't be devastating.

FAE - I have a couple dozen holes drilled into the floor of the FC as well, so any excess water from misting can drain out. The holes in the floor of the Rubbermaid also help to let the CO_2 seep out. Water doesn't evaporate well into CO_2, so getting rid of it helps the perlite work better, as well as stimulate pinsets.

FFAE IS THE WAY TO GO - In nature there is no fanning, there is constant, full air exchange which is what starts the chain reaction to pinning, so the more air you're providing via open air exchange, the better, farms don't use fruiting chambers they use huge trays in open rooms, as that's how they grow best.

FILTERED AIR - Best way for filtered air exchange in a TIGHT clean room, or grow room is POSITIVE PRESSURE. Meaning, pump in hepa filtered air in a volume much larger than the outlet. Which creates mild positive pressure. Enough that nothing wisps in, except what you carry on you.

FAE. KEEPING COBWEB MOLD AT BAY - You should have just hit it with a mild H202 mist **-** spurt. Then, or NOW increase your FAE. For Cobweb. Give it another spurt of H202, and then about triple your FAE. Plenty of FAE is the trick to holding cobweb at bay. It thrives, when there is little or no

FILTERING AIR NO REASON TO FC - Actually, polyfill is a filter, but there's absolutely no reason to use it on a fruiting chamber. If you have gnat problems, you can use window screen, which will allow much more air to circulate, thus lowering the risk of contamination.

FAE/FC - Just remember with small holes, it takes four times as many holes to equal twice the area. In other words, two 1/4-inch holes are not the same as one 1/2-inch hole. It would take four of them. It helps to bear that in mind. Good luck.

FAE - Four air exchanges per HOUR are recommended. I'd suggest fanning three times per day, and drilling a hundred or more holes in your terrarium to get you by between fannings so you can leave for work, play, etc.

FAE - Stamets recommends 4 to 5 air exchanges per hour. I try to give a bit more than that because in addition to getting rid of the CO_2, we're also trying to make an environment that is inhospitable for contaminants.

FAE - Correct. Nothing covers the holes. It's near my balcony where we keep the sliding glass door open all the time. The breeze from the open door helps with the FAE too, and the natural sunlight is a plus.

AIR EXCHANGE FC - We filter uncolonized grain spawn, but once it's fully colonized, there is no reason to filter. Air exchange is the key to contamination prevention in the fruiting environment.

FAE FC - Mushrooms like 3-6 COMPLETE FAE's an hour, which can't even hope to get near most of the time and if they do, it typically will cause a problem with over-Drying of the substrate.

FC AIR - There is no reason to worry about contaminants in your fresh air supply, because your cakes are already colonized. Stale air is much more of a threat than contaminated air.

CONTAMINANTS WITH FAE - All the FAE. The constantly circulating air outdoors gives contams little room to take hold of the patch. Unlimited FAE is the key factor.

FAE. FAE FC - You want about 4 air exchanges per hour if it's in fruiting mode, so watch your humidity as agar said and be sure to replace the moisture you lose to

MUSHROOMS WITHOUT FAE - Insufficient fresh air exchange leads to the long twisted stems, and poor lighting leads to very small caps.

PROBLEMS WITHOUT FFAE - The sign of high CO_2 is baseball bat fruits with fat stems and little tiny caps or long skinny ones.

FC - Air exchange in the fruiting environment will do way more for contaminant control than filtering.

FAE FANS - Fans are unnecessary, and tend to dry out the air too much.

FC FILTERING AIR NO NEED - You don't filter air to fruiting chambers!!!

FFAE - FFAE = Frequent Fresh Air Exchange.

FC - It all depends on the size of the FC. If you can maintain upper 90's humidity, then the more holes the better. Air exchange is the key to contaminant avoidance and good pinsets. However, if you over do it on the holes, performance will suffer if you can't keep up with good humidity. If you're unable to maintain humidity with all your holes, begin taping them up until you can maintain 95%. That will be the sweet spot. Many people also don't realize that if you double the diameter of a hole, you increase its area by four times. That means a 1/4" hole is four times as large as a 1/8" hole, and a 1/2" hole is four times as large as a 1/4" hole. You can dry out your terrarium in a hurry if you have too much. With this system, it also helps to run a humidifier in the room your terrarium is located, if you live in a dry or air conditioned climate. If your ambient humidity is in the 50% range, your terrarium will do much better than if it's in the 10% range.

FC - The fruiting chamber I designed has holes in all six sides. This results in convection and circulation. It is NOT a still air environment! The mushroom substrates produce heat, and also the lighting that shines through the fruiting chamber produces heat. These two produce convection. Perhaps if you'd read posts before jumping into shit you know nothing of, you'd have seen that. Sorry, but this pisses me off. Don't attack my work because you don't understand the science behind it. Now, in a so-called 'shotgun' fruiting chamber with holes on all six sides, would you suppose the CO_2 drains out the bottom? It doesn't. It mixes with the air. I see absolutely NO change in CO_2 concentration from the top to the bottom of the fruiting chamber. CO_2 levels are higher than ambient in the room, but lower than they would be in a 'still air' terrarium, as if anyone who has knowledge of the life cycle of fungi would ever make such a thing.

PERLITE FC - The perlite should stay fully hydrated and provide humidity for four to six weeks. This is plenty for a crop cycle. I simply take the perlite from the tub, place in strainer and run water through it again to re-hydrate it. You should be able to use the same perlite for years. When I filmed this part for my dvd, I bought a new bag of perlite so it would be nice and pretty white. My old perlite, which is still perfectly fine, is several years old and has been used for dozens of cycles, and is stained various colors from different substrates and spores getting spilled onto it over the years. If you have a bad trichoderma outbreak, It can't hurt to boil the perlite in a large kettle before re-use.

SPAWN BAGS FC - I seal after sterilization and inoculation. You'll have to make provisions to allow the pressure to escape from the bag as the PC cools down or the bag will burst. I use a tyvek sleeve placed the entire length of the flap from the substrate to the end of the bag. This allows the pressure to escape, but also filters any air that tries to seep back into the bags. Using this method, I've left them to sit on a countertop in open air for several days prior to inoculation. The tyvek prevents contaminants from entering. I use steel tie-wire to seal the bags. I don't even own an impulse sealer.

CONDENSATION/FAE/PINNING FC - Correct. The temperature differential causes the condensation, and the holes help to keep the temperature equalized, thus no condensation. If you've dunked and rolled your cakes, you still want to mist to keep the vermiculite damp. If you have cased substrates, you also want to mist. All those holes provide for constant FAE, which is a major pinning trigger, but the constant FAE also causes evaporation from your substrate (another pinning trigger), which needs to be replaced by misting.

TEMPERATURE PROBLEM FC - If you have a freezer, freeze water in several plastic containers. You can then rotate the jugs from your freezer to your FC and back as needed. No, I meant to put the ice inside the DT. Get imaginative. The jug can hang from a wire if the whole tub is covered with substrate. Don't put the ice on the outside or you'll stunt the mycelium in that location. You can open fruiting chambers whenever you want. The more the better in fact as long as you maintain humidity.

FC - Massive air exchange is what you want for a fruiting chamber. By the time fruiting comes, CO_2 production has fallen off dramatically. You want large amounts of air exchange in order to prevent contaminants such as cobweb, which thrive in stale, still air. Have several vents both top and bottom in a FC, so you can get circulation as well as intake and exhaust. Positive pressure is not necessary. A FC by nature isn't sterile, nor does it need to be. Just keep the humidity up.

FRUITING CHAMBER - Perlite will remain hydrated for months, so you don't need to wet it every weekend. Your mushrooms won't abort because of going two days without misting, provided you've built a proper terrarium and have 3 to 5 inches of well-drained perlite inside. Something else is wrong. You can mist mushrooms. They thrive in the rain. What's your air exchange provisions?

CONDENSATION HUMIDITY FC - Condensation does not begin on all surfaces at about 95%. Condensation is a function of the temperature differential on either side of a surface. Condensation forms on the warm side. Condensation won't even form on your mushrooms at 100% humidity. If they get wet, it's because liquid water droplets were thrown on them, not humidity in the air.

PERLITE IN FC - Also, make sure your perlite isn't packed down tight. If it is, it can't work. Rake your fingers through it from top to bottom to fluff it up. You want your perlite very loose and airy so it can evaporate the moisture it holds into the air. The more surface area of perlite, the better it works. Make little mountains and valleys for best results.

FC - Drill as many as you can drill until the humidity begins to fall. Then, cover up the last hole you drilled. The more air exchange during fruiting, the better. Just keep your substrate thin, and also keep the casing layer thin. Pans don't like thick substrates. 1 1/2" deep works for the manure, and 1/4" is plenty for a casing layer.

FC/HUMIDITY/CONDENSATION - You need high humidity in a fruiting chamber, and heating one will cause excessive condensation. The humidity you want for the mushrooms will be wasted sticking to the sides as condensation if there's a temperature difference between the fruiting chamber and the room it's located in.

CONTAINER FC - Use black plastic glad ware baking dishes. I've seen aluminum containers with holes in the bottom before the first flush comes in. Even if the metals are not transferred to the fruits (which nobody has the equipment to test to know for sure), the holes in the bottom cause unwanted pinning down there.

FC - A humidifier inside the greenhouse works great, and mine last several times as long inside the greenhouse as outside. Have it on a timer so it runs no more than two minutes at a time. One minute on, six minutes off works great for me. Just leave lots of gaps in the plastic so you have continuous air exchange.

CONDENSATION FC - Condensation on the walls only indicates that the temperature of the walls is equal to or less than the dew-point of the terrarium, and is not an indication of humidity. In other words, condensation indicates a temperature differential and not moisture content.

PULLING AWAY FROM THE SIDES CASING/FC - With a good pinset, they'll need lots of water. Be sure to give it to them. As said, it's normal for the substrate to pull away from the sides. The mycelium is munching down its food, so the substrate naturally is going to get smaller.

FC - Elevate the terrarium off your table on blocks so the holes in the bottom are open. Built as directed, it will maintain humidity fine if your ambient humidity is 50% or more. If necessary, run a cool mist humidifier in the room your terrarium will be located in.

FC MOISTURE - Droplets on your pins will not cause aborts. It's recommended to mist mushrooms. Air exchange must be provided because stagnant water sitting on a mushroom in stagnant air for an extended period WILL cause aborts.

CONDENSATION FC - Condensation has nothing to do with humidity. Condensation is caused by a temperature differential between inside and outside your tub. Use plastic or a drip shield to prevent drops from falling on the fruits.

HEAT A FC - NEVER heat a terrarium. It causes condensation, which robs the humidity from the air within, and turns it into condensation on the sides. You're supposed to heat the room the terrarium is located in.

FC - Warmer air has the molecules farther apart, thus humidity is lower, even in a sealed chamber. A 20F rise in temperature doubles the capacity of the air to hold moisture, thus it cuts the humidity in half.

USING PERLITE FC - Be sure your perlite is well drained, and you'll have 98% humidity for three weeks or more, at which time you can remove, wash, drain and replace the perlite for the next cycle.

CONDENSATION FC - Condensation in a FC is actually stealing moisture from your air, lowering the humidity inside. Avoid it. As said above, the water droplets falling on your mushrooms is bad as well.

FC - It's normal for the substrate to pull away from the sides of the tray. It's not just from drying though. As the mycelium consumes the substrate, it actually gets smaller because it's being 'eaten'.

FRUITING CHAMBER - Depending on what you're growing, you need a bit more air exchange than that. I like to see three to four air exchanges per hour, with a co2 level around 1,000 or less.

CONDENSATION FC - Condensation is not caused by humidity. It's caused by a temperature differential between inside the box and outside. Don't use heat.

CONDENSATION FC - True, but condensation can only form if the humidity is 100% OR there is a temperature differential between inside and outside.

FC - You don't heat fruiting chambers. You heat the room they're in to avoid condensation. If you desire 80, you'll want to heat the room that warm.

COLONIZING PERLITE PF TEK / FC - Don't force the mycelium to colonize the perlite that has no food for it anyway. It will waste needless energy.

SUBSTRATE FC - They break in half all the time when I'm dunking. They do just fine. Try to avoid breaking them, but if they do, don't worry.

CONDENSATION FC - You don't heat fruiting chambers or they get condensation on the walls, which sucks moisture out of the air inside.

FC - Standing water lowers humidity. Drain fully, then put the perlite in your terrarium. That will deliver the highest possible humidity.

FC - FYI placing in the FC slows vegetative growth and covering your knots with casing would destroy your initial pinset.

SUCCESS FC - High humidity and massive amounts of air exchange is the key to success with mushroom growing.

HEATING FC - Don't heat the terrarium. You'll only make condensation that will suck the humidity out of the air.

FC - How to incubate Monotub...Drill a bunch of holes...put Micropore tape over holes for colonization.

FC - You really need to get your humidity as close to 100% as possible for hyphal knot formation.

FC - On the next grow; provide more air exchange for shorter, fatter stems and larger caps.

CONDENSATION FC - Condensation is caused by excessive temperature inside the jars.

FC - High humidity, plus high air exchange will give the best results.

CONDITIONS TO INDUCE FRUITING - The major pinning triggers are in order of importance, full colonization, a decrease in CO_2 levels due to increased air exchange (not gas exchange which is minimal), a steady rate of evaporation from the substrate or casing layer, and lastly, light.
Hyphal knots form best in 100% humidity, but I didn't list that because it's not a pinning trigger, but rather an environmental condition that is necessary. That's why we use casing layers. The casing helps to provide the 100% humidity right at the surface of the substrate where the hyphal knots form.
I have seen no correlation with temperature drop whatsoever. In the summer, my growing chambers are 10 or more degrees warmer than the open shelves I incubate on due to the heating effects of the lights. Even with a

temperature increase, I still get wall-to-wall pinsets, so I don't consider temp drop relevant at all to tropical species. Other growers disagree of course, but that's just my observation after many years.

Full colonization of the substrate is the number 1 pinning trigger. Full colonization can be when the mycelium reaches the physical border of the container they are in, or when they run up against a biological border, such as a contaminant species. Either way, they see they have colonized all of what is available to them, so they then enter the next phase, which is reproduction.

There must be evaporation of moisture from the substrate for pins to form. A waterlogged substrate will just sit there forever without pinning. Even in 99% humidity, as long as you provide fresh air, moisture will be evaporating away from the substrate, and this is necessary for pinning. We mist to replenish the lost moisture, and then allow it to dry slightly before misting again. This keeps the moisture content high, and keeps the humidity at the casing surface near 100%, but at the same time provides the evaporation of moisture that is a very important pinning trigger.

During colonization, we provide very small holes in the jars or tubs for gas exchange. We want a high CO_2 environment during colonization, because this prevents the mycelium from consuming all of the substrate. The mycelium colonizes the substrate, but doesn't 'eat it all up' due to the high CO_2 levels. During fruiting, we remove the covers to provide air exchange, which is at a much higher level then the minimal gas exchange provided during colonization. This increase in air exchange lowers the CO_2 levels, and is a major pinning trigger. At this time, the mycelium begins to consume the substrate it has previously colonized, and we notice during fruiting that our substrates pull away from the sides of the container. This is not due to moisture loss, but rather due to the mycelium 'eating' the substrate and turning it into CO_2, a waste product. It is easily proved that this shrinking isn't related to moisture loss, because even when we dunk a bulk substrate, it doesn't return to its pre-flush size.

Last, but not by any means least is exposure to light. Light does much more than just tell the mushrooms which way to grow. There are mechanisms in the light that stimulate the formation of hyphal knots as well, and light at the higher end of the spectrum (blue) definitely, absolutely stimulate more hyphal knots (which grow into primordia, which then morph into pins) than light at the lower end of the spectrum (red) This does not mean to get a 'mood light' with a blue lens, but rather to select lights such as metal halide, or much more economical is 'natural daylight' fluorescent that emit light at around 6,000 Kelvin to 7,500 Kelvin depending on the brand. Cool white fluorescent emit light at around 5,000 Kelvin and the 'red' incandescent emit light at around 3,000 Kelvin. The higher the light temperature in Kelvin, the more stimulatory it is to hyphal knot formation. I hope this helps.

PINSET INITIATION FACTORS - I rarely start new threads anymore, but the same questions and misunderstandings seem to keep popping up regarding what makes our fungi enter the pinning stage. The reply below is one I posted in another thread earlier, so I'll take the liberty of cutting and pasting it here for those who would otherwise miss it. Hopefully it will stimulate some more research and discussion on everyone's part and clear up a few things. Here it is:

LIGHT IS NOT THE MAJOR PINNING TRIGGER FOR MUSHROOMS!

In fact, light isn't even the major factor in which direction mushrooms grow. Wind or other air currents is the first. Light is the second, and then finally gravity is the third.

As for pinning, full colonization of the substrate is the most important pinning trigger. If there are contaminants present in a substrate, the mushroom mycelium generally stops growing when it contacts them. This represents full colonization because the mycelium has hit a natural barrier, and often pins begin to develop, whether light is present or not.

The second most important pinning trigger is an increase in air exchange, with the corresponding drop in CO_2 levels that occurs simultaneously. When you uncover a tray to look at it, you allow the CO_2 to escape and be replaced by fresh air. THIS is a pinning trigger, even if you do it in the dark.

Third, which goes along with second, is a steady rate of evaporation of moisture from the substrate or casing layer. In the artificial environment of a small tray, we must mist to keep the substrate or casing from drying out, but we also must allow that moisture to evaporate off between mistings.

Fourth, when the above three triggers are active, light becomes a pinning/growth initiation factor.

If one waits too long to apply the casing layer, or the other factors listed above are in effect prior to light OR the casing layer being applied, primordia will begin to form, which will then push up through to the surface, whether or not it has been fully or even partially colonized. By the same token, if light is applied and the other, more important factors have not been met, primordia will NOT form.

This is why experienced growers, such as commercial spawn producers who make their entire living incubating mushroom mycelium, make absolutely NO effort to incubate in the dark. It isn't necessary. People will have much more success in the hobby when they understand that.

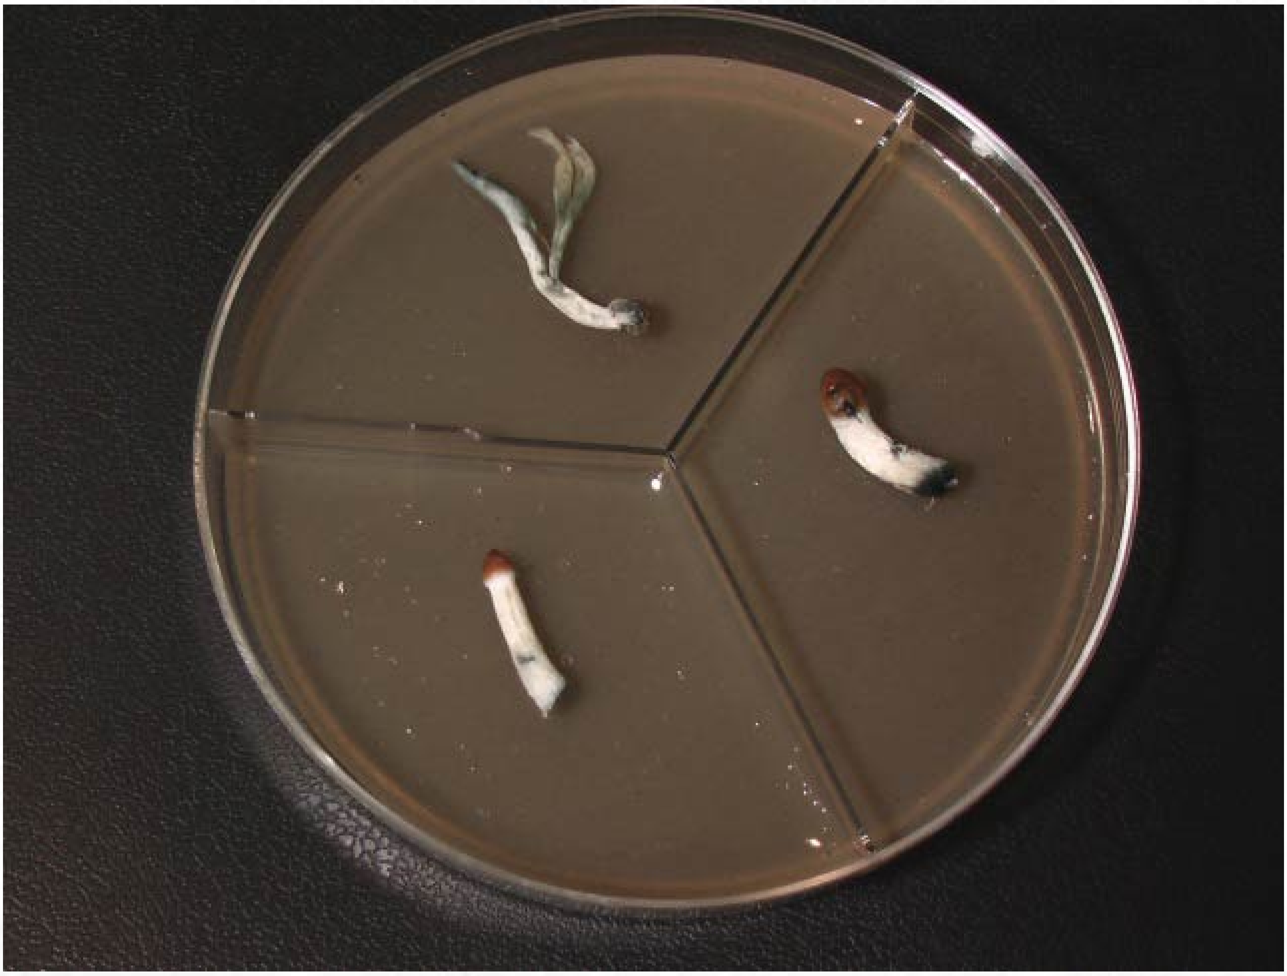
PINNING STRATEGY - Here are the facts. It DOES matter if you sterilize your casing layer. It will perform poorly. It's a well-known fact that the beneficial organisms in a casing layer stimulate pinning. This was very well known in 1985 when Paul Stamets wrote 'The Mushroom Cultivator' and it's still known today. Casing layers should be pasteurized, not sterilized.
In addition, coir is a substrate material, not a casing material. If you wish to use it for casing, it should be mixed at the 60/40 ratio (60% vermiculite, 40% coir) in the tek, or better yet, 70/30. However, peat mixed 50/50 with vermiculite is a far superior casing. The reason peats works better is the beneficial microorganisms that are not present in as high a concentration in coir.
Furthermore, sterilizing a casing makes it MORE prone to contaminants, not less. A sterile substrate is a prime breeding ground for the first organism to land on it, or the fastest growing. Mold mycelium, being imperfect fungi grows and sporulates much faster than mushroom mycelium because they get to skip the fruiting body stage.
Field capacity for casing layers says when you pick up a handful of material no water should drip out. If you squeeze gently a few drops will fall, and if you squeeze hard, a small stream will fall. It sounds like your casing might be getting prepared too dry as well.
Fanning 4 to 5 times per day is not sufficient unless you have another method of providing fresh air exchange. It is recommended to have 4 air exchanges per hour, not day.
My suggestion is to use a peat/vermiculite casing with gypsum added (very important) at a rate of one part to each ten parts of peat, and limed to an initial pH of 7.5 to 8. Pasteurize, don't sterilize and increase air exchange. Good luck.

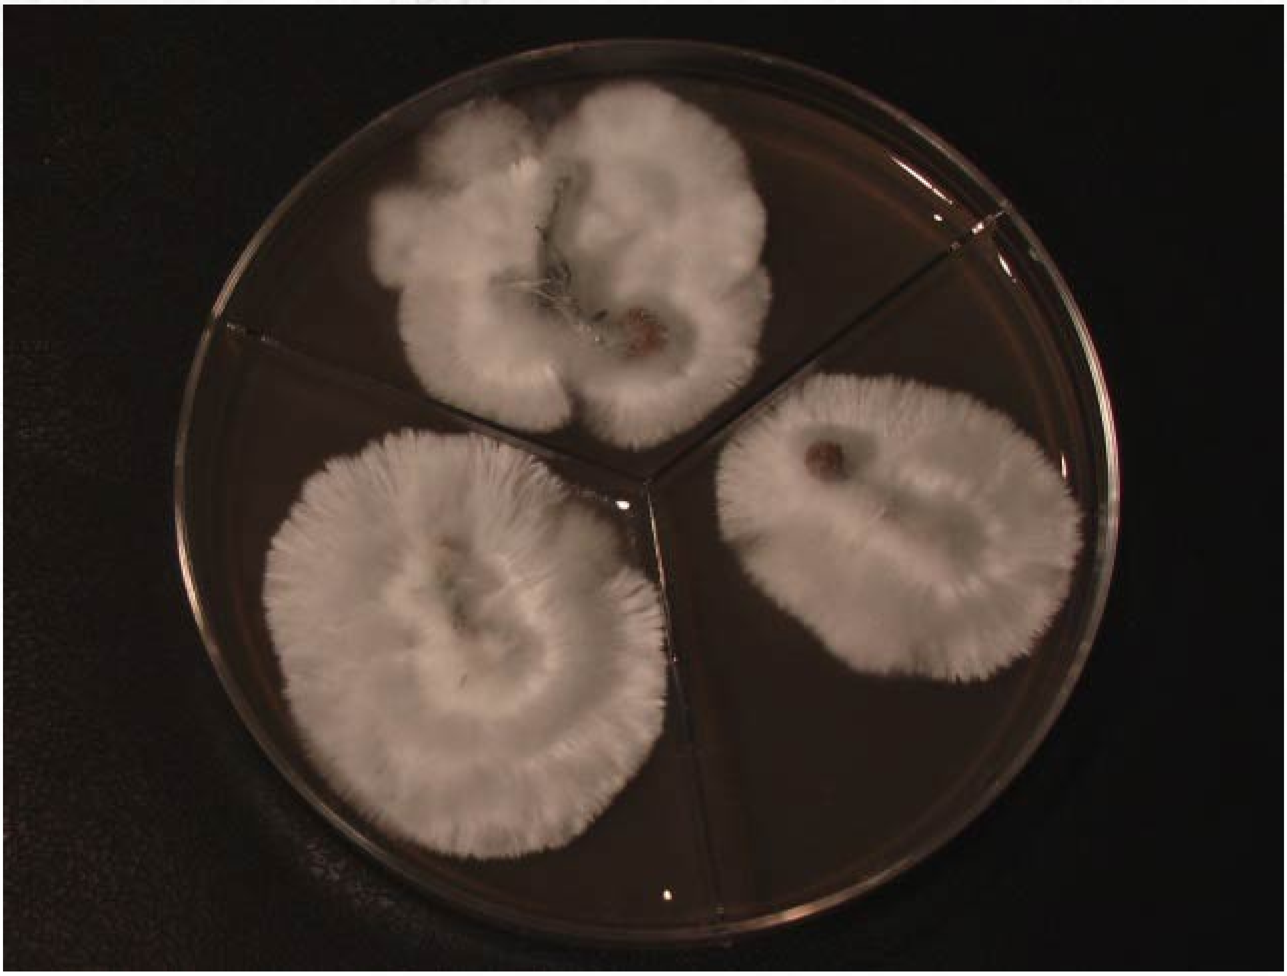
FRUITING CHAMBER - You want three things in a Fruiting Chamber. FAE to keep contaminants at bay and to get a nice pinset. Humidity to get a nice pinset. Moisture for yield and pinsets. Mushrooms ideally want 4-6 FFAE every hour so it's best to put 1/4th inch holes everywhere around the terrarium. As much as so humidity doesn't escape and the CO_2 levels are low. Massive air exchange is what you want for a fruiting chamber. By the time fruiting comes, CO_2 production has fallen off dramatically. You want large amounts of air exchange in order to prevent contaminants such as cobweb, which thrive in stale, still air. Have several vents both top and bottom in a FC, so you can get circulation as well as intake and exhaust. Positive pressure is not necessary. A FC by nature isn't sterile, nor does it need to be. Just keep the humidity up.

FRUITING - As for fruiting temperatures, the lower 70's seem to produce the best fruit quality. For years, I didn't AC my house in the summer because I live in a generally mild climate, and they still fruited fine into the 90's, which my grow area would often reach on summer afternoons. I found that temperatures which would fry the mycelium during colonization, would hardly be a factor during fruiting, but the fruits grew very fast, were not very meaty, and the 'other' quality we look for was often lacking. When I switched over to all edible and medicinal mushrooms, I installed a refrigeration unit on my mini-greenhouse, because mushrooms such as shiitake would refuse to fruit at all in those hot temperatures.

PINNING - I doubt it was the light. Light is horribly over rated as a pinning trigger. It was most likely the air exchange that was allowed through the landscape fabric.
If you want an awesome pinset, it's important to only allow gas exchange and not air exchange as the mycelium colonizes the substrate. There's a big difference. During colonization, you actually want CO_2 levels to be extremely high, which prevents fruiting. Upon full colonization, you increase FAE (air exchange) and expose to light at the same time. This results in a sudden and massive pinset.

SPAWNING WITH PINS IN JARS - You can spawn a cake with pins right into manure/straw, or even use it for grain-to-grain transfers. It's a myth that pins will rot. I've proved that hundreds of times. Here's what happens when you put pins on a Petri dish. The two pictures below were taken five days apart. The same thing happens regardless of substrate. Just be sure they're small, growing pins and not large fruits. You should pick the mature fruits.





PINNING - Mycelium will pin best at or near saturation humidity and plenty of fresh air, whether the substrate is cased or not. A casing layer simply helps to hold humidity high right at the surface, under less than ideal ambient conditions. Of course, once pins form, the casing layer also helps to supply the substrate below with moisture, so you want to keep the humidity high to prevent the casing layer from drying out too much between mistings.

ABORTS - Grey or black heads indicate aborts. Pins that have simply stopped growing but have normal color are NOT aborts and should not be picked. It's common for many species including cubensis to set all the primordia for the first few flushes when primordia for first flush is set. They stop growing until their time comes, at which time they kick into gear again. If you pick them, you ruin future flushes.

PINNING EARLY CASING - What I meant above about pinning early in the presence of contaminants is when you see pinning in a jar prior to full colonization. It's because the mycelium ran up against the contaminant and said, "Oh heck, this stuff might kick my butt. I better reproduce by dropping some spores so I'll survive". That's why they pin. It's not because you had the light on when you checked the jars.

CRACKED/SPLIT CAPS - There is a difference between cracked caps and split caps. Cracked caps are caused by low humidity, which cracks the caps to give them a reptile type appearance. What you see above is split caps. It's part genetic and part just from very rapid growth where the cap simply rips apart. Split caps are not environment related.

PINNING - Many things. I've found the brightest light stimulates more pins. You need to look at pinning triggers like the instruments in a band. One instrument can be slightly off, and the band still plays the song. Often one instrument can be taken away and the music still sounds ok. However, if all are working together, it's awesome.

PINNING TRIGGERS - The pinning triggers are: Full colonization, 100% humidity, increased air exchange, and light. If all that happened within 24 hours of what you did, the primordia were already formed, so it was going to happen anyway. The rooster may crow at sunrise, but he isn't responsible for the sun coming up.

COLONIZING HIGH CO_2 - One benefit of a high CO_2 level during colonization is that less of the actual carbon in the substrate is converted to CO_2 gas. In other words, if you allowed too much fresh air during colonization, more of the substrate would be 'consumed' by the time the mycelium got to the fruiting stage.

CRACKED CAPS - Cracked caps are from low humidity and also really don't hurt anything. In fact, many Shiitake growers deliberately lower humidity a day or two before harvest to crack the caps. They feel it leads to a better product and in Japan; cracked cap Shiitake brings a higher price.

SPLIT/CRACKED CAPS - Usually, spit caps are caused by rapid growth. Contrast that with cracked caps, which is a sign of too low a humidity. Either is usually harmless. Vertically can also cause caps and stems to split, but it's a fungal disease so the fruits would also look unhealthy.

PREMATURE PINNING - Too much air exchange during colonization leads to early pinning too. If the holes in your jar lid are too big, your grains or whatever is exposed to air exchange rather than just gas exchange, which would keep CO_2 levels high and prevent pinning.

SMALL MUSHROOMS FC - Small mushrooms are caused by one or more of the following: Too small a substrate or too thin a casing layer, improper substrate or ph level for the species, or too little moisture in the substrate or casing layer. The latter is most often the cause.

SPLIT CAPS - There are two phenomena that are often called 'split caps'. One is from growing fast and is normal. The other is more correctly called 'cracked' caps and is related to low humidity. Either is usually fine to eat. Post a picture if you want a better diagnosis.

SMALL MUSHROOMS - The only reason they're small is that there is only so much water in the cake. More mushies mean smaller ones. One tip for next time ...you can inject a bit of water into the cake during the flush with a syringe. Don't overdo it, just 3 or 4 cc.

PINNING ON EDGES - Your substrate is pinning on the edges because that's the only place where there is near 100% humidity to stimulate primordia formation. You can get more pins in the middle by laying a sheet of wax paper over the top of the tray.

FRUITING LOW CO_2 - A rapid and sudden decrease in the ambient CO_2 levels is a pinning trigger in cultivation, so adding fresh air at the same time as full colonization and the other pinning triggers helps ensure a full, even flush.

UNCASED SUBSTRATES - Uncased substrates should be treated as cakes. Primordia form best in near 100% humidity. Yes, lay wax paper right over the substrate. Replace every second day with a fresh sheet. Lift it to fan for air exchange.

FRUITING SUBSTRATE - However, you can mix it in with horse or cow manure, or compost at 5% by volume. In other words, for each 20 cups of compost or manure, you can add one cup of chicken manure. Don't forget to lime for ph.

FC SIDE PINNING - Black plastic glad ware fruiting trays. I've never had one single side pin when using those until second flush when the substrate is pulling away from the sides a bit due to shrinkage, which is normal.

SMALL MUSHROOMS - Small mushrooms are caused by a shortage of water. After this flush, dunk. It's not strain related. All strains we see are of the same species and I've seen huge amazons.

FRUITING TEMPERATURE CASING - Mushrooms grow more quickly at higher temps, but there is no doubt that they are denser and more potent when fruited at a lower temperature.

ABORTS - Misting doesn't cause aborts. Leaving pins wet after misting with no air exchange causes aborts. When misting pins, be sure to increase air exchange afterwards.

FRUITING TEMPS - Cubes will actually fruit well in temps that would fry the mycelium in the colonizing stages. However, quality is better when they fruit at lower temps.

CASING FRUITING SIDES - If the fruits are only forming on the edges, it could be because the casing layer Ph is too far off, or it could mean the casing layer is too dry.

MYCELIUM ON CAPS - It's a combination of two types of mycelium on the fruiting body. It's more genetic in nature, occurring in some sustains more than others.

PINNING TRIGGERS CRITICAL - The other pinning triggers of full colonization, steady evaporation of moisture, and air exchange are much more critical than light.

FRUITING TEMPS AND WHY - Benefits from fruiting at 68-72F. 1. Better Fruit Quality, 2. Easier To Control Harvest Time, 3. Easier To Control Evaporation!

SMALL MUSHROOMS - Fruit size is mostly determined by substrate moisture level. Small fruits mean your substrate is too dry.

MYCELIUM FC - Pins are live, growing mycelium. Live, growing mycelium does not rot. Aborts rot. The above are not shiitake.

FRUITING - Better food quality and slower growth occurs in the high 60's low 70's, that's why it's the true preferred range.

PINNING TRIGGERS - It's air exchange, full colonization, or contaminant presence which is what makes them pin.

HYPHAE TRIGGER - Aerial hyphae, attracted to the fresh air/humidity, no digital can actually read that high.

COOLER TEMPS, LIGHT!! LOWER RELATIVE HUMIDITY - PINNING TRIGGER: FAE (3 PER HOUR),

PINNING - One of the biggest pinning triggers is the sudden reduction in CO_2 buildup.

SKINNY MUSHROOMS - Poor air exchange causes long skinny stems, not fat Asses.

ABORTS FC - If the head is black, it has already aborted. Aborts don't recover.

LATE PINNING - Late pinning is caused by poor air exchange 90% of the time.

SPLIT CAPS - Split caps, not related to humidity or moisture content.

CRACKED CAPS - No. Lack of humidity causes cracked caps.

PIN - Hyphal knots are tiny. Perhaps 1mm in diameter.

HUMIDITY FC - Hang on a second. 100% humidity means the air is saturated. Having the air saturated in no way is going to flood your cakes. What WILL flood your cakes is pumping from a humidifier AFTER the air is already at 100%. That's why I recommend three to five inches of well-drained perlite for a terrarium, and no mechanical humidifier. This way, if your humidity reads less than 95%, it means you need to calibrate your hygrometer. Mycelium will pin best at or near saturation humidity and plenty of fresh air, whether the substrate is cased or not. A casing layer simply helps to hold humidity high right at the surface, under less than ideal ambient conditions. Of course, once pins form, the casing layer also helps to supply the substrate below with moisture, so you want to keep the humidity high to prevent the casing layer from drying out too much between mistings.

HUMIDITY - I recently cleaned out one of my terrariums after 8 weeks. The perlite was still damp, and at least half of this time, the lid was off. I think you're mistaken. You can judge moisture content of the perlite by lifting the tub. Dry perlite is almost weightless. My huge 3 cubic foot bag probably weighs a pound or less. The terrarium I lifted up weighed at least ten pounds. However, if your house is extremely dry, you'd be well advised to run a humidifier in the room your grow is located in. It will make it better for your plants, and it will be easier on your own skin and lungs as well. Shoot for an indoor humidity of 50% or better for comfort. It will also make it much easier to heat your house in winter because the humidity will hold heat much better than dry air.

WAX PAPER HUMIDITY - What I have said is not to wait a week before using wax paper or it could stimulate the germination of contaminant spores that have landed. If you use it from the start, those contaminant spores will have mostly landed on the surface of the wax paper, which is discarded every two to three days. After four or five days, you can simply wash the surface of your substrate very well under the water faucet to rinse off most of the contaminant spores that have landed. Wax paper simply helps to hold a high humidity at the pinning surface. It's even more effective with uncased substrates than with cased.

FC HUMIDITY - I'm now convinced the closer to 100% humidity we can get, provided we have proper air exchange, the better. This applies to cakes, substrate blocks and cased substrates. Perlite in a terrarium with a cased substrate tray allows us to leave the lid or door propped open to allow for constant air exchange, which promotes pinning and suppresses contaminant molds. Without the perlite, we need to keep the terrarium closed up tighter, which promotes contaminant molds. I think the 90% humidity suggestion when casing comes from stamets' books, but I respectfully disagree.

FC/HUMIDITY/HOLES - I drill dozens of holes all over my terrariums, including the very bottom. The holes on the bottom actually increase humidity, while letting the CO_2 drain. The reason the holes on bottom increase humidity is because air currents travel from cold to warm, due to the pressure difference caused by the molecules being farther apart in warm air. The warm air in the terrarium causes air to percolate up through the perlite, wicking moisture as it passes through.

CASING HUMIDITY - Why would one want to avoid getting moisture on the mushrooms? Mushrooms are 90% water and benefit greatly from misting. The other benefit to misting is to replenish moisture in the casing layer or on the surface of the cake. You can't do that with humidity, even at 100%. It must be done by misting. Opening the lid of a fruiting chamber a few times per day is a great idea. A total influx of fresh air is always good for the pinning/fruiting mushrooms.

WAX PAPER HUMIDITY - Wax paper will work better if you'll wrinkle it up into a ball first, then flatten it back out and lay over your uncased (or cased) substrate. By wrinkling, you open up lots of little air passageways while still keeping the humidity tent. It also helps cut down on the surface area of the caps touching the wax paper as they push it out of the way. Be sure to lift it up a couple of times a day to let all the built up CO_2 from around the substrate escape.

HUMIDITY - Mushrooms grow best in upper 90's to 100% humidity. It makes no difference if the substrate is cased or uncased. A cased substrate can still get some pinning at a lower humidity than cakes, but performance is always better when high humidity is maintained. The old adage of 85% for cased substrates, 100% for cakes is just plain wrong. None of the experienced, successful growers fruit casings at lower humidifies.

HUMIDITY FC - If you have three to five inches of well-drained perlite, with holes cut in all six sides of the terrarium, humidity will be in the upper 90% range. A 20F rise in temperature cuts the humidity in half until more moisture evaporates from the perlite. That is just a fact of physics. Warm air can hold more moisture, so if you heat it, more moisture is required to have the same relative humidity.

HUMIDITY - If your ambient room humidity is very low, I'd suggest running a coolmist humidifier to bring your room humidity up to fifty percent or so, and then you'll be fine in your terrarium. As said, get an analog hygrometer and properly calibrate it at the high end of the scale. I'd also get rid of the aquarium light and get a fluorescent in the range suggested above.

HUMIDITY CASING - Perlite is best of course. If you don't have it, paper or cloth towels work fine. I've used them in pinches for years. Wring them out of excess moisture, and make sure they're fluffed up in the terrarium. You can even paste them to the sides. They won't contaminate for weeks, so if you change them for fresh every few days, you'll be fine.

WAX PAPER HUMIDITY - Wax paper in a monotub type grow is generally of little benefit. If you're using tray culture in a mini greenhouse where humidity is often less than optimal, wax paper can help keep humidity in the correct range for pinning. In a tub, humidity is usually close to 100% anyway, negating the need for wax paper.

CASING/HUMIDITY - Hyphal knots and primordia form best in 100% humidity. They don't care one whit whether the substrate is cased or uncased. You should maintain humidity in the upper 90% range for best results when growing mushrooms. The oft-repeated advice that 'casings only require 80% humidity' is wrong.

HUMIDITY - Raise humidity to near one hundred percent during primordia formation. Once pins are set, humidity can be reduced a bit, but don't get out of the 90's. The 'old' advice of keeping humidity lower for cased substrates is incorrect. As hyphae said, keep humidity high, and air exchange high.

CASING HUMIDITY/FAE - Never. I fruit cased substrates in the high 90% range too. The key is air exchange. Even at 99% humidity, moisture will be evaporating from your casing layer, provided you have enough air exchange, giving you two of the three major pinning triggers.

HUMIDITY/FC - A fact of physics is that a 20F(11C) rise in temperature cuts humidity in half, and a 20F(11C) drop in temperature doubles humidity, providing the amount of moisture stays the same. You're better off fruiting at 22-24C than at 27C anyway. Fruit quality will be better.

HUMIDITY FC - Recent experiments (over the last 23 years) have shown100% humidity means the air is saturated. Having the air saturated in no way is going to flood your cakes.

HUMIDITY FC 92% - Humidity will be fine with a good casing layer. I prefer higher, but lower will also still work, only requiring more frequent misting.

HUMIDITY/CASING - It's hard to get total saturation humidity with lots of air exchange. At 99% humidity with five to six air exchanges per hour as recommended, a casing layer will dry out daily and this moisture needs to be replaced by misting.

CASED SUBSTRATES - If you're going to case substrates, you want the humidity no more than 90%, with 80% being ideal. Too high a humidity is a major cause of weak or no pinsets on cased substrates.

HUMIDITY % CASING/FC - The maximum amount of air exchange possible while still maintaining humidity is what you want in a growing chamber. Fully colonized substrates are very resistant to contaminants.

HUMIDITY FC PRIMORDIA - During primordia formation, the higher the better. Once pins have formed, humidity can be reduced, but don't go less than 80% or you'll see a lot of cracked caps.

HUMIDITY/FC - You'll never get a good pinset at humidity below 90%. 95% and above is recommended, even with a casing layer. It's easy to get 99% humidity with perlite in a terrarium.

HUMIDITY - Contrary to popular belief and constant repetition, fuzzy stems are not an indication of too high humidity.

FC HUMIDITY - One cool mist is plenty for your terrarium for both air exchange and humidity.

HUMIDITY FC - There is no such thing as too much humidity when growing mushrooms.

SOAKING - Simply put the tray under a gently running faucet for a few hours. Allow the water to fill the tray and run over and down the drain. The running water prevents contaminants during the soaking process. Place a jar, rock or something similar on top of the substrate if necessary to prevent floating. After the soak, fill in the divots caused by picking with fresh casing material. You don't need to apply a whole new layer because it won't colonize anyway. Never pick pins that aren't aborts. Primordia for the first two or three flushes commonly forms at the same time, and then remain dormant until their time comes. If you pick the substrate clean, you ruin the next flush. Just be sure to drain out any excess water before returning to the FC. Don't get anal about draining; just get what pours off easily. The rest will continue to be absorbed by the substrate over the next 24 hours or so. You can throttle down the faucet too. You don't need a lot of water overflowing, just a trickle.

SOAKING/CASING/UNCASED - Dunk first. Personally, I've seen little benefit to adding a casing layer over bulk substrates with cubensis. Very experienced growers can definitely get a boost with a well-managed casing, but for the majority of new growers, I feel you'd be better off getting your feet wet by fruiting uncased. Of course, straight rye or wbs requires a casing to perform well, but bulk substrates such as coir or manure do not. You can dunk the coir/coffee substrate, and then introduce directly to fruiting conditions. This way, you get your harvest a bit sooner, and don't have the other problems to deal with that casing causes. As you gain experience, add casing layers to future crops. You can lay a sheet of wax paper over the uncased substrate to hold a high humidity right at the substrate surface, which will stimulate pinning. Lift it up to fan several times per day, and replace with a fresh sheet every two to three days, or if/when it gets damp.

MISTING - Droplets on your pins will not cause aborts. It's recommended to mist mushrooms. Air exchange must be provided because stagnant water sitting on a mushroom in stagnant air for an extended period WILL cause aborts. Condensation does not begin on all surfaces at about 95%. My can of cold beer gets condensation in Arizona in the summer. I know it's not 95% there. Condensation forms on my windows in winter, even when humidity in the house is less than 50%. Condensation is a function of the temperature differential on either side of a surface. Condensation forms on the warm side. Condensation won't even form on your mushrooms at 100% humidity. If they get wet, it's because liquid water droplets were thrown on them, not humidity in the air. 92% humidity will be fine with a good casing layer. I prefer higher, but lower will also still work, only requiring more frequent misting.

COLD SHOCKING - You dunk in the refrigerator to prevent bacteria buildup that would otherwise contaminate your brf if you dunked at room temperature. Don't confuse that with cold shocking, although it does cold shock them...lol. As for cased bulk substrates, I ran several experiments a few years ago where half the trays were placed in the refrigerator for 24 hours, while the second half were left at room temperature. Both sets of trays went to the fruiting chamber at the same time. Every single tray that had been 'cold shocked' pinned two or more days later than trays that had not been cold shocked. That is not to say a temperature change can't be a pinning trigger. However, along with light, a fully colonized substrate, and an increase in air exchange, it is only one of the triggers. However, cold shock being beneficial or not, you need to dunk your cakes in the refrigerator.

CASING SOAKING - The casing layer will never re-colonize after first flush. Simply dunk to rehydrate the substrate and return to fruiting conditions. I used to recommend dunking in the refrigerator, because in part, that was the conventional wisdom. I no longer believe that's the best course of action, so dunk at normal room temperature, beginning the dunk with cold tap water, but no ice. Larger trays can be easily soaked by placing under the kitchen or bathtub faucet, allowing the tray to fill up and gently run over the edge for a few hours. Put something on top of the substrate if it tries to float. The running water will help to wash away contaminant spores that may have landed, while preventing excess bacterial blooms that may occur under still water.

REHYDRATING SPAWN BAGS - Your mistake was injecting into the middle instead of along the edges. It's best to squirt solution in the area between the bag and the grains. This lets you see right away after germination what you have. Five to seven days is about normal for first growth to be seen if you inject the edges. Since you injected the middle, double that at least. I'd suggest waiting two weeks, then kneading the bag between your fingers to mix it up. Doing so should reveal some mycelium from the center of the bag, and the kneading will spread it around the bag. Only do this once, ten days from now.

FANNING/MISTING FC - Fanning is when you take the lid of the tote and wave it back and forth over the terrarium to blow out the stale air and replace it with fresh. Fan for fifteen seconds or so each time. I'd suggest drilling a hundred or more 1/4" holes into all six sides of the terrarium, elevate it an inch or two off the shelf, and then fan a couple of times per day also. Mist each time you fan, just before fanning. There is no maintenance free terrariums, so keep it simple and give your mushrooms lots of humidity, lots of fresh air, and lots of bright fluorescent light.

SOAKING - No, just use tap water unless you live in an area with contaminated drinking water. It's best to refrigerate or otherwise keep the water cool during the soak period to prevent the growth of unwanted organisms in the anaerobic conditions underwater. Put the cakes in a pot of water, and then use a heavy glass dinner plate or something similar to hold them submerged, as they'll try to float. Rinse well under the faucet both before and after the soak period. It's a good idea to roll the cakes in dry vermiculite after the soak. Read up on 'dunk and roll'.

SMALL MUSHROOOM HYDRATING - Small fruit size is related to substrate moisture content. It's easy to hydrate a substrate block during fruiting by simply pouring water around the edges so it slides down and under the substrate. If you pour a few tablespoons of water around the edges a couple of times a day, the substrate will readily absorb it and transfer the moisture to your fruits. Cubes will benefit from a casing layer, but by no means is one necessary to get a nice flush of large fruits.

MISTING - You can mist pins, but they must be left open to fresh air after misting. If you mist small pins, and then put the lid on the fc, they'll usually abort. They also must be misted with a very fine mist sprayed up into the air, so that it settles down gently on the casing layer. A direct spray will abort pins. Never mist when they're in the primordia stage. Simply lay a sheet of wax paper over the top of the tray to hold humidity at that time. Pick off any moldy pins from the substrate.

REASON FOR COLD DUNKING CUBIES - Cold water is recommended for dunking for only one reason-it helps to keep bacteria from growing during the time the mycelium is underwater. Tap water is fine, unless your local water supply is polluted. Many people add 1/2 teaspoon of bleach per gallon of water to the dunk water. I recommend rinsing the cake under the faucet with running water after the dunk to remove any bacteria or slime that develops during the dunk.

MISTING - Your substrate is dry. You can mist pins, so mist away. It will take several mistings an hour apart over a day or two to get your moisture back. I'd also pour, yes pour water around the edges. Wait two hours, and then pour any excess back out. Once pins are the size of yours they won't abort from misting as long as you up the FAE to let them dry off. Misting, then closing a container up tight will cause them to abort. Don't allow them to sit wet is the idea.

SOAKING CASING - Just give it an hour or two under gently running water. The kitchen sink works fine. Just put a rock or something else heavy to keep the substrate down in the pan, and let it fill up and gently run over the edges. After a couple of hours, drain off the excess water and place back in fruiting conditions. You can patch the divots from picking, but don't recase. It won't colonize anyway and will just serve as a place for contaminants to get a start.

PEROXIDE/NO TO SOAKING - Peroxide breaks down within minutes in the presence of organic material such as a substrate, so is ineffective for an overnight soak. Peroxide is toxic to fungi so don't use it except to control a cobweb outbreak. It's ineffective as I said in dunk water because it breaks down so fast. Besides, it's not necessary. Yes, the only reason for using the refrigerator during the soak is to prevent bacteria from growing unabated.

REHYDRATING FC - I like to dunk cased substrates under running water. Just let the faucet fill up the tub and run over the edges. Use whatever you need to keep the substrate block from floating. Allow the water to run for an hour, then drain and return to fruiting conditions. The running water prevents contaminants building up during the dunk and also helps to wash contaminant spores that may have landed on your project down the drain.

SOAKING - I like to dunk cased substrates under running water. Just let the faucet fill up the tub and run over the edges. Use whatever you need to keep the substrate block from floating. Allow the water to run for an hour, then drain and return to fruiting conditions. The running water prevents contaminants building up during the dunk and also helps to wash contaminant spores that may have landed on your project down the drain.

DUNKING IN BLEACH - If you still have problems with contaminants after using peroxide, you can also dip tissue into a ten percent bleach solution for a couple of minutes. Believe it or not, the mycelium can withstand this, but molds and bacteria can't. The bleach works really well when cloning dry tissue. Live tissue needs a week or two to recover from the bleach, but dry tissue is dormant so hardly even gets smacked.

SOAKING WITHOUT A FRIDGE - You can pad your bet by changing the water every few hours, or using very gently running water from the sink. Just hold the cakes underwater, and allow the faucet to drip slowly into the pan until it overflows and runs down the drain. The moving water will prevent growths as well. It's also a good idea to rinse the cakes very well under running water both before and after the soak.

DUNKING - You can dunk right in the tray it grows in. Just leave it under the gently running kitchen faucet for a few hours. Let the water overflow the tray and run down the drain. The running water will prevent bacteria buildup during the dunk and might even wash a few contaminant spores off in the process. Put a couple of rocks or whatever you have on top of the substrate to hold it submerged.

MISTING - You can mist mushrooms. You can mist the casing layer directly to moisturize it. In fact, you can put your thumb over a garden hose and blast your mushrooms and they'll do fine (slight exaggeration) as long as you don't seal them up in a closed terrarium while wet. Mist, and then increase air exchange until the visible moisture on the fruits themselves has dried or been absorbed.

MISTING CASING - You want your casing layer to dry a bit between mistings. This is one of the major secondary pinning triggers. Replace that lost moisture with misting. An ultrasonic can easily saturate the casing layer, taking away this major pinning trigger. I'd go from misting once a day to three or four times, and keep the air exchange up, provided you have mid to upper 90's humidity.

HYDRATING - You should be misting several times per day to keep it nice and moist. You can also pour water right from a bottle between the pins to super-hydrate the casing. If the substrate is also dry, as I suspect, you can inject water directly into it with a syringe, and/or pour water around the edges of the tray, filling it up. Pour off the excess a few hours later.

REHYDRATING - If the substrate dries out, you can always inject some water with a syringe. I tried all sorts of hoses, pipes with holes, and straws in the middle of substrates for hydration and had an increased rate of contamination every time. It seems that trich spores migrate into the well you cut, and then grow there in the stale, still air until they ruin the project.

MISTINGS - Mist cakes a couple of times per day, especially if they've been dunked and rolled. Keep that vermiculite damp. What you need is a higher priced mister. It should spray a very fine mist and not puke out large droplets that will damage your mushrooms. Aim it up so the mist gently falls onto your cakes. This won't damage the fruits.

HYDRATING - You can do it either way. However, since it isn't the 'soil' or 'substrate' we're hydrating, but rather the individual cells of mycelium, soaking overnight has become the preferred method. Cells take on water by osmosis; therefore the water pressure helps to hydrate them faster than simply misting.

SOAKING/DUNKING - In addition, dunking causes the cakes to expand, so in jars they stop expanding when they hit the glass, thus they stop in taking moisture. In addition, it pushes the cake tightly against the glass, making birthing harder. It's best to birth before the dunk so the cakes slide right out of the jars.

HYDRATING/CASING - You can pour water directly on the casing layer between pins to fully hydrate it. We use high humidity to slow down the rate of evaporation, but you still need to mist directly to replace what is used by the growing fruits, as well as to replace what moisture naturally evaporates.

MISTING CASINGS - You can tell when to mist by looking carefully at the cakes or casing layer. Allow them to dry slightly, then mist lightly. After a few grows, you'll be able to instantly tell when a project needs to be misted. You don't want them to dry completely out, or get waterlogged.

MISTING/SOAKING - Misting lightly or even heavily does not abort mushrooms. Soaking wet mushrooms in stale air causes aborts. Always provide plenty of fresh air and you can mist like crazy. That's the reason for building a terrarium with holes in all six sides.

DUNKING - Dunking before first flush is optional, but it's best to dunk between flushes for sure. There is no reason to use mineral water. I use plain tap water, but if your local water supply sucks, it's probably best to filter it or use spring water.

DUNKING WITH PINS - Leave them. Dunking won't hurt healthy pins. I've actually seen them double in size during the dunk. Also, pins for the second flush often form during the first flush. Just leave them and after the dunk, they'll begin to grow.

MISTING - You don't want the cake to dry out. Mist as needed until hyphal knots form. Then back off until the pins are well established. Always fan after misting. Don't allow a pin to sit there soaking wet after you close up the terrarium.

MISTING - If the casing layer is saturated, it means you've over misted, or possibly made it too wet to begin with, but high humidity will not get your casing layer wet, but rather will only slow down the evaporation of moisture from it.

HYDRATE - Yes, that's a very small substrate to have to support all those pins. I'm sure it's dry. Put about 1/2" of water in the pan and let it soak for a day, and then dump out the excess. Repeat every 48 hours until the flush is done.

MISTING - Misting is fine, but be sure to increase air exchange afterward until all the misted water either evaporates or is absorbed into the fruits by osmosis. If you leave pins wet in a still-air environment, many will abort.

MISTING - You should not stop misting. Mushrooms are 90% water and the purpose of a casing layer is to supply moisture to the flush. Daily, or several times daily misting is required for large fruits and good performance.

SOAKING - Tap water is best for soaking/dunking in my opinion. I use it right out of the tap. The small amount of chlorine will actually help to prevent bacteria buildup during the soak. I use spring or distilled for misting.

DUNKING - After the dunk, replace the casing that is missing from the divots or from washing off during the dunk. You can also dump extra casing material around the edges to fill in the gap.

COLD SHOCKING - Cubensis benefit NONE from cold shocking, as they are a hot tropical species; Cold Shocking is used for cold climate edible mushrooms.

SOAKING - You don't need to pick them off before dunking. If they abort later, pick them, but it's rare for fruits to abort from an overnight soak.

DUNKING - I've never found that dunking damages these pins. Just be careful not to scrape or otherwise physically damage them.

COLD SHOCKING - You should soak in the refrigerator to avoid bacteria buildup in the anaerobic environment under water.

CASING MISTING - You're supposed to mist your casing layer several times per day to replace moisture that is evaporating.

DUNK IN CHLORINE - I never have. If anything, the chlorine will help kill bacteria. It sure doesn't hinder the mycelium.

MISTING - You're supposed to mist your casing layer several times per day to replace moisture that is evaporating.

MISTING - Use filtered, spring, or distilled for misting though.

OUTDOORS GROW - For an outdoor grow, all you need to do is gather up some of your field-aged manure and make a bed of it in a nice shady spot. Make the bed no more than about six inches deep. Dig a hole and put the manure in that, so the ground can help keep it from drying out. Wet the manure down well, but no pasteurization is required for outdoor grows. Obtain some spores and inoculate some pf cakes, made from brown rice flour and vermiculite. You can find the pf tek on here in the FAQ link at the top of the page. When 8 or 10 jars are fully colonized, you can spawn them into your manure outdoors, and the mycelium will jump off from the brown rice flour cakes into your manure. Lay a sheet of cardboard, or a few inches of straw over the top to shade and hold in moisture while the mycelium colonizes your manure. It will fruit later in the summer after heavy rains.

OUTDOORS GROW - If you're going to grow outdoors using bagged cow manure unpasteurized, put it in the ground, not in a Tupperware. It needs the organisms in the soil to prevent contamination. I'd also suspect your cake was contaminated prior to spawning to the manure if it was green within a week. I've stored bagged cow manure outdoors for months without it growing trich. If you spread the bagged cow manure out on a tarp in the hot sun, the ammonia is gone within hours. If it's cool weather, it might take a few days.

OUTDOOR - Wait until June to plant them outdoors. If you put grains in the ground, the damn squirrels will dig up every single kernel to eat, and destroy your patch. Mix the grains with manure indoors, and then in June or July, bury them into a shallow hole with horse or cow manure spread all around the substrates you're planting. If you want to spawn directly to manure outdoors, use pf cakes, not grain.

OUTDOORS - Cakes can be grown outdoors, but those temperatures are at the extreme end of the scale. I would suggest to partially burying the cakes after full colonization, in the shade under some thick bushes. By burying the cakes half way, they can draw moisture from the soil, preventing them from drying out. It will help to run a lawn sprinkler in the area for several minutes, a few times per day.

OUTDOORS BED - You can pick up the cow pies and break them up into a compost pile or shallow manure bed in your yard. Mulch over the top with straw. This is how I originally started out in the early 70's; when there was no Internet, no grow guides, nothing.

OUTDOORS GROW - Chop up the fruit into manure or compost. It should clone right into the new substrate, provided temperatures are still in the right range.

STERILIZING CASING - Do not sterilize A Casing! EVER! In fact, most of the casings I use these days are simply peat/vermiculite with lime and gypsum, and zero heat-treating of any kind, because many edibles won't fruit on sterile or pasteurized casing layers. You can pasteurize casing material and it works well with cubes. However, sterilization will give a higher rate of contamination then doing nothing. You have to assume that mold spores are going to land on your casing layer. If it's been sterilized, they will germinate and grow because nothing else is there to stop them. The beneficial bacteria that are in peat moss will help protect against molds such as trichoderma, and some of these will survive the pasteurization process, which should kill all the mold spores that are present at the time. Once the casing layer is in place, the key to preventing molds is proper air exchange. Lime raises the ph, and gypsum keeps it stable. They both provide calcium, but gypsum also helps with texture.

STERILIZING CASINGS - In fact, most of the casings I use these days are simply peat/vermiculite with lime and gypsum, and zero heat-treating of any kind, because many edibles won't fruit on sterile or pasteurized casing layers.
You can pasteurize casing material and it works well with cubes. However, sterilization will give a higher rate of contamination then doing nothing.
You have to assume that mold spores are going to land on your casing layer. If it's been sterilized, they will germinate and grow because nothing else is there to stop them. The beneficial bacteria that are in peat moss will help protect against molds such as trichoderma, and some of these will survive the pasteurization process, which should kill all the mold spores that are present at the time. Once the casing layer is in place, the key to preventing molds is proper air exchange.

STERILIZING CASING - My main point about sterilizing casing layers is that one; it makes them more prone to contamination, not less. A sterilized substrate is prime food for whatever organism is the first to land on it. Second, many gourmet species will not fruit on a pasteurized or sterilized substrate/casing. Eventually, most growers either move from cubes to more difficult species to grow, or they lose interest in the hobby and quit growing. I just feel it's important to learn procedures that you can use later. I hope this clears it up.

STERILIZING CASING - The reason you don't sterilize casing layers is because a sterilized media is a prime target for contamination to grow on because there's no competitors.

MARTHA NEEDS REDUE... I THOUGHT I CAN JUST COPY AND PASTE A BUNCH OF SENTENCES TOGETHER BUT IT DIDN'T WORK SO

MARTHA/GREENHOUSE (REDO)

Once you've fixed up your mini greenhouse it's time to go over some guidelines. You want 100% humidity regardless if it's cased or not. You do not want your cool mist/humidifier/ultrasonic on the ground. It will pick up the contaminants from that air and bring them inside your growing chamber. Put your cool mist inside the greenhouse for optimally so it humidifies the entire thing and doesn't come in from just one spot. You want to cut slits in your greenhouse for FAE or open vents or doors are for air exchange, you also can use a fan if it's not moving at all. Using a cool mist, as a fae will only last a very short time due to the static pressure produced, which ruins the motor and bushings. For best results, use a humidifier for humidity, and vents for air exchange. I have openings cut all over my greenhouse so air can circulate in and out top, bottom, and sides. Constant air exchange, with the humidifier inside the greenhouse gives excellent performance. I can actually maintain 99% humidity, just like a terrarium. Place the humidifier(s) on a bottom shelf or floor of the greenhouse. Humidity in mini-greenhouses seems to stratify into layers with higher humidity near the top and lower at the bottom. By placing the humidifiers on the bottom of the unit, the air drawn into the humidifier will cause circulation from the top back down, thus equalizing the humidity.
You need a floor. Easiest is to use plastic sheeting and duct tape it to the sides. To catch drips, use trays of damp perlite. These will return the drips to the air as humidity.
I spent years modifying humidifiers before I worked out this method. A humidifier that has been modified has a life span in weeks, sometimes months, but not years the way an unmodified unit has. My two cool mists on the floor of my greenhouse are now over two years old without failing. Also, when it fails, you can't return a drilled out humidifier to the store.
Using the above system, I can easily keep my greenhouse at 95% to 99% humidity, which is what's required for cakes or substrate blocks of sawdust during fruiting. You'll need a good cycle timer for the humidifiers. Don't let them run more than a few minutes at a time, followed by another few minutes of 'off' time.

When you're first filling up the greenhouse, place trays of damp perlite on any empty shelf space. A greenhouse full of substrate is much easier to keep moist than an empty one, so the trays of perlite make up the difference. Supply air to the bottom, and return air out the top if you're circulating. This helps to counter the natural tendency of the humidity to stratify in layers.

You don't need to worry about removing CO_2 in a mini greenhouse. Just have a few openings top and bottom and that will take care of itself. You want air circulation and turbulence to help prevent molds. For best results, have constant air exchange during fruiting. It's counterproductive to use a humidifier for air exchange. You will never get the humidity high enough for cakes if you're pumping in fresh air with a humidifier. Rather, leave the door unzipped or cut slits in the sides of the plastic both top and bottom to allow for constant air exchange and circulation. Cool mist humidifiers have no problem keeping the humidity right around 85% to 90%, which is perfect for cased substrates. Wax paper works great to put over cased substrates from the time you first expose to fruiting conditions. It will keep the humidity near 100% right on the surface where primordia form, then as the pins grow, they will push the wax paper out of the way, opening the edges to allow for less humidity. It's sort of a self-regulating system. Just be sure to change the wax paper out for a clean sheet every second day. Also, you must use this tek right from the start. If your casing has already been open and exposed, placing wax paper over it will help the contaminant spores to germinate and grow. If used from the start, most contaminant spores falling from gravity will land on the wax paper, which you carefully remove and replace every 48 hours. Just lay the wax paper over the top. Don't try to tuck it under the cake or other substrate or you'll do more damage than good. You can fold it if necessary to fit, but don't try to make a tight seal. Tiny drops won't hurt, but if they build up, you're in for problems. This is a very common problem when running cool mists 24/7 because the air can't absorb all the moisture you're pumping into the greenhouse. If your casing layer becomes waterlogged, it won't pin. If you'll put trays of damp perlite on the empty shelf space and floor, you can easily get 99% humidity in a martha with a cool mist. I place mine inside the greenhouse, which raises humidity even more because it recirculates already humid air through the cool mist. I only use cool mists, with trays of perlite on the floor to catch drips. As you can see, it's steady at 95%. Put the cool mist inside the greenhouse and run it no more than 25% of the time. You want a Vicks 400 humidifier. I'd put two cool mists on timers or a humidistat inside the greenhouse for humidity, then simply cut about ten to twenty holes big enough to stick your arm through at various points in the sides. Put half the holes you cut high, and the other half of the holes down low. If you open windows while doing sterile work, it hurts. If you open windows near your greenhouse or terrarium, it won't hurt at all. In fact, I have a 4" clothes dryer hose connecting my mini greenhouse to the outside. Just make sure you shut everything before you do any sterile work. You want totally still air for that, plus a glove box. You still want the greenhouse open though. The more openings the better as long as you can maintain humidity. I know from experience if I allow the cool mists to run for more than two minutes, they begin to drip because the air can't absorb the moisture as fast as one of those can put it out. However, you can run them one minute on, then two to ten minutes off and get 80 to 90 percent humidity with no drips. It takes a good cycle timer to do it, but the results are worth it. I agree. Short cycles are the key. I'm running mine about a minute on, then about six minutes off. The link below will get you a good prewired timer for $120. Scroll to the bottom of the page and look at the Cycle stat 4 timer. It's what I've used for two years now and it's still working great.

http://www.littlegreenhouse.com/accessory/controls2.shtml. If you're going to run a cool mist into a terrarium for air exchange, run it no more than one or two minutes per hour. That is enough to fully exchange the air without drying anything out. I run the humidifier for two minutes every fifteen.

GREENHOUSE - I think you said you're growing cakes. A mini-greenhouse is really not suitable for cakes unless you put the cool mist directly INSIDE the greenhouse so it can recirculate your moist air, adding additional humidity to it. CO_2 should not be allowed to build up, then vented. For best results, have constant air exchange during fruiting. It's counterproductive to use a humidifier for air exchange. You will never get the humidity high enough for cakes if you're pumping in fresh air with a humidifier. Rather, leave the door unzipped or cut slits in the sides of the plastic both top and bottom to allow for constant air exchange and circulation. Place the humidifier(s) on a bottom shelf or floor of the greenhouse. Humidity in mini-greenhouses seems to stratify into layers with higher humidity near the top and lower at the bottom. By placing the humidifiers on the bottom of the unit, the air drawn into the humidifier will cause circulation from the top back down, thus equalizing the humidity. You need a floor. Easiest is to use plastic sheeting and duct tape it to the sides. To catch drips, use trays of damp perlite. These will return the drips to the air as humidity. I spent years modifying humidifiers before I worked out this method. A humidifier that has been modified has a life span in weeks, sometimes months, but not years the way an unmodified unit has. My two coolmists on the floor of my greenhouse are now over two years old without failing. Also, when it fails, you can't return a drilled out humidifier to the store. Using the above system, I can easily keep my greenhouse at 95% to 99% humidity, which is what's required for cakes or substrate blocks of sawdust during fruiting. You'll need a good cycle timer for the humidifiers. Don't let them run more than a few minutes at a time, followed by another few minutes of 'off' time. When you're first filling up the greenhouse, place trays of damp perlite on any empty shelf space. A greenhouse full of substrate is much easier to keep moist than an empty one, so the trays of perlite make up the difference. Supply air to the bottom, and return air out the top if you're circulating. This helps to counter the natural tendency of the humidity to stratify in layers. You don't need to worry about removing CO_2 in a mini greenhouse. Just have a few openings top and bottom and that will take care of itself. You want air circulation and turbulence to help prevent molds.

GREENHOUSE FC - Greenhouse: Air exchange is provided by the very loose fitting door. My greenhouse is framed with PVC pipe and covered with plastic sheeting. I got all the parts at the hardware store for less than $35. I'd say it's twice to three times the size of the Martha closet. I didn't put zippers or anything else to seal the door, so it's open on both sides from floor to ceiling. This provides for plenty of air exchange, and the cool mist humidifiers have no problem keeping the humidity right around 85% to 90%, which is perfect for cased substrates. When I use it for cakes or straw logs, etc., that require higher humidity, I simply cover them with wax paper which holds in the humidity in that specific area while still fitting loose enough to allow gas/air exchange. Wax paper works great to put over cased substrates from the time you first expose to fruiting conditions. It will keep the humidity near 100% right on the surface where primordia form, then as the pins grow, they will push the wax paper out of the way, opening the edges to allow for less humidity. It's sort of a self-regulating system. Just be sure to change the wax paper out for a clean sheet every second day. Also, you must use this tek right from the start. If your casing has already been open and exposed, placing wax paper over it will help the contaminant spores to germinate and grow. If used from the start, most contaminant spores falling from gravity will land on the wax paper, which you carefully remove and replace every 48 hours. Just lay the wax paper over the top. Don't try to tuck it under the cake or other substrate or you'll do more damage than good. You can fold it if necessary to fit, but don't try to make a tight seal.

GREENHOUSE - I get 90% to 95% with cool mists alone. I have never used an ultrasonic because I've found them not necessary. Never seal a fruiting chamber or greenhouse up tight. You want massive amounts of air exchange to stimulate pinning and to prevent contaminants, which thrive in stale, still, moist air. I have several 4" holes cut in the sides of my greenhouse, and the door is a simple piece of plastic sheeting that hangs from the ceiling all the way to the floor and is not attached at all except at the top. This leaves two slits the full vertical length of the greenhouse. All of the above provides plenty of air exchange, and an impeller type cool mist inside the greenhouse provides the humidity by only running one to two minutes on, five to seven minutes off. I tweak the cycle timer depending on how full of substrate trays it is at any given time. It also helps to get a bunch of plastic trays and fill each one with damp perlite. Use these to line the floor to catch drips, and also to fill up any empty shelf space within the greenhouse. Doing the above will provide you with 90% to 95% humidity along with ample air exchange. You can also do a search, and you'll find all of this has been covered many, many times before with experienced growers using all sorts of methods. This is my method, but by no means is it the only one that will work. Other growers prefer to put the cool mist outside the greenhouse, and then modify it to pipe the humidity in, but that isn't my personal choice for reasons I've previously posted, but it certainly works and they have the pictures to prove it.

GREENHOUSE - I have two 4" holes near the bottom on each side. Two more 4" holes are at the top on each side. The door is an opening that covers the entire front, nearly 5 feet across. It's a sheet of plastic that hangs down from the top; with a piece of PVC pipe at the bottom to hold it shut by gravity. The side slits are not attached to anything, thus air exchanges the full length from top to bottom on each side of the door, and the other 4 holes also pass air. There are also a few smaller holes I've cut for taking pictures and never sealed up. The idea is to have as much air exchange as you can possibly have and still keep mid 90's percent humidity. I use 2 vicks kaz cool mists sitting inside the greenhouse, set to run 1 minute on, 4 to 6 minutes off depending on ambient humidity. I'll tweak it daily due to local conditions. When things get really dry weather-wise, I'll often run a third cool mist in the room the greenhouse is located to raise the ambient humidity. Good luck. The weight of the PVC pipe is whatever a 2" X 5' length of it weighs. Perhaps two or three pounds. Yes, I built a place for it to hang. To open it, I simply roll up the PVC and 'door' from the bottom. It makes a nice little roll to hang on the hooks at the top. My entire greenhouse is framed with PVC pipe and covered with plastic sheeting. I also have a self-contained air conditioning system to use when fruiting cold weather loving mushrooms such as oyster and shiitake. I can keep the greenhouse at 58F, while the room outside is 70F.

GREENHOUSE - There is absolutely no need or reason to even attempt to keep a greenhouse sterile. We use sterile procedure to colonize grains, but once they're colonized, everything else is done in normal air. You don't need a fan to provide air exchange in a greenhouse. Simply take a knife and slice the plastic from top to bottom in a few places. This will allow normal room air to circulate into and out of the mini greenhouse. Use a cool mist humidifier (or two) depending on size to provide humidity, not air exchange. Trays of damp, well-drained perlite placed on empty shelf spaces and the floor will help to catch drips and return them to the air as humidity. To repeat, a mini-greenhouse should have high humidity and high air exchange, with very bright high frequency lights such as natural daylight fluorescent on a 12/12 cycle for best results. Don't waste time stressing over filters or other means of scrubbing the air. It isn't necessary.

HUMIDIFIER/GREENHOUSE - You don't need distilled water for your humidifier. I've used tap water for many years in different parts of the world. It's fine. You also don't need to clean it with bleach once a week. When it starts to get nasty, clean it in the sink with soap and water. Impeller type humidifiers DO move air, but not much. They are the type to use for mycology. You don't need one for a monotub or terrarium, but when you move up to a mini-greenhouse, you'll want one. Wicking type humidifiers will work fine in the room your grow is located in, as a way to boost the ambient humidity, but they can't produce enough humidity for mushrooms. After about 60% to 70%, they won't evaporate any more moisture into the air.

GREENHOUSE FC - http://www.littlegreenhouse.com/accessory/controls2.shtml
I also have the humidistat they sell on that same page, but if you order it, be very careful to always harvest before a major spore drop occurs, because the spores will jam up the mechanism, causing the humidistat to fail. The cycle timer mounts outside the greenhouse so it's safe. Also, the humidistat won't provide over 80%, which is fine for cased substrates as long as you put a sheet of wax paper over the casing layer during pinning initiation.

GREENHOUSE/COOLMIST - With mine inside the greenhouse, it only needs to run one or two minutes, followed by five to seven minutes off. I tweak the cycle timer depending on season and ambient humidity in the room. If you run it longer than fifteen minutes, you'll have water everywhere. I burned up at least 20 cool mists before I stopped modding them and placed them inside. The same two cool mists have now been in the mini-greenhouse for over two years. Using hoses creates static pressure that ruins the bushings, thus burning out the motor in a very short time. Cool mists are designed to provide humidity, not move air.

HUMIDIFIER - I've always recommended people in dry climates run a humidifier in the general area or room their grow is located. If you can bring the ambient humidity up to 50%, you'll have no problems. While it's true that Seattle has a damp climate in the fall, winter and spring, summers are very dry here. I always run a cool mist 24/7 in the room my terrariums are located. This becomes especially important if using a terrarium with many holes drilled into it. Air exchange is a major pinning trigger as well as preventer of contamination, so make sure your ambient humidity is up to the task.

HUMIDIFICATION CASING/CAKES/GREENHOUSE/FC - Get rid of standing water. If you can't find perlite, you can use paper or cloth towels in the terrarium. Replace paper towels or wash cloth ones every three days to prevent molds and/or bacteria from growing on them. I've ran terrariums with a large bath towel soaked, then well rung out and folded loosely, then laid into the bottom of the tub. Humidity stays as high as several inches of perlite. People with humidity problems in mini-greenhouses can also hang a damp bath towel or two inside the greenhouse for a great boost.

GREENHOUSE, HUMIDITY - Simply run an additional humidifier or two 24/7 in the room your greenhouse is located. Get your ambient room humidity up to 50%, and you'll not have trouble maintaining humidity in the martha. This will also make your house more comfortable and much more economical to heat. In fact, you should run several humidifiers in your house during the winter. The wax paper tek works great. Lift it to mist, and change it with a fresh sheet every two days. Wrinkle it up, and then flatten it back out so plenty of air can still circulate under it.

GREENHOUSE FC AIR EXCHANGE - I have several large slits, and even a few holes cut in the plastic for air exchange. In fact, the door is simply a large sheet of plastic sheeting hanging from the top, with a weight on the bottom to hold it down. The full length of both sides is not connected, so two large slits run from the ceiling to the floor of the greenhouse. The more air exchange you can give the better, as long as you can maintain humidity. That is the reason I moved the cool mist into the inside, rather than on the outside.

GREENHOUSE COOLMIST - Put it at the bottom. A cool mist needs to shoot a mist straight up about 5 feet to work properly. Mine sit on the floor of the mini-greenhouse, one on each side of the shelves. Cut a hole in the plastic right next to where the humidifier sits, and it will draw in some fresh air and also mix with the air inside to give you a nice 95% humidity easily. Giving lots of fresh air in a greenhouse is easy. Simply use a knife to cut slits and holes in several places.

GREENHOUSE - For years, I've been running a self-contained AC unit in my mini-greenhouse during the summer months. It will seriously dry out the air, so you'll have to provide for increased humidification. Get a stand-alone unit so you can circulate the same air. Don't use the central AC unit from your house. The house AC will push the humidity out. A good humidifier might be able to keep up, but it will take some tweaking, so you'll just have to experiment.

MARTHA HUMIDIFIER - One hour is too long to run the humidifier. More than a few minutes at a time will cause drips to form. I run mine less than five minutes on followed by five to ten minutes off. This maintains a high humidity without excessive dripping. You need to seal the bottom and put several trays of perlite down there to catch whatever drips do form. At the very least, get a timer with 15-minute intervals. They're cheap. Try running 15 on, 30 off.

HUMIDIFIER/GREENHOUSE - The inside of a cool mist type humidifier is always at 100% humidity because of all the mist flying around in there. You can run a cool mist, such as the vicks kaz models inside the greenhouse without problems. I've done so for years and wouldn't recommend something that wasn't safe. I'm an electrical engineer, as well as licensed journeyman electrician, so am qualified to make that determination.

HUMIDIFIER/COOLMIST - They don't crap out because of humidity. They crap out due to backpressure in the hose, which forces moisture into the motor bearings, ruining them, which then burns up the motor due to the extra load. That's why they're best used inside a greenhouse. They will also raise the humidity more because they're recycling already humid air, rather than dry air from outside.

MARTHA - FAE is 'Fresh Air Exchange' and is provided by ventilation holes cut into the mini-greenhouse. Cool mist humidifiers are designed to raise humidity, not move air. If you try to use one to move air, it will only last a very short time due to the static pressure produced, which ruins the motor and bushings. For best results, use a humidifier for humidity, and vents for air exchange.

MARTHA FC HUMIDITY - I know from experience if I allow the cool mists to run for more than two minutes, they begin to drip because the air can't absorb the moisture as fast as one of those can put it out. However, you can run them one minute on, then two to ten minutes off and get 80 to 90 percent humidity with no drips. It takes a good cycle timer to do it, but the results are worth it.

GREENHOUSE AIR EXCHANGE - Humidifiers are for humidity. Fans, fanning, open vents or doors are for air exchange. I have openings cut all over my greenhouse so air can circulate in and out top, bottom, and sides. Constant air exchange, with the humidifier inside the greenhouse gives excellent performance. I can actually maintain 99% humidity, just like a terrarium.

MARTHA TIMER FC - I agree. Short cycles are the key. I'm running mine about a minute on, then about six minutes off. The link below will get you a good prewired timer for $120. Scroll to the bottom of the page and look at the Cyclestat 4 timer. It's what I've used for two years now and it's still working great. http://www.littlegreenhouse.com/accessory/controls2.shtml

FAE GREENHOUSE - If you open windows while doing sterile work, it hurts. If you open windows near your greenhouse or terrarium, it won't hurt at all. In fact, I have a 4" clothes dryer hose connecting my mini greenhouse to the outside. Just make sure you shut everything before you do any sterile work. You want totally still air for that, plus a glove box.

GREENHOUSE - Toss out the ultrasonic and get a spinning impeller type cool mist, and set it inside the greenhouse. Adjust the timer so you get the desired level. I use one minute on, six minutes off. In the winter when ambient humidity is lower, I use one minute on, four minutes off. You'll have to tweak your own setup depending on your ambient conditions.

HUMIDIFIERS - Cool mist humidifiers cost from $15 to $35 brand new, and a fraction of that at thrift shops. If necessary, run one in the room your fruiting chamber is located in. Right now, the ambient humidity in my house is 11% and my FC is at 98%, using only perlite and 1/4" holes drilled into all six sides. I fail to see why you're having so much trouble.

COOLMIST FOR FAE - Actually, the spinning disk type humidifiers burn out from the static pressure. The problem is that it forces moisture into the motor bushings, ruining them. I've used up to a 2" PVC pipe leaving the humidifiers and still had them burn up within two months. By leaving them inside the greenhouse, they last a year or more.

GREENHOUSE TEMPERATURE - Check your thermometers. There might be a degree or two of evaporative cooling until the humidity stabilizes, but the temperature of the room and the greenhouse will be the same. Usually, the greenhouse is a few degrees warmer with the lights on, then exactly the same as the room with the lights off.

MARTHA PROBLEMS FC - The tiny drops won't hurt, but if they build up, you're in for problems. This is a very common problem when running cool mists 24/7 because the air can't absorb all the moisture you're pumping into the greenhouse. If your casing layer becomes waterlogged, it won't pin.

COOLMIST - Cool mists can't build static pressure or the motor bushings get wet and ruin. If you use hoses from the humidifier to the GH, you cause static pressure to build. If you put the cool mist inside, you get high humidity, and if you cut slits you get FAE, plus the humidifier will last for years.

GREENHOUSE - Unzip and leave it unzipped. Continuous air exchange if preferable to occasional air exchange. I have holes cut all over mine and keep the door half open all the time, and easily maintain high humidity with two cool mists. My greenhouse is about the size of three martha units.

GREENHOUSE - Cool mist humidifiers need a free space of at least five feet above them to work properly. Your mist is blowing right on the bottom of the trays above, thus the mist can't evaporate into the air, but drips back down. For a fruiting chamber of that size, perlite is recommended.

MARTHA/GREENHOUSE - If you'll put trays of damp perlite on the empty shelf space and floor, you can easily get 99% humidity in a martha with a cool mist. I place mine inside the greenhouse, which raises humidity even more because it recirculates already humid air through the cool mist.

MARTHA FAE - I'd put two cool mists on timers or a humidistat inside the greenhouse for humidity, then simply cut about ten to twenty holes big enough to stick your arm through at various points in the sides. Put half the holes you cut high, and the other half of the holes down low.

COOLMIST - On the vics cool mists, the V shaped nozzle that spins in the water is detachable. Simply prevent the disk from turning, and rotate the nozzle half a turn and it will separate. It might have become clogged up inside where the rifling is, when you cleaned.

GREENHOUSE FC - I used a cool mist as you are for a year or two before settling on the way I now do it, with the cool mist sitting directly on a shelf inside the greenhouse. You'll need to connect it to a humidistat or timer to keep it from saturating everything inside.

MARTHA GREENHOUSE - Just put it inside for humidity, and leave a flap open or the door unzipped, etc., for constant air exchange. This system will get you to 95% humidity. You can use trays of perlite to catch drips and return them to the air as humidity.

HUMIDIFIER - I run mine less than five minutes on followed by five to ten minutes off. This maintains a high humidity without excessive dripping. You need to seal the bottom and put several trays of perlite down there to catch whatever drips do form.

GREENHOUSE - CO_2 isn't a problem in a greenhouse if you cut lots of small holes or windows. You can also leave the door cracked open. Put the humidifier on the floor or a lower shelf so it can shoot up and dissipate, rather than hit the ceiling of the unit.

MARTHA HUMIDITY - If you need even more humidity until you get it filled up, you can put trays of damp perlite everywhere you don't have a project sitting. It can sometimes be hard to keep enough humidity in an empty greenhouse.

FC. GREENHOUSE COOLMIST - If you live in the desert, you should run a cool mist 24/7 in the room your grow area is located. That will raise the humidity up to around 50% or so, making it easier to maintain 90+ in your

COOLMIST GREENHOUSE/MARTHA - I only use cool mists, with trays of perlite on the floor to catch drips. As you can see, it's steady at 95%. Put the cool mist inside the greenhouse and run it no more than 25% of the time.

GREENHOUSE FC - When fruiting cased substrates, I run it one minute on, six minutes off. Of course, these figures are based on my unique setup, so you'll have to experiment to find the sweet spot in your operation.

COOLMIST - An impeller type cool mist unmodified sitting on the floor or bottom shelf running a few minutes on, then a few minutes off will deliver 90% to 95% humidity.

FC MARTHA - MARTHA! Using a sonic Humidifier and Cool Mist...Providing plenty of FAE (Fresh Air Exchange) and RH (Relative Humidity) holes, flaps, cut open.

GREENHOUSE - If you're going to run a cool mist into a terrarium for air exchange, run it no more than one or two minutes per hour. That is a fact.

GREENHOUSE FC - You still want the greenhouse open though. The more openings the better as long as you can maintain humidity.

HUMIDIFICATION FC - Line the bottom of your terrarium with 2" of damp but not wet perlite, and watch your humidity go to 99%.

DROPLETS MARTHA - Lay wax paper loosely over the trays to prevent water droplets from falling on them.

HUMIDIFIER TIMING FC - I run the humidifier for two minutes every fifteen.

COOLMIST/HUMIDIFER/ULTRASONIC - Vicks 400 humidifier'

HUMIDIFIER - A vicks 400, 420, or similar will last for years.

TEK/SUBSTRATE/CASING ADDATIVES

PASTERUIZING TEK - Pasteurization tek
Load the pre-moistened to field capacity casing mix, compost or manure into quart mason jars. Place a lid and/or foil over the top. Put the jars into a large covered pot of cold water, with the water filled to 2/3 to ¾ of the way up the jars. A large kettle or pressure cooker works well. If necessary, put a plate or some other weight over the jars to prevent them from floating. Make sure you have a spacer or dishtowel under the jars to prevent the direct heat of the stove burner or flame from cracking your jars. Place the lid on the pot and turn on the stove. Bring the water to a boil, but watch over it and as soon as the water actually reaches a boil, shut off the stove, but leave the pot sitting on the burner. The preceding is for an electric stove that will remain hot for a little while after shutting off power. If you use gas, allow the water to boil for one to two minutes before shutting off the stove. After a couple of hours when they've cooled, the jars can be removed and used.
The first time or two you use this technique, monitor the interior of your jars with a meat thermometer. Place it right into the center of the peat or compost. You want to make sure the center of the jar reaches at least 140F and stays there for an hour, but don't allow it to exceed 170F. Depending on the thickness and capacity of your kettle and lid, you may need to adjust the above times slightly. This tek works because glass is an

insulator, so the temperature inside the jars lags the water in the kettle. When I use the above procedure with 7 full quart jars in my All American 921, it comes out perfectly just as written. If you use a smaller pot, you may need to turn the stove on briefly at the ½ hour mark for a few minutes.
The advantage to this tek is there is no pillowcase, etc., to drain and little to no mess or stink is made in your kitchen or pressure cooker. The disadvantage is you have a bunch of jars to wash when you're done.

WOOD LOVERS TEK, NO PC! - Wood Lover Smoothie Tek
Last year I had an idea for a cultivation of wood lovers that absolutely begged to be put to the test. I have put it to the test, and I succeeded.
There was NO sterile technique.
There was NO agar.
There was NO grain.
There was NO Pressure Cooking.
There was NO oven heating.
And yet I succeeded. I am now the proud owner of a storage box with 15 liters bright white, strongly rhizomorphic Psilocybe cyanescens mycelium, with that special mycelia odor I have come to love so much.
What did I do?

- -

WOODLOVER SMOOTHIE TEK

1.soak the right kinds of dried woodchips in desinfecting water for three hours.
You can prepare this solution easily by adding 100ml household bleach (5% sodium hypochlorite without additives) to 10 liters of water. Don't worry; it's what they use in swimming pools and in commercial edible mushroom cultivation.
2.leach the woodchips for several hours to get rid of excess moisture.
3.take fresh woodlover mushrooms, add ten parts of water and blenderize it to a "woodlover smoothie". Your goal is to create a suspension of very fine mycelium bits and spores in the water, so blenderize for a full minute, even when the job seems done in 15 seconds. You are creating very heavy mycelia inoculants in a liquid that has as much spores as spore syringe fluid. I used 30gr fresh Psilocybe cyanescens mushrooms in 300ml water to inoculate 15 liters of soaked woodchips.
4.spread out the woodchips and sprinkle the mycelial solution over it, turning it regularly with very clean hands or gloves. Your goal is to get a dab of the mycelium/spore inoculant on every bit of wood. When you are done, keep mixing up the woodchips because the inoculated chips will rub off mycelium onto the untreated chips.
5.put the woodchips into a plastic storage box and cover it with a sheet of plastic, which you fasten with clothespins. It should breathe, but not let dust fall in. Store this in the dark at room temperature. The woodchips will colonize in the usual time of a spawn inoculation.
There you have it! With wood lover mushrooms you collect in the wild you can very easily create loads upon loads of mycelium. Once the mycelium has colonized the woodchips, you can use one part of this spawn to inoculate five parts of moistened woodchips.
A couple of small wood lover mushrooms inoculate a storage box, a storage box inoculates a thrashcan and a thrashcan full of spawn can be used to inoculate several gardens and wild patches.
This TEK can be used on any scale. You can inoculate a few jars with one tiny mushroom you found, or load up a super soaker water gun and guerilla-inoculate a whole mulched park.

PHONEBOOK TEK - Phonebook Tek
You can inoculate pf cakes with oyster mycelium and grow out your spawn that way without a pressure cooker. Cut out a couple of dvd case sized holes out of the middle of the phone book, so you'll have a place to put a few slices of your cakes so they can inoculate the paper. After cutting the openings, you can boil the phonebook in water for a few minutes to sterilize/hydrate it, and then when it cools, simply open it up with clean hands and put your spawn into the places you've previously cut out. Did you see my phone book thread in the gourmet and medicinal mushroom forum? If not, take a look. Below are Hericium (Lion's Mane) but oysters grow from the same substrates. I'll have some oyster pictures on phonebooks soon. They're pinning now along with the Shiitake.

CASING TEK - Casing tek

Measure the appropriate amount of dry peat moss for your application. For the first few times you make up casing mix, you'll just have to take an educated guess as to how much to prepare, then add or subtract from that amount as needed for future projects.

Place the dry peat into a large bowl, five gallon bucket, wheelbarrow, etc., depending on amount. Leave room for the quantity to double, and still allow space to stir. Break up the dry peat very well. There should be no chunks when you get finished, having carefully broken up the peat until it's all the same consistency. To each cup of peat moss, add one teaspoon of hydrated horticultural lime, and one to two tablespoons of gypsum. Certain species can benefit from two tablespoons or even more of gypsum per cup, so don't be afraid to experiment, up to ten percent of the amount of peat.

Mix these dry ingredients together well. After mixing, slowly add water to the mix, stirring constantly. Add moisture until field capacity is achieved. I define field capacity as being reached when you can pick up a handful of the mix and no water drips out. If you squeeze lightly a few drops will come out, and if you squeeze very hard, a small rivulet or stream will flow out. Remember, the peat will not absorb all the water at once, so when you reach field capacity, let the mix sit for ten minutes and check again. Chances are, you'll have to add more moisture.

In a separate bowl, place an equal amount by volume of vermiculite. Fill the bowl with water so the vermiculite begins to float a bit. Turn the bowl over and allow all the water to drain off. A fine mesh strainer works well for larger amounts.

Mix the moistened vermiculite with the moistened peat/lime/gypsum very well and pasteurize at 140F to 160F for one hour. Use as soon as it's cooled. If you don't use it all, it's best to discard or use for your houseplants. Make a fresh batch every time for best results.

MY RYE TEK - My rye tek:

Measure out your organic rye berries from a health food store, one cup for each quart jar you intend to make. Place them in a large pot. Rinse the heck out of them. Fill the pot with hot tap water, shake and swirl it around and pour it out. Do this three or four times until the water you pour out is clear. You'll be able to see when you have nice clean water to pour off instead of water filled with chaff and dirt.

You want to now cover the rye berries with three times as much hot tap water as you have rye. Use half coffee and half plain water. In other words, if you have two inches of rye in the bottom of your pan, you should have six inches of water/coffee above that, for a total of 8 inches.

Add 1/4 teaspoon per cup of rye of gypsum. Stir into the water/grain well. Cover and leave this to sit for 24-36 hours. Don't freak out if you go 48 hours and it smells like it's fermenting. No problem.

Stir well and set the pot on the stove. Bring to a boil. Boil for ten minutes, then, WHILE BOILING, drain the contents through a very large colander. (Spaghetti strainer) If you're making a large batch, you may need more than one colander. Tip the colander side to side to get the rye to drain as much of the water as you can. Then, shake the colander in order to 'toss' the grain. This will cause a lot of steam to rise from your rye. Great. Do this a time or two, and then let it sit for five minutes, then repeat. When all the moisture that will drip or evaporate from your rye has already done so, load your jars. The rye should look and feel dry to the touch when you load the jars. All the moisture you need is inside the grain.

Fill jars no more than 2/3 full if they are to receive grain-to-grain transfers, or no more than 3/4 full if they are to be inoculated by spore syringe or agar wedge. Use a lid with a synthetic filter disk, polyfill, tyvek or similar. Cover with foil and PC the jars for at least 90 minutes at 15lbs. When the jars are cool, they're ready to inoculate.

AGAR TEK - Here's how to do it. Get a whiskey or wine bottle with a screw on lid that will fit in your PC. Drill a hole in the lid and stuff it with polyfill or cut a synthetic filter disk to fit inside the lid. Prepare your agar and pc in the normal way. The filter will prevent contaminants from entering the agar as it cools.

Build a glove box. You can make one for the price of a clear Rubbermaid. All you need is a couple of arm holes. You don't even need-attached gloves, but if not, then be sure to wear latex gloves when you pour your dishes.

Allow the agar to cool almost to room temperature without opening the filtered whiskey bottle it's in. When it is cooled off, but still liquid is when you want to open it up to pour. Work fast. Open your sleeve of presterilized dishes just before use. Wash the outside of the sleeve with alcohol before opening carefully from one end.

Stack your dishes in two piles of ten. Pour the bottom dish by lifting the entire stack, then set it down and pick up the other nine. Repeat until you've filled both stacks, then CAREFULLY insert the sleeve back over the Petri dishes and seal the bottom so it's airtight.

The above procedure should give you a 100% success ratio with a bit of practice. I find no difference in contamination rates with a glove box or flow hood, but of course the flow hood gives you more elbowroom and is much easier to work in front of.

GYPSUM SOAK TEK - I add gypsum to the water the grains soak in. The first step is to wash the grains very well. Put them in a pot of water and swirl it around, then drain the water out. Repeat a few times until the water pours off clear. If you skip this step, your grains will be clumped up and sticking together whether you use gypsum or not.

Fill the pot with hot tap water and soak the grains for 24 hours. Add one tablespoon of gypsum for each two gallons of soak water.

After 24 hours, bring the pot of water/grain/gypsum to a boil for five minutes. Drain while still boiling into a strainer and allow to drain well for five minutes. Shake the colander to toss the grains in the air a bit to let the steam evaporate the moisture off the surface of the grains. Fill jars 2/3 full, cover with filtered lid and pc for 90 minutes after covering the top of the jar with aluminum foil.

If you'll follow the above instructions, you can leave the PC'd jars in the pressure cooker overnight to cool to room temperature. When you remove the cold jars and turn them upside down, every single kernel will separate from every other kernel, and they'll flow almost like sand in an hour glass, with absolutely no sticking or clumping. I'm no fan of micropore tape. Drill two very small holes of 1mm or 1/16" in the lid, then use a synthetic filter disk or extra thick (not post office) tyvek. Good luck.

AGAR POURING TEST TUBES - Fill your test tubes 1/2 full. I always insert a piece of wood, such as a medical tongue depressor into each slant. The mycelium colonizes the wood and lasts much longer under storage.

Get test tubes with screw on lids. Drill a 1/8" hole in the lid. Cut a synthetic filter disk to fit inside the test tube lid. Screw the lid down tight, and PC in a rack with the test tubes standing upright.

When removed from the PC, lay the rack over with a jar lid or something under one side so the test tubes are

at an angle as they cool. Try to get the mycelium within 1/2" or so of the opening, so you don't have to reach in as far when you want to get some myceium out. You'll have to flame any part of your scalpel that penetrates into the slant, so it's easier if you don't have to reach in as far.
I use triple the usual amount of water in the PC when I make agar so that the PC cools down slower and releases pressure slower to prevent boil over. One should NEVER lift the weight or release the valve to let pressure off a PC. It ruins the product inside. Agar boils over and grains (or your pot roast) dry out.
You also shouldn't use a jar for preparing agar. Use a whiskey bottle or something similar with a long neck that is made for pouring. It also will have a smaller opening that will be less prone to allowing contaminants to enter.

ALDER - I have an excellent source of hardwood (Alder) sawdust and chips in Seattle, but I've already looked into selling it in bulk and the shipping would cost more than the chips. You can call a local tree trimming company and ask them to dump any hardwood chips they collect in your yard. They're free that way because they need a place to dump them. You really need to find a sawmill to get the sawdust though. You don't want what you'd get from a woodworker or furniture shop because it's too fine. You want course sawdust. Sometimes, the pellet fuel you get for stoves is made from hardwood sawdust, and if so it works great. Most of what I've seen lately is pine, and not usable.

GENTAMICIN SULPHATE - Gentamicin sulphate has a place in agar work. Some growers have added it to grains, but I would discourage the practice. Not only is it expensive, costing about $5 to $10 for enough to do a 1 quart grain jar, but I'd worry about creating super strains of antibiotic resistant bacteria.

SEAWEED - Seaweed is extremely high in natural tryptophans, thus the reported increases in potency. I live on the coast, so go out and pick up seaweed off the beach. After drying, I mix it in with my bulk substrates at about ten to twenty percent. The myc colonizes it almost as well and fast as straw.

BLOODMEAL ONLY IF COMPOSTED - For nitrogen, you can add blood meal to all substrate materials including horse manure, at the rate of one tablespoon to ten cups of substrate. It really does make a difference in the quality of your crop after harvest.

HAIR - Yes. In fact, you can compost hair and grow mushrooms on it. I've been wanting to do a 'barber shop' grow for some time now, but just haven't gotten around to it.

PINE SUBSTRATES - Pine shavings are antifungal and used to control odors.

BROWN RICE GRAIN - Brown rice flour has more food for mycelium per gram than grains such as wbs. Your contention that BRF isn't 'nutritious' is in error. Have you ever noticed a 1/2-pint brf cake flushing? There are only a few tablespoons of brown rice flour in a cake. No other grain will perform as well in such small quantities.

BROWN RICE FLOUR - Actually, brown rice flour is far more nutritious than manure. All grains are. That's why when we use manure we use a much larger substrate. There are only a few tablespoons of brf in a 1/2-pint jar, yet they can grow some crazy mushrooms. A few tablespoons of manure will get you nowhere.

COCO COIR - About 4 years ago, I was the very first one to post that coir is a substrate material. After a year of flames from people claiming that "Coir has NO nutes", somebody else finally tried it, and then somebody else, and so on. Experimenting is how we learn. Plain vermiculite has been used as a casing layer hundreds, if not thousands of times. I used it many times myself, but I've said this for years, and the results of many experiments still hold true; Plain vermiculite is a horrible choice for a casing layer. It would be really nice for a change to see someone actually experiment and then report the results, rather than endless posts about 'will this work?' or 'will that work?' and then arguing about it. Just do it. If you really want to experiment, try something that hasn't already been tried a thousand times. Look in your kitchen, find something silly, and then grow mushrooms on it. It's fun.

COCO COIR - There are no rules for mixing substrates. Coir can be used as is, or you can dump in a few days worth of coffee grinds from your leftover morning pots of coffee. Worm castings, horse manure, etc., can all be added by the handful, or each can even be used for 100% of the substrate. Use between 5% and 10% gypsum by volume. Use 1/2 teaspoon of hydrated lime per cup of manure-based substrates.

COCO COIR - Coco coir is much better suited as a substrate material. It's superior to cow manure and nearly as good as horse. In fact, lots of growers use coir to fluff up their manure or other compost. I do not recommend using coir in a casing layer, although many growers do. In my opinion, the best casing mixture is peat/vermiculite. I'll bet that coir compost would make an excellent substrate.

COCO COIR - Every brick of coir I've ever tested was in the pH 5.0 to pH 6.0 ranges. You need to use gypsum and lime.

COCO COIR - Add 10% coir to your casing mix. That is somewhat like CAC'ing that some edible growers do.

COIR - Coir has as much food for fungi as horse manure and will grow very similar crops to horse manure.

COFFEE - Whether you believe it or not, the evidence is overwhelming with thousands of growers using it for many years. In fact, at least one commercial oyster farm in my area uses it exclusively for a substrate. Weak liquid coffee is used to hydrate grains instead of plain water. This provides a nutrient boost, and also lowers pH, which decreases colonization time. As a substrate additive to other ingredients, it raises the nitrogen levels, and nobody even knows how many of the other hundreds of ingredients such as antioxidants play a part as well. Use the search function and you'll find several hundred posts on coffee going back to my original experiments in 2003. You can use weak coffee in the pf cakes, and use spent coffee grinds mixed into the coir. Don't use liquid coffee in the coir or you're likely to get mold. Also, coir is much better to use as a substrate than a casing. It tends to overlay when used for casing.

COFFEE - First, simply spread the coffee grinds out in the sun so they can dry. Once totally dry, they won't mold and you can store them until ready to use. Use them at up to fifty percent of any bulk substrate. Actually, you can use coffee grinds as 100% of the substrate if you want. I know a commercial oyster farm that uses free coffee from starbucks as their only substrate. However, if you're growing cubes, mix the coffee with any other bulk substrate for a great boost. They do NOT contaminate before you can get them colonized if you pasteurize first and have them at the proper moisture content. As with all bulk substrates, add gypsum at up to ten percent by volume.

COFFEE - Quite often, the whole is greater than the sum of the parts. Coffee has thousands of elements, nitrogen only being one of them. Coffee works, period. Who really cares 'what' causes it to work? Folgers and Hills Bros work as well as Starbucks. I've seen no real evidence that coffee increases potency. It does decrease colonization times, and provides for more prolific flushes. The results are particularly astounding with sclerotia producing species, but every mushroom species I've ever grown has done better with coffee than without it. Reishi on coffee can even.

COFFEE - I was the first one to bring the use of coffee to the community a few years ago. Here's a 50+ page thread to read if you have the energy.
http://www.shroomery.org/forums/showflat.php/Number/2283143#Post2283143 You can use weak coffee to hydrate your pf cakes. Use it at 1/2 drinking strength, but no more. Too much coffee actually slows down colonization. Some growers thing it's the nitrogen, some think it's the 'nutes', others think it's the antioxidants, etc. All I know is it works and helps, but as said, use weak coffee, not drinking strength.

COFFEE - If you don't drink coffee, try using something else instead, like bagged chicken manure from the nursery. Use it at no more than 1 part chicken manure to 20 parts of the other substrate materials. The reason I say that is coffee is pretty darned expensive to buy for a substrate. If you drink coffee anyway, no problem, but otherwise there are other materials that work as well. Coffee should be brewed before using. You can brew up a pot of coffee, then use the liquid coffee to hydrate your rye or wbs, and save the spent grinds for your substrate.

COFFEE - Properly used, coffee will decrease colonization time, and provide more prolific flushes. I've proved that for many years. A common mistake with coffee is using it too strong. As I've said countless times, it needs to be at 1/2 normal drinking strength. That means if you use a standard amount of coffee in your trusty Mr. Coffee, mix it half and half with plain water after brewing, and then use that to hydrate your grains. Mixing it stronger is counterproductive and will increase colonization times.

COFFEE - Correct. Spent coffee grinds are an excellent substrate material/additive, and 1/2 the normal drinking strength (or less) liquid coffee can be used to hydrate grains prior to sterilization. It doesn't matter if it's rye or wbs. If you use it stronger than 1/2 drinking strength, it will slow down colonization. That means for every cup of brewed coffee you use, add one or two cups of plain water, and use that to hydrate the grains.

SPENT COFFEE GRINDS - In addition to Starbucks, just about any restaurant such as Denny's, IHOP, or your neighborhood greasy spoon, will give you their spent coffee grinds. Just tell the waitress to toss in filter and all, because the mycelium will munch those too. I once scored nearly a five-gallon bucket of free coffee grinds from IHOP that was generated during the hour I was eating my breakfast.

COFFEE GROUNDS - IHOP and Denny's also give away all their coffee grinds to whomever asks. It's better for our substrates and gardens than the landfills. You can leave the coffee filters in with the grinds when you use them too, especially for edibles such as oysters. This has all been posted before, but it's good for the new folks to see it again.

LIME SUBSTRATES COFFEE - Correct. I add a teaspoon of hydrated lime to each two to three gallons of weak coffee/water mix. Use coffee at no more than 1/2 the normal 'drinking' strength. Too much coffee will actually slow down growth, lime or not.

SUBSTRATES COFFEE GROUNDS - I'm inclined to think the benefits of coffee come from the anti-oxidants rather than the nitrogen or caffeine, but I'll be the first to admit it's just a hunch based on a few years of observation.

COFFEE - Use weak liquid coffee. Instant would be fine. It's part nutrients and part the lower pH that coffee provides. Rinsing before the soak is also an important part. That gets all the dust and chaff out of the grain.

COFFEE GROUNDS - I stopped at starbucks yesterday and picked up ten pounds. They keep it in bags right by the door. The employees at your store must be lazy and throw it in the garbage.

COFFEE GROUNDS SUBSTRATES - You can leave the filter in the mix too. Coffee filters make pretty good substrate. If it sits more than a few hours after brewing, pasteurize.

COFFEE - Nobody buys coffee for substrate. You either get it free from starbucks, Dennys, IHOP, etc., or you use your own leftover grounds.

COFFEE - Coffee prevents sprouting. Don't ask me why, but when I use coffee, the seeds don't sprout.

COFFEE GRINDS - Coffee grinds hold as much water per cup as vermiculite.

COTTON SEED MEAL - Cottonseed meal doesn't need to break down to become available. It becomes available as soon as the mycelium consumes it.

D/E RATIO - I'd put about a teaspoon of DE per cup of peat in casing and substrate mixes. It will help provide moisture for the flush.

DIATOMACEOUS EARTH - Diatomaceous Earth is also an excellent additive that holds tons of water. If you use DE, add it dry to the dry peat and lime, then hydrate. I think it was Agar that pointed me to using DE in casings. It definitely holds moisture and gives bigger fruits because the same amount of casing material holds much more water without being saturated.

D/E - Use DE at up to 5% by volume of the dry ingredients. In other words, one cup of DE for each 20 cups of dry horse manure, etc. I always mix all dry ingredients together first, then add water. With DE, you'll think you have the moisture content right, and then ten minutes later when you check, it's dry again. The stuff really absorbs a lot of water. I check and adjust at least three times at 20-minute intervals before loading into jars and pasteurizing.

GYPSUM - That makes no sense. In addition, every commercial agaricus farm I know of uses gypsum in their substrates. Gypsum is not used to change pH. That's the job of lime to raise pH or sulfur to lower it. Gypsum contains both calcium carbonate and sulfur, thus it tends to keep the pH near neutral, preventing swings as the metabolites try to push the pH down. We add lime to make the casing layer inhospitable to competitor fungi, which are less tolerant of a high pH than established mushroom mycelium. Calcium carbonate or hydrated lime is not used to counter the effect of the metabolites. As said above, that's what the gypsum does. Use gypsum on substrates such as compost or horse manure, but don't use lime. Save the lime for the casing mix, where you should use gypsum and lime together. It's more of a stabilizer. Gypsum helps to prevent swings in either direction. The ability to prevent clumping is why we use a small amount in grain jars. I'm sure it's a side benefit in substrates and casings as well. The other benefit of gypsum is to supply calcium and sulfur, which are both essential for good fruit body formation. Some substrates seem to have enough of both to develop great fruits without it, but it's still there for the pH stability. I pay just over $3 for a 25-pound bag, which goes a long way, so there's no reason not to use it.

GYPSUM - Studies at commercial mushroom farms have shown up to a 20% increase in yield when gypsum is used over the exact same strain and substrate without gypsum. I've been saying it for years, Paul Stamets has been saying it for years, and you can google gypsum & mushroom farms, and see the results for yourself. Mushrooms are one of the best sources for humans to get calcium. The calcium in mushrooms is much easier to absorb into your system than calcium from dairy products. Doesn't it make sense to make sure your substrate has plenty?
A few years ago, they said I was nuts when I reported that coir is a useful substrate material. Everyone said, "coir has no nutes", as if mushrooms somehow need NPK. Search 'coir' and my username here and in advanced from 2003-2004 and you'll see what I mean. Then they said mushrooms would never grow on coffee-it's too acidic. Now they say gypsum provides little benefit, despite evidence to the contrary.
You can grow cubes without using gypsum, as we well know. However, you'll get more bang for the buck when using it. In addition, it keeps the substrate nice and loose for the mycelium to easily colonize, and it resists pH swings as the mushroom metabolites try to swing the pH lower.

GYPSUM CASING - 10% by volume the amount of substrate is the correct amount of gypsum to use. Just eyeball it. Anywhere from 5% to 10% is fine. Lime isn't necessary in bulk substrates, but don't forget to use it if/when you use a casing layer. It's necessary for casing material because it doesn't fully colonize with mushroom mycelium, and therefore the uncolonized parts are susceptible to contamination.
Mushroom size, provided you used a good substrate is related to moisture content. If you had coir/coffee then you had a good substrate. I'd speculate the small fruits were related to not having enough moisture. Next time, dunk after full colonization. I like to make my substrates up a tad on the dry side because they colonize faster that way and are less prone to contamination. Then, at full colonization, give a 6-hour dunk to re-hydrate the substrate before placing into fruiting conditions.

GYPSUM - Gypsum is calcium sulphate. It should be available at any nursery or garden center. If you can't find it, drywall (sheetrock) is made from gypsum. You can get a sheet of it and smash with a hammer to get the gypsum out. In fact, the garden gypsum I get at a nursery is a byproduct of the drywall industry. It even has some of the white and brown paper mixed in. Use gypsum at 5% or so by volume of the total amount of bulk substrate. You don't have to measure it exactly. If you have twenty handfuls of manure, toss in a handful or two of gypsum.

GYPSUM - Actually, that's right on. Gypsum isn't used to adjust the pH. A side benefit of gypsum is it tends to hold the pH stable, preventing a swing to acidic conditions caused by metabolism of the fungi. Sulfur and calcium are both essential for good fruitbody formation, so gypsum helps to ensure that our substrates have plenty. In addition, it's a soil conditioner that helps prevent clumping. In some species, such as Shiitake, gypsum has shown a 20% increase in yields over the same substrate without gypsum.

GYPSUM - Gypsum isn't used to adjust the pH. A side benefit of gypsum is it tends to hold the pH stable, preventing a swing to acidic conditions caused by metabolism of the fungi. Sulfur and calcium are both essential for good fruitbody formation, so gypsum helps to ensure that our substrates have plenty. In addition, it's a soil conditioner that helps prevent clumping. In some species, such as Shiitake, gypsum has shown a 20% increase in yields over the same substrate without gypsum.

GYPSUM YIELDS - Commercial mushroom growers report up to a 40% increase in total biomass harvested when gypsum is added to the casing mix. Shiitake growers report up to a 30% increase in harvests when gypsum is added to the woodchip/sawdust substrate. Gypsum supplies calcium and sulfur, both essential nutrients in mushroom metabolism. It's used in grains to prevent clumping, but it's used in substrate and casing mixes to supply valuable nutrients.

GYPSUM - Gypsum contains both calcium carbonate and sulfur, thus it tends to keep the pH near neutral, preventing swings as the metabolites try to push the pH down. We add lime to make the casing layer inhospitable to competitor fungi, which are less tolerant of a high pH than established mushroom mycelium. Calcium carbonate or hydrated lime is not used to counter the effect of the metabolites. As said above, that's what the gypsum does.

GYPSUM - Calcium carbonate is lime. Hydrated lime is calcium carbonate (crushed limestone) that has been heated in a kiln. The result in brief, is that it becomes water soluable so it goes to work right away, making it my personal choice for pH control. If you use limestone, oyster shell flour, or calcium carbonate, there is a lag time before the lime raises the pH. You'll want to pH balance your casing material to a pH of around 8 to start.

GYPSUM - The horticultural grade gypsum I get here is obviously a biproduct of the drywall industry. It has lots of pieces of white and brown paper mixed in, just like sheetrock. I think it's the broken pieces from the manufacturing process that they chop up and put into bags. It works great. Remove the paper, but don't get too anal about a few scraps you might miss. The mycelium will colonize them easily.

GYPSUM - Gypsum adds calcium and sulfur, both essential mushroom nutrients and can provide for up to a 25% increase in yields. In addition, gypsum prevents the grains from sticking together, which makes it harder for the mycelium to colonize. There's not a commercial grow operation in the world that doesn't use gypsum, and their livelihood depends on maximizing yields and performance.

COIR GYPSUM - If coir is your substrate you 'can' skip the lime and just use gypsum. Coir has a pH of around 5, which is pretty darn low. Trichoderma prefers a pH of 5, so without lime or gypsum, coir and peat are perfect trich foods. We can get away without balancing coir because it colonizes so fast, but I'd still use gypsum, which tends to set the pH in the mid 6 range.

GYPSUM - Without ph strips, try using equal amounts of peat and vermiculite. Add gypsum at the rate of one cup to each ten cups of peat. Add one teaspoon of hydrated lime to each cup of peat. Mix all the dry ingredients except the vermiculite together, and then moisten. Add moisture to the vermiculite, and then combine the two. Let sit for half an hour, then begin adjusting for field capacity.

GYPSUM - Every agaricus farm in the world that I'm aware of uses gypsum in their substrates and casing. All you have to do is google 'agaricus' and 'gypsum' and you'll see. Gypsum tends to hold the pH stable, as the mushroom metabolites try to swing it lower. Gypsum is not a substitute for lime. You still need to pH correct casing material with lime.

GYPSUM - Gypsum has been used as a soil conditioner for a very long time, and in mycology since I've been around. I know several articles that came out in the 70's, showing a dramatic increase in yields across many species when gypsum at up to ten percent was added to the substrate.

GYPSUM - Gypsum will actually lower the PH slightly due to its sulphur content. Gypsum supplies both calcium and sulphur which mushrooms need. The advantage to gypsum is that it tends to hold the PH steady, not allowing radical swings either direction.

GYPSUM - The other benefit of gypsum is to supply calcium and sulfur, which are both essential for good fruit body formation. Some substrates seem to have enough of both to develop great fruits without it, but it's still there for the pH stability.

GYPSUM MANURE - Gypsum keeps the manure nice and fluffy and loose afterwards. Many hobby growers skip this step, but it really helps. I don't know of any commercial ops that don't use gypsum. It's well worth the few seconds it takes to add.

GYPSUM - Yes, sheetrock is gypsum. I had a muddy as hell pond on my property, so when I sheetrocked my new house, I threw all the leftover scraps into the pond. The water was crystal clear in two weeks!

GYPSUM - Use gypsum on substrates such as compost or horse manure, but don't use lime. Save the lime for the casing mix, where you should use gypsum and lime together.

GYPSUM - Every commercial agaricus farm I know of uses gypsum in their substrates. Gypsum is not used to change pH. That's the job of lime to raise pH or sulfur to lower it.

GYPSUM - To provide calcium and sulfur, and also to prevent pH swings. Gypsum tends to hold the pH stable, wherever you set it with lime.

GYPSUM - Don't forget the gypsum. It increases yields considerably and is well worth the effort to find. Lime to an initial Ph of 8.

GYPSUM - Gypsum also tends to stabilize the Ph, preventing swings either direction. I consider it mandatory for all substrates.

GYPSUM - The metabolites want to decrease pH, as in lower it. The gypsum tends to keep pH stable.

GYPSUM/LIME - If you add gypsum there's no need for anything other than lime.

CHEAP GYPSUM - A 50lb bag of gypsum is only like 4 bucks though.

GYPSUM - Most important one for pH stability is Gypsum.

MIXING DRY INGREDIENTS - Try baking a cake by mixing the flour in after you've added the wet ingredients and see what happens. It won't look like, taste like, or even BE a cake. The reason for mixing the dry ingredients together first, is because dry ingredients WILL mix together. Wet ingredients will clump and bond to each other, and not mix properly. It ain't dogma, it's common sense.

POPCORN - The large kernel size, means a larger space between the kernels, thus more WASTED space in a jar. You can observe this by simply looking. The larger kernel size also means less total surface area within the jar, thus LESS mycelium is produced. It's no secret that a quart of popcorn will colonize faster than a quart of rye, but it has only about 10% as much mycelium as the same sized jar of rye, therefore it's MUCH slower than rye for producing mycelium. There are far fewer inoculation points with popcorn, therefore it doesn't go nearly as far when used to spawn to bulk. There is no doubt that despite its higher contamination rate, it does work, but you could get the same results with rye or wbs by simply using 1/10th of a jar to inoculate a substrate rather than the whole jar.Once spawned, the larger kernels are more prone to drying out, which weakens the mycelium on them, then when re-hydrated, the mold spores that have landed get the advantage over the weakened mushroom mycelium, therefore the higher contamination rate also continues right through fruiting, with more trichoderma contamination later on down the line. In short, if there's NOTHING else available, use popcorn as a last resort, but only while you look for something more suitable. You're paying twice the price per pound of product to get ten percent of the mycelium, and that assumes that you have 100% success, which you won't.

CORN - Corn often harbors an insanely high amount of bacterial endospores that survive pressure cooking. In addition, the large kernel size of corn means there is far fewer kernels in each jar, thus less mycelium in each jar than if a traditional spawn such as rye was used. Corn was never good and now bad. It was always bad. That's why not one single mushroom farm uses it for spawn generation, and they depend on success to make a living. Some people have success with corn. I made hundreds of projects with corn and had success, but not at the same rate as with rye, and it was never as good as rye when it comes to grain to grain transfers or spawning, because you need to grow out four or five times as many jars to get the same amount of mycelium, thus further increasing your chances for contamination.

DIATOMACEOUS EARTH - It won't do squat for the gnats once it's mixed into the substrate. DE has other benefits though, such as holding a LOT of water, so it's good to use. At one time, I'd put about a teaspoon of DE per cup of peat in casing and substrate mixes. It will help provide moisture for the flush. DE must be totally dry to work on insects. It works in much the same way a pile of broken glass would cut you up if you had to crawl naked on your belly across it.

DIATOMACEOUS EARTH - Don't go over 5%. That might even be a bit much. The only real benefit is it holds so much water. I've used the baited and unbaited and both work equally.

HAY - Hay doesn't work. It has flat stalks and seeds which will contaminate. You want straw instead. Straw needs to be pasteurized, never sterilized.

HYDRATED LIME/GYPSUM - Calcium carbonate is lime. Hydrated lime is calcium carbonate(crushed limestone) that has been heated in a kiln. The result in brief, is that it becomes water soluable so it goes to work right away, making it my personal choice for pH control. If you use limestone, oyster shell flour, or calcium carbonate, there is a lag time before the lime raises the pH. You'll want to pH balance your casing material to a pH of around 8 to start. I won't speak for why someone made a mistake on their website, other than stuff happens like that in any technical field. In addition, my experience isn't the last word on any subject. I have however, sent them a pm. With the amount of gypsum you'll use, and the fact that it's heavy and expensive to ship, I'd suggest a local nursery. I've never yet been to one that doesn't carry it. I get 25 lb bags of horticultural grade gypsum right up the street for just over $3. If you can't find it locally, and don't want to smash up a sheet of drywall (sheetrock) order your gypsum from a vendor.

GYPSUM/LIME - Actually, gypsum contains calcium which raises pH, and sulfur which lowers pH, resulting in a buffer that prevents wild swings in either direction. We use lime to raise the pH only for the reason that mushroom mycelium is more tolerant of a high pH than mold mycelium is. Both mushroom and mold mycelium grow best in a pH of around 5.5 to 6, but since mushroom mycelium can tolerate the higher pH, we do that so our casing layer favors it over molds. I use 1 teaspoon of hydrated lime per cup of peat. Don't figure the verm when calculating lime. Use gypsum at 5% to 10% by volume of the amount of peat. In other words, for ten cups of peat, use 1/2 to 1 cup of gypsum. As said above, always mix the dry ingredients first, then add water.Gypsum, as I said, prevents swings in either direction, but the commercial growers long ago realized that it also increases disease resistance and also increases the size of the mushrooms by providing valuable trace nutrients and minerals.

GYPSUM/LIME - 'Spawn' is your grains, and you can add a pinch of gypsum between your thumb and forefinger to each jar, or add a tablespoon to each few gallons of soak water that you soak the grains in to hydrate them. Add gypsum to your coir and manure substrates, but lime is usually optional because they're not generally exposed to contaminants except during colonization, and they've already been pasteurized just prior to that. Lime is for casing layers that are exposed to the natural contaminants in the air for extended times. We don't lime for the mushroom mycelium, because it actually prefers acid conditions. We lime for the contaminants because they are less tolerant of a high pH than mushroom mycelium.

HYDRATED LIME/GYPSUM - Actually, you want hydrated garden lime. Ground limestone takes too long to break down and go to work. Hydrated lime is water soluable and goes to work right away. A combination of hydrated lime and gypsum is the best way to buffer a casing layer. The most critical time for contaminants to enter a casing is during the initial colonization and first flush stages. Once the layer is fully colonized, it's very contaminant resistant. Hydrated lime and gypsum protect your casing layer during this critical early stage, where ground limestone or other buffers that take weeks or even months to break down do not.

GYPSUM/LIME - We use lime to raise the pH only for the reason that mushroom mycelium is more tolerant of a high pH than mold mycelium is. Both mushroom and mold mycelium grow best in a pH of around 5.5 to 6, but since mushroom mycelium can tolerate the higher pH, we do that so our casing layer favors it over molds. I use 1 teaspoon of hydrated lime per cup of peat. Don't figure the verm when calculating lime. Use gypsum at 5% to 10% by volume of the amount of peat. In other words, for ten cups of peat, use 1/2 to 1 cup of gypsum. As said above, always mix the dry ingredients first, then add water.

HYDRATED LIME - Make sure you use horticultural grade hydrated lime. If you got the masonry lime for mixing with mortar, it will cause the problem you're seeing. Using horticultural hydrated lime, a good ballpark figure is to use one teaspoon per cup of peat. Don't count the verm when adding lime. Also, make sure you mix the lime and gypsum together first, and then mix those into the DRY peat before adding moisture. If the peat is wet, the lime will dissolve and clump, meaning it won't mix well. You'll have zones of very high pH and zones of low pH.

HYDRATED LIME - The calcium carbonate is used to raise the pH. I prefer hydrated lime because it goes to work right away when you need it. We don't lime for the mushroom mycelium, because it actually prefers a slightly acid pH. We lime because contaminant molds require a low ph, so by making it 7 or above, the casing layer favors mushroom mycelium over molds. I'd suggest a teaspoon of hydrated lime per cup of peat. That will get you into the ballpark without danger of making the casing too sweet.

HYDRATED LIME - Mushroom mycelium prefers a pH of 5 to 6, so you're fine. We pH balance casing layers because they're left exposed and non-colonized on top of the substrate. For casing layers, hydrated lime is best because it goes to work right away. Calcium carbonate takes time to break down, so is of less use since the average life of a casing is only a few weeks.

HYDRATED LIME - As we know, mushroom mycelium grows fastest and is perhaps the happiest with a ph of around 6. Unfortunately, that is also the ph favored by most other fungi, which includes the mold fungi that are the enemy. We use lime because mushroom mycelium can tolerate a higher ph than the green molds can.

FINDING LIME - Lime can be hard to find locally if you live in an area that has alkaline soil. In areas where the soil is acidic, lime is sold everywhere. You can order it online from doitbest.com Just search for 'hydrated lime' when you get to their site. They have two industrial types, and two horticultural types of hydrated lime.

HYDRATED LIME - The high ph does indeed slow down the mycelium a bit, but it kicks the trich in the butt. Another good trick is to sprinkle a bit of lime right on the surface of your casing layer. This creates a high ph zone right on the top where the trich and other contaminant spores land. Hope this helps.

HYDRATED LIME - If it says "Safer than hydrated lime" on the bag, it's the WRONG type of lime. Consider 2% Mg to be the upper limit. Use HYDRATED LIME. You don't want to adjust the pH of your casing material next year; you want to adjust the pH now. That means using hydrated (water soluble) lime.

HYDRATED LIME - You want to use hydrated lime or calcium carbonate for pH adjustment. However, hydrated lime is water-soluble so it balances the pH right away. Calcium carbonate is a long term buffer that is better suited to gardens, since mushroom casing layers are not used long term.

HYDRATED LIME - Coir has a pH of around 5, which is pretty darn low. Trichoderma prefers a pH of 5, so without lime or gypsum, coir and peat are perfect trich foods. We can get away without balancing coir because it colonizes so fast, but I'd still use gypsum, which tends to set the pH in the mid 6 range.

HYDRATED LIME - I recommend horticultural hydrated lime for ph control. It goes to work immediately, and lasts the life of the average casing layer. If you skip the lime, your casing layer will have trich quicker than it can flush. I also recommend using ten percent gypsum in a casing layer.

HYDRATED LIME - Oyster shell flour can be used, but isn't as effective as hydrated lime because hydrated lime goes to work right away when you need it. Once the substrate is fully colonized, it can take care of itself, making so-called 'long term buffers' unnecessary.

HYDRATED LIME - Consider 2% Mg to be the upper limit. Use HYDRATED LIME. You don't want to adjust the pH of your casing material next year; you want to adjust the pH now. That means using hydrated (water soluble) lime.

HYDRATED LIME - About one teaspoon of hydrated lime per cup of coir (after hydration) will balance it pretty close. Be sure to use agricultural grade hydrated lime, not the stuff for mixing cement or mortar for bricklayers.

LIMESTONE - Limestone isn't dangerous. It's calcium carbonate. Some people pay big money for it in pill form when they have heartburn. (Tums)

HYDRATED LIME - It's in Stamet's GGMM, page 189 in my edition. He says to use 2 to 4 pounds of hydrated lime for each 50 gallons of water.

HYDRATED LIME - Don't use lime anywhere near your pressure cooker. It's highly caustic and will pit the aluminum. Use a plastic tub.

HYDRATED LIME - Hydrated means water-soluble, thus it's ground to a fine powder in order to be effective right away.

HYDRATED LIME - Try fifty with lime next time, there will be an assurance of zero contamination then.

HYDRATED LIME - Only use horticultural/agricultural hydrated lime, never slaking or masonry lime.

STERILIZING MANURE - Ponder this.
Manure is 3-tier gangbang. Bovine eats it, in bovines gut other microbes/bacteria have a go at it, once expelled everything out there as a go at it. Only the strong survive. So the turd pile is pretty well occupied with whatever is still munching down on it. It is also depleted on most nutrients other things - besides those microbes in it - even look for. Hey, it's a shit pile. On top of that, the microbes that do occupy that turd pile defend their space fairly well. So, any outside microbe tries to get a foothold, the homey's either eject them, kill or eat them. All in all, the turd pile is some well-defended turf.
Now, sterilize that third pile.
Suddenly, it is no longer - well defended turf. So, any blue/green mold gang that happens to wander by can enter & set up housekeeping. So, if you sterilize manure. Treat it like you would an LC. In other words, be very careful not to allow anything to come in contact with it. Except, what you want to introduce into it.

HORSE/COW MANURE - A cow does not have 4 stomachs. A cow has 1 stomach. A single stomach with four compartments is not 4 stomachs.
Cow manure is NOT already composted when it comes out.
Aged horse manure or cow manure does NOT need to be leached.
Washing/leaching manure does NOT remove ammonia. It needs to be air dried or cured in the sun to evaporate the ammonia.
You do not want fresh cow manure. You want aged manure. Cow patties work fine. In fact, when I first started growing mushrooms in 1971, picking up cow pies and bringing them home to place in compost was the only way we knew to home cultivate. All the current teks have evolved from those early trials.
Exactly which shroomery manure teks suck for people in colder climates? What difference does a cold climate make? Moisture and ammonia will sublimate from frozen manure as fast as it will evaporate from manure in a warm climate.
Growers can be successful with aged manure by simply breaking it up and using after hydration and pasteurization. In fact, I've NEVER leached manure.

HORSE MANURE - You'll find these outside any horse ranch. They're not rare. The problem is they're usually stable sweepings and often have cedar chips mixed in to control odor, which prevents much mycelium growth. In addition, they're usually fresh manure, not aged. What you want to grow on is field aged. A truckload delivered to your back yard might be good after you spread it out to dry and leach in the sun and rain, but I doubt dumping some spawn into a large pile at a horse ranch is going to do much. They constantly dump fresh manure with a front-end loader on top of the earlier pile, burying any spawn you put deep into the pile. Not to burst your bubble, but I doubt it would work unless it's an abandoned ranch and the pile is aged, in which case it's probably already got pan subbs growing/colonizing it.

COW MANURE SUBSTRATE - The coffee grinds, castings and coir are to break up the store bought cow manure which is ok to use, but too heavy by itself and the myc has a hard time colonizing it. The other problem with store bought cow manure is it has a lot of urea in it because it comes from crowded feed lots and the cows urinate as much as they defecate and it all gets scooped up together. Be sure when you open the bag of cow manure, if it smells like ammonia, spread it out on the back porch in the sun for a day or two and the ammonia will flash off, leaving it ok to use.

CHICKEN MANURE - Agreed. As said, just don't use very much. I've used the composted chicken manure available at nurseries with success, at no more than one cup of chicken manure to 20 cups of other substrate ingredients. Lay it on a tarp in the sun for a few days until there is no ammonia smell, then mix with your other ingredients and pasteurize. Bat guano is no good for mycology.

COW MANURE DEHYDRATED - Dehydrated would be better, but be sure if there's any ammonia smell to it that you dump it out of the bag and lay it out in the sun for a few days. Cut the store-bought cow manure by mixing it evenly with coir/vermiculite. You will end up with a substrate of 33% bagged cow manure, and 33% each of coir and vermiculite. Mix well and pasteurize.

STEER MANURE - Be sure to cut it with some coir or vermiculite, because the bagged cow manure tends to compress due to its texture, which makes it hard for the mycelium to colonize. The bag stuff you get at the nursery needs to be layed out and dried in the sun for a few weeks so all the ammonia evaporates.

CHICKEN MANURE - Composted chicken manure is great. Use at no more than 5%, which is one cup of chicken manure to each 20 cups of coir or horse manure. Be sure to open the bag and lay what you're going to use out in the air for a couple of days to evaporate the ammonia out before pasteurizing.

MANURE SUBSTRATE - Next time, leave the substrate loose and airy. I like to add a touch of vermiculite to manure for that purpose as well. A slightly dry substrate will actually colonize faster, so I don't think that's the problem. I make mine dry on purpose, and then dunk before first flush.

COW MANURE AND HORSE MANURE - Cow manure gets fed better/it's more compacted and has more nutrition. Horse manure is basically half digested straw and hey which is less nutrition and holds less moisture.

GYPSUM MANURE - Gypsum keeps the manure nice and fluffy and loose afterwards. Many hobby growers skip this step, but it really helps. I don't know of any commercial ops that don't use gypsum.

CHICKEN MANURE - Chicken manure makes an excellent addition to your compost/poo mix. Use no more than 5% by volume.

CHICKEN MANURE - Chicken Manure Gets Way to hot. It would BURN myc. Use only in small quantities.

OYSTER SHELLS - You can use oyster shell flour in both substrates and casing layers. Crushed oyster shells are sometimes added to casing material for texture,

REUSING PERLITE - I put the whole darn terrarium in the shower, and let cold water run for an hour or two to wash it clean. Of course, I have holes in the bottom of the terrarium for the water to escape. If there has been a contaminant outbreak, I'll pour some water mixed with bleach on first, then let that sit for half an hour before turning on the shower. Before any of the 'conserve water' people jump my ass, bear in mind I live where the more water we use, the less the rivers and reservoirs flood. If you live in a desert with limited water supplies, simply bleach soak and rinse the perlite if contaminants were present. Otherwise, simply rehydrate the perlite, drain well and use. Perlite is a mineral that will last for many years.

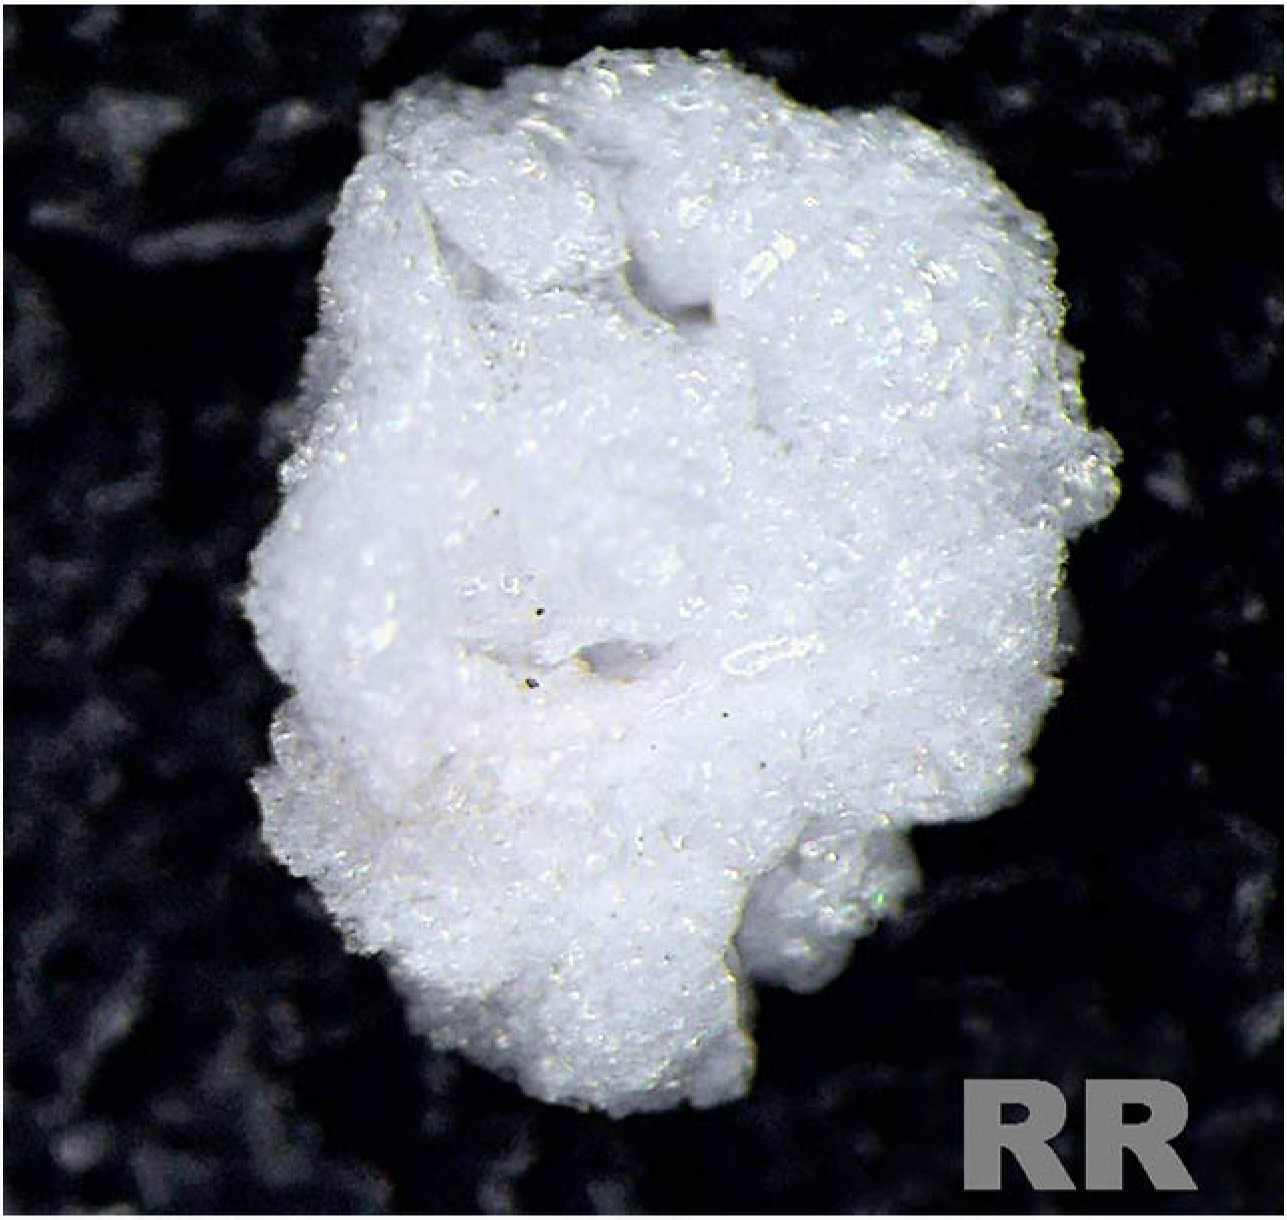
PERLITE - Using paper towels in the bottom of terrariums for humidity is a long-proven technique. In fact, for many years I've kept them stuffed into any spot in my mini-greenhouse that tends to collect drips of water. Change them out once a week or so, and keep them fairly well squeezed of excess moisture so that what's in the paper towel can evaporate back out. You can even press damp paper towels against the back and/or sides of the FC to give more surface area. Clean cloth towels can also be used, and simply tossed into the washing machine once a week.

PERLITE - Perlite is a hydrated volcanic ore from the Pennsylvanian era of geology, with the approximate chemical composition of glass. Expansion is due to between 2-6% bound water. When heated to 1400+ degrees, the water vaporizes forcing the rock to expand. Perlite in its crude form weighs 70 pounds per cubic foot, after expansion the weight is reduced to 2-10 pounds per cubic foot depending upon the application.

PERLITE - Perlite is a crystalline mineral that doesn't absorb water, so it would NOT absorb water in 24 hours, or 24 years. Perlite that is under water may as well not be there. This has been proved by hundreds of growers with humidity problems, who dumped the standing water out, and watched in awe as their humidity rose to 99%.

PERLITE - Perlite is crystalline and impervious to water, but with a large surface area to hold and evaporate it off from. Perlite is for humidifying terrariums and/or adding air and fluff to casing layers. A bit of perlite can also be added to casings, but then, it's to provide fresh air pockets that are conducive to hyphal knot formation.

PERLITE - Perlite is crystalline, like glass or quartz crystals, and it does NOT wick water any more than broken pieces of glass will wick water. Submerged perlite is useless, period. Look at the picture of perlite below and describe how it would wick anything if you doubt the above.



PERLITE - Misting should be enough to keep the perlite damp. You might also try 'raking' the perlite with your fingers to fluff it up. If it gets packed down, it won't work right. Fluff it up and that's probably all you need to do. I've had perlite still damp after two months. Peroxide and bleach are a waste on perlite. Just use plain water. You're not growing mushrooms on the perlite; it's only for humidity.

PERLITE - I've been using perlite from the same bag for at least ten years. All you have to do is rinse it off well, and bake in the oven for an hour or so, and it's just like new again. You never have to toss it out.

PERLITE - Perlite is not hydrophilic, although it can be treated to have hydrophilic type properties.

PH - It's important to mix the dry peat with the lime before adding moisture or the vermiculite. I also see you didn't add gypsum, which helps to moderate ph swings. In addition, I have not yet seen a probe type ph tester that was worth the powder it would take to blow it to hell. They are designed for soil, and just don't perform

properly in peat/vermiculite/manure.
I get a starting ph of 8 to 8.5 by mixing one teaspoon of hydrated garden lime and two tablespoons of garden gypsum to each cup of dry peat. Mix the peat, lime and gypsum, then add water to approximately field capacity, then set aside.
While the peat sits, mix the vermiculite with water in a separate container to approximately field capacity.
Now, you can mix the two together and make the final adjustments in moisture content. Be sure to let it sit for fifteen minutes, then check moisture content again by squeezing a handful of material. When you hold a handful of the casing mix, no water at all should drip out. Squeeze a bit, and a small amount will drip out. Squeeze hard and a small stream will flow out. This is field capacity.
Pasteurize and use. For home grower amounts, a great way to pasteurize is in quart mason jars sitting in a large pot of water. A pc or large kettle with a tight fitting lid is great for this. You want the interior of the jars to reach at least 140F for an hour, but not to exceed 170F. The use of quart jars preserves your ph and moisture content. Good luck.

PH - If coir is your substrate you 'can' skip the lime and just use gypsum. Coir has a pH of around 5, which is pretty darn low. Trichoderma prefers a pH of 5, so without lime or gypsum, coir and peat are perfect trich foods. We can get away without balancing coir because it colonizes so fast, but I'd still use gypsum, which tends to set the pH in the mid 6 range. Casing layers should be set to an initial pH of 8 because peat/vermiculite rarely colonizes fully, so you want protection from trichoderma, and a high pH is the best way to do it. For pasteurizing straw, you need hydrated lime. The others won't cut it. 'Hydrated' means water soluble, so it raises the pasteurization bath water to a pH of around 12, which nukes most organisms. Nobody can say exactly how much hydrated lime to use for casing layers. My 1-teaspoon per cup of peat is a safe starting point, but the correct amount to use is what it takes to get an initial pH of 8 to 8.5.

PH - Liquid coffee is slightly acidic, but coir is even more so. Coir runs pH 5 to pH 6.5 depending on origin. Acids lower pH, not raise them. I've found no evidence that coffee boosts potency. It does however; speed up colonization, because it's excellent fungi food. In addition, the lower pH results in faster growth because Cubensis prefers a substrate in the pH 5.5 to pH 6 range. Using a substrate with an acidic pH like yours results in faster colonization and better performance overall, but also exposes the project to an increased risk of contamination, because molds such as trichoderma also prefer an acidic food source. In my area, the mold spore count is so high; I'd never be able to get a substrate that had been hydrated with liquid coffee colonized before parts of it were green from molds. Hopefully, yours will work out. It's almost colonized. Good luck.

PH - While mushroom mycelium prefers a slightly acidic substrate, contaminants do also. What we've found from experience is that by adjusting the pH upwards with lime, the mushroom mycelium can 'tolerate' it, but the contaminants have a harder time. There is usually no need to adjust pH of substrates, but casing layers, which don't ever fully colonize, can benefit from a higher pH of 7.5 to 8. This will allow the mushroom mycelium to get the benefits of the casing layer, but will slow the onset of mold contaminants. However, remember that after a flush or two, the uncolonized parts of your casing layer are going to be susceptible to molds, so be sure to watch daily and toss out any tray at the first signs of 'green' molds. Good luck.

PH CASINGS - Actually, you want hydrated garden lime because ground limestone takes too long to break down and go to work. Hydrated lime is water-soluble and goes to work right away. A combination of hydrated lime and gypsum is the best way to buffer a casing layer. The most critical time for contaminants to enter a casing is during the initial colonization and first flush stages. Once the layer is fully colonized, it's very contaminant resistant. Hydrated lime and gypsum protect your casing layer during this critical early stage, where ground limestone or other buffers that take weeks or even months to break down do not.

PH - You don't need to pH balance bulk substrates. In fact, mushroom mycelium actually prefers an acidic substrate. We pH balance casing material because it remains partially uncolonized throughout the fruiting cycle, thus is prone to contamination. Bulk substrates colonize fully, thus are resistant to contaminants, so you can leave them slightly acidic and they'll do just fine. Mushroom mycelium is more tolerant of a basic pH than molds, and that's why we add lime to casings.

PH OF CASING - Pickling lime is hydrated lime. It's my favorite, and many commercial grow operations DO use it. Use one teaspoon of hydrated lime, and one tablespoon of gypsum per cup of peat, and mix into the dry peat. Mix the dry ingredients very well, then slowly bring to field moisture level and pasteurize. If you can't find hydrated lime, you can get it online at www.doitbest.com When you get to their website, do a search for hydrated lime.

PH CASINGS - A buffers resist change in ph. Lime is not a buffer. Gypsum is an excellent buffer. If you wish to bring the ph of your casings higher, you would want to use hydrated (water soluble) lime. Limestone is for long-term use, such as in a garden. Casings, which flush for a month or so, do not need long-term ph adjustment. They need short term, therefore hydrated lime is what you would want to use.

PH - A pH of 8 is a good place to make your casing mix initially. Mushroom mycelium grows and fruits best at a lower pH of around 5-6, but unfortunately, that pH also favors contaminants as well. Mushroom mycelium is more tolerant of a higher pH than molds, which is why we add lime.

PH - Oyster shell raises Ph. Mushroom mycelium grows fastest with a slightly acid ph. You don't Ph adjust spawn. The only reason we use Ph buffers to raise Ph in bulk substrates is because mushroom mycelium, while it prefers a Ph of 6, is tolerant of Ph up to 8.5, while trichoderma is not tolerant of a high Ph. Thus, the hydrated lime or oyster shell flour makes our substrate selective for mushroom mycelium.

PH - A high pH will slow down trichoderma, as well as helping to prevent trich spores from germinating. It also stresses mushroom mycelium, which prefers a lower pH, but not as much. The mushroom mycelium is more tolerant of high pH than most molds.

PH - For a substrate, 5.5 to 6 will probably give the fastest colonization. It would be the same for casing layers as well, but since molds also thrive at a low pH, we lime our casings to sweet of neutral. A good starting pH for a casing is 8.

PH - In my opinion, a good starting point is around 9-10. I know that's sweet, but the myc doesn't seem to mind much, and most contams like a slightly acid ph. It keeps the little bastards at bay while the myc colonizes your casing.

PH BENEFITS - Lime raises the ph, and gypsum keeps it stable. They both provide calcium, but gypsum also helps with texture.

PH STRIPS - Squeeze some water out of the casing mix after it has sat for at least an hour, and then measure that with your strip.

PH - Contaminants prefer a low ph; a high ph is unfavorable for them.

PH - Gypsum added to an acidic soil will raise the pH.

RATIO SUBSTRATES - Use the chicken manure at up to 5% of the total substrate. It gives a nice boost. Most commercial mushroom farms use it at that percentage. Composted cow manure from the nursery also works well when mixed with coir or vermiculite to cut it a bit. If any bulk substrate you mix up seems a bit 'heavy' just add ten to twenty percent vermiculite to keep it nice and loose. Another benefit of vermiculite in bulk substrates is it makes an excellent moisture reservoir for use during fruiting.

PF/MANURE RATIO CASING - Break up your pf cakes into four times as much manure. That means one pf cake can inoculate 2 pints of manure. Don't crumble and case pf cakes. It's a waste. If you want to fruit your cakes as is, simply birth them, and then do a dunk and roll and place in fruiting conditions. This is the quickest way to a harvest, and spawning to manure is the best way to a larger harvest, although it takes a couple of weeks longer.

SUBSTRATE RATIOS - That's about right. 1 cup of hydrated chicken manure per 20 cups hydrated coir would make 5%. Add gypsum at ten percent as well. 1/2 teaspoon of hydrated lime per cup of coir/chicken manure will help give a bit of contaminant resistance, but it's optional. Lime is far more important in casings where part of it never colonizes. Substrates colonize fully, therefore can hold their own.

COMPOST - They use urine as a nitrogen boost to heat up the compost pile. If you're not composting, use aged manure.

SUBSTRATE RATIO - Spawn to manure, and then at full colonization, case. 1 to 4 is fine. I usually go 1 to 3 for the extra food the grains provide.

CAKE TO MANURE RATIO - Use one part colonized cakes or other spawn to three or four parts manure.

STRAW SUBSTRATE PASTURIZATION RR VIDEO - After pasteurization, I lift the straw out of the tote with a strainer, allow it to drain for a few seconds, and then place on a screen that is laying in the bottom of a second tote. When the pasteurization tote is empty (of straw), I take pot fulls of hot water out of it, and pour them into the toilet to get rid of them. By the time the straw has cooled, it has also drained long enough. Remember, you're going to have holes in your straw log and/or laundry basket, so any excess water will drain out during the first few days, leaving it at the perfect moisture content.

LIME FOR STRAW - I think hydrated lime is the BEST choice for pasteurizing straw. It causes a very rapid swing upward in PH, which is fatal to living organisms, which is the purpose of pasteurization. It's the only lime I use. I don't recommend chemical pasteurization alone for straw. Use 1 cup of hydrated lime per ten gallons of 140F to 150F water and pasteurize the straw for one to at most two hours. Drain and use. Be sure to soak the straw in warm water for two hours prior to the pasteurization to hydrate it.

STRAW - I soak in warm soapy water for two hours, and then transfer the straw to water that is kept at 140F to 160F for 60 to 90 minutes, and then it is removed and drained/cooled, and spawned. I use one cup of hydrated lime for each ten to fifteen gallons of pasteurization water. I don't add lime or bleach to the pre-soak, and don't use bleach at all in the pasteurization. There's a short sample clip of my procedure on youtube and also on my website. It should be enough to give you the basic idea.

STRAW - I use an electric weed whacker with the straw in a tote with the lid on it. I cut a very skinny rectangle out of the center of the lid so I can move the weed eater around in the box to get it all. It takes about five minutes or less to do a 125 quart sterlite container full of straw. I do this right in my living room, since I also live in a condo. There's some mess, but not much.

STRAW - Yea, 1 cup of lime should be plenty for a pillowcase. If the pot is aluminum, the lime will eat through it pretty fast, but it's your stuff, so you make the call. It's easy to boil the water in one pot and then pour it into a plastic tote or bucket with the lime. That way, you don't ruin the kettle.

STRAW - Straw is dry. Therefore, the 'straw juice' is the dirt, pesticides, and other debris that is stuck to the surface of the straw. Don't use it for anything. Mushroom mycelium doesn't want the dirty brown water you wash off the straw. Mushroom mycelium wants to eat the straw itself.

STRAW - Straw has a pretty good texture for fruiting uncased, and the hollow straw holds a LOT of water, negating the need for a casing layer, providing you maintain near 100% humidity at the surface of the straw.

SOAP IN STRAW SOAK - Soap for straw would help break down the waxyness of the straw. To absorb water better. Because it's anti-bacterial.

STRAW SUBSTRATE - Chopped straw. Wheat and Barley are the two most common ones in the US, and both work fine.

STRAW - Straw, something that contaminates the most, does better at pasteurization temps of 140-150.

STRAW - BE up to 200% is fairly common with straw.

SUBSTRATES! - People need to make a distinction between growing plants and fungi.
Worm castings are an excellent substrate additive material, but not because of nitrogen content. They are lower in nitrogen then either straw or horse manure, which are both lower in nitrogen than steer manure.
Blood meal is high in nitrogen, but is totally unusable to fungi unless it is applied in the composting process, which most home mushroom growers do not do. The use of blood meal added to manure or coir is a waste of resources and actually encourages algae to form on the surface of the substrate or casing layer, leading inexperienced growers to throw out a perfectly fine project thinking they have 'green mold'.
Chicken manure is high in nitrogen, but once again it needs to be added at the composting stage. However,

composted chicken manure available in bags at nurseries is an excellent additive to manure or straw because it's already composted, therefore available to the fungi.

Fish emulsion, available at garden centers is also an excellent additive to manure or coir substrates because it has already been composted or otherwise broken down anaerobically at the processing facility.

Gypsum should be added to all substrates for the texture it helps to provide as well as the calcium and sulfur, both essential nutrients for mycelia metabolism. An added benefit of gypsum is that it tends to hold Ph levels steady, preventing wild swings as the mycelium colonizes a substrate.

Coir, worm castings, horse manure, chicken manure etc., are all acidic and should be buffered with lime to a starting Ph of around 8. This high Ph favors mushroom mycelium that is tolerant of sweet substrates, but prevents germination of contaminant spores that favor sour substrates.

SUBSTRATES - Coir is very close in performance to horse manure. Cow manure can perform nearly as well too, but will benefit from a bit of coffee grinds and some loosening up with vermiculite. As I've said hundreds of times, a combination of substrate ingredients will give better performance than any one by itself. That means, you'll get more bang by mixing cow, horse, and a bit of chicken manure with coir, coffee grinds, compost and straw. Horse manure is a preferred substrate because its texture is easy for the mycelium to penetrate, and works fine by itself, as do any of the bulk substrate ingredients listed above. Horse manure edges them out a bit in my opinion, but coir runs a close second. My preferred spawn material hands down over all the others is organic rye berries. Rye grass seed would be second, with wbs coming in third.

COMPOST SUBSTRATES - I have a local source for yard waste compost and it's a great addition to substrates. It works best if you mix it with some manure, and even the composted cow manure from nurseries works well mixed with the garden compost. Add a small amount of bagged chicken manure from the nursery and you have a great substrate. If it seems thick, cut it with a bit of vermiculite and/or coir. You can also add perlite to bulk substrates to fluff them up. The perlite holds air, which comes in handy in manure-based substrates. You can also throw in a few days worth of spent coffee grinds. In other words, the more different things you add to your substrate, the better it will perform.

LIME FOR SUBSTRATES - Gypsum yes, but no lime. Mushroom mycelium prefers an acidic substrate, and since we pasteurize horse manure and then allow it to fully colonize, it's resistant to contamination. Therefore, a pH in the 5.5 to 6.5 range is perfect. I used to add a touch of lime to bulk substrates, but no longer do and performance is better. We add lime to casing layers to protect them against molds, since they don't fully colonize with mushroom mycelium. No lime in manure substrates. Cased or uncased. Performance will be higher. Besides, gypsum tends to stabilize the substrate into the mid to upper 6's.

SUBSTRATES - The coffee you use in substrates is ONLY what you empty out of the strainer or filter after brewing a pot. In other words, leached coffee grinds. Do not use instant or liquid coffee in substrates. Mix coffee in any percentage you want. I've grown on pure coffee. The more items you mix into the substrate, the better. If you have manure, coir, worm castings, compost, coffee grinds, straw, etc., use a little of all of them. Add up to ten percent by volume of gypsum and mix all the dry ingredients. Then, add water to field capacity and pasteurize.

SUBSTRATES - Coir in a substrate helps to provide food the horse manure doesn't. It's part of a balanced diet. Vermiculite is great mixed with everything mycological except straw. Used coffee grinds from your morning pot of coffee are also an excellent additive. Ditto for worm castings. A small amount of chicken manure is also beneficial but don't go over 5% by volume of the substrate. Put a combination of all-together in your substrate and watch your mushrooms thank you for it.

SUBSTRATE MIX - I like to mix store bought composted cow manure, coir, coffee grinds, and worm castings all together, then add 1/2 tablespoon of hydrated lime per cup of mix. Then, mix all that with an equal amount of damp vermiculite.

Bring it all to field consistency and pasteurize. It works like a charm.

BULK SUBSTRATES - Bulk substrate IS less nutritious than grains. That's why we need to use so much of it. Bulk substrate can be simply pasteurized, while the much more nutritious grains must be sterilized and kept sterile until colonized. Then, they add significantly to the total nutrients in the bulk substrate they're spawned into.

SUBSTRATES - Complex substrates are always better. Mix as many ingredients as you have. Coir, horse manure, worm castings, coffee grinds, cow manure, chicken manure, compost, straw, etc., are all good, and mixed they're even better. Don't go over 5% of the total as chicken manure though. Use gypsum at ten percent.

SUBSTRATE ADDATIVE - I did a few experiments several years ago where I added fish emulsion and several other nitrogen boosters such as blood meal to manure and compost mixes and saw no effect on the crop. I then added small amounts of chicken manure and saw a very noticeable increase in yield.

SUBSTRATES - Cow and horse manure are equally suitable for growing dung and straw loving mushrooms. Getting the texture right is part of the skills of growing. Horse manure is ready to use once it's been field aged. Cow manure works better when fluffed up with vermiculite, coir, straw, etc., but it's all-good.

SUBSTRATES - Performance will be poor at best. BRF has at least ten to twenty times the nutrition of manure or coir either one. They will only dilute the substrate. That's why they're bulk substrates. They need to be used in large quantities, not small.

SUBSTRATE ADDATIVE - It's been used successfully in substrates before, but it was a mistake to use in a casing. Casing layers should be non-nutritious.

SUBSTRATE - Dried pumpkin seeds have been used in the past, but the flesh of the pumpkin is ...garbage.

SUBSTRATES - Pick out the logs. The little sticks are fine, as they'll colonize.

VERMICULITE - Fine vermiculite holds more moisture per volume of measurement than course vermiculite, due to there being more of it. The basic formula of 2-1-1 works great with fine or medium vermiculite, but if you're using course vermiculite, you might want to cut down a bit on the water. I've found that cakes as well as grains, and even bulk substrates colonize a bit better and faster if made up on the dry side. With cakes, it's easy to adjust the water down, and then simply do a dunk and roll at birthing to put the moisture in for the flush at that time.

VERMICULITE - Vermiculite is soft and resembles a mineral sponge, able to soak up water and hold it. Vermiculite also has lots of passageways the mycelium can colonize while absorbing the moisture within. Vermiculite is for holding water as a reservoir and releasing it to the mycelium as needed. Vermiculite is used in pf cakes and casing recipes. It will also provide fluff and a rez effect (reservoir) in manure and compost mixes.

VERMICULITE - I use the fine vermiculite, which holds more water per cup then the medium grade vermiculite, but still use the basic 1-1-2-pf recipes. This makes a drier substrate that colonizes in two weeks. Give an extra week to consolidate, then birth, dunk and roll. I see pins regularly 48 hours after birthing this way instead of having the cakes sit there for a week or two.

VERMICULITE - Vermiculite is an excellent moisture reservoir that holds more water for its size than anything else. Any substrate, including sawdust/woodchips or manure can benefit from the addition of vermiculite. There is also no other method of growing that can grow more mushrooms on less substrate than pf cakes. That's a fact.

VERMICULITE STERILIZATION - I've done it both without and with sterilizing the vermiculite. Vermiculite is an inert mineral that does not harbor or grow contaminants, but if mold spores are present, they might have an opportunity to grow. I usually put mine on a baking sheet for half an hour at 350F, just because it makes me feel better.

VERMICULITE - In addition, the danger with asbestos is from inhaling dust from the fibers over a long time, such as working in a mine 8 hours a day for 20 years. It isn't from eating mushrooms from a cake with vermiculite in it, even if it DID have asbestos, which it doesn't.

VERMICULITE - I also use fine vermiculite, and it works fine. In fact, it holds a bit more water than course vermiculite, and the mycelium seems to colonize it just fine. It's also better for use as the contaminant barrier on top.

SOAKED VERM SUBSTRATE - I have soaked straight vermiculite in various nutrient laden solutions. It will colonize, just fine - without anything else added.

METABOLITES/LIGHTING

METABOLITES - That quote above by Stamets in TMC written in 1985 when he was fairly new to cultivation was a mistake. He corrected it very well in the 1990's when he wrote 'Growing Gourmet and Medicinal Mushrooms', where he correctly stated they are antibiotic compounds.
Furthermore, the journal of medicinal mushrooms publishes articles on a regular basis identifying the various antibiotic compounds in various species of mushroom mycelia metabolites.
The first mass use of metabolites in medicine was in WW2 when the production of metabolites from the Penicillium mold saved thousands of Allied soldiers lives due to a product that was named Penicillin after the mycelium metabolites it was made from. I'm completely in awe that you folks don't know this. It should have been taught in elementary and junior high school, both in history and science. It's not brand new news.
Furthermore, there is a time and place for vulgarities. I'm no prude and no religious freak by a long shot, but in science one need not use vulgar terms if he wishes to be taken seriously. I'll be the first one to let out a four-letter tirade over politics when I'm having a few beers down at the pub, but not here, and not in conjunction with mycology. I hope this clears it up. I'll stay on it until people stop using the wrong terms. It's no different than correcting someone for referring to an uncased bulk substrate incorrectly as a 'casing' or referring to manure as a spawn, rather than a substrate, etc. It's simply incorrect and should be corrected or new growers trying to learn get fed the wrong information.

METABOLITES MYCELIUM PISS - Mushroom mycelium secretions do not equate to human urine in any way, shape or form. That is disinformation and it makes the hair on my neck stand on end when I see it constantly repeated. They are unrelated. In fact, the secretions from many fungi are used to make antibiotics. Read up on the production of penicillin, tetracycline, erythromycin and other antibiotics that are made from the secretions of fungi. This has been known for a long time in professional circles. For some reason, people around here keep repeating the same old 'mushroom piss' crap and others read it and repeat it ad nauseum. The secretions, which contain acetone and other volatile compounds can actually be fermented and distilled out of the liquid culture the fungi mycelium is being grown in. In commercial penicillin production, large fermentation tanks of over 30,000 gallons are common. It is not the penicillium mold itself that they make penicillin from, but its secretions. Please stop using urine as an analogy for the antibiotic secretions of our precious fungi.

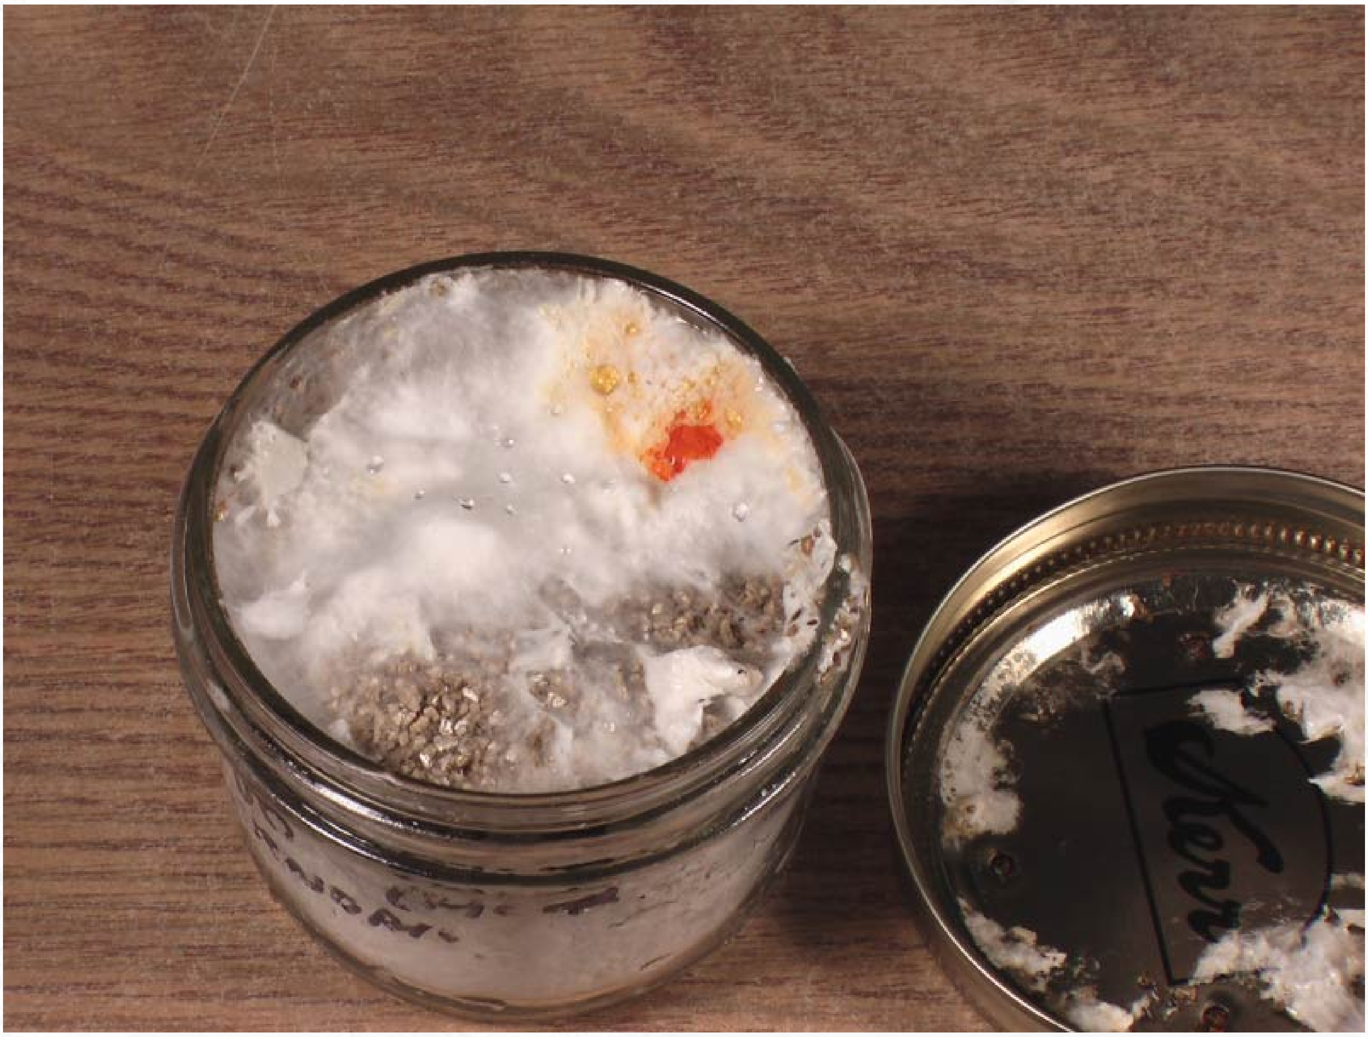
METABOLITES FIGHT - Actually, I have harvested metabolites and used them on other molds, which they kill. Often, when a grain jar is left too long after full colonization, metabolites will begin building up in the bottom of the jar. These can be poured right on an infection in another tray. If caught in time, many molds can be neutralized this way. I doubt it's the antibiotic properties of the metabolites at work against molds, but rather the solvents. Antibiotics are effective against bacteria, which isn't a contaminant of casing layers.

METABOLITES PURPOSE - Mycelium produces metabolites in response to contaminants or stress. These are antibiotic compounds that the mycelium produces to kill competitor fungi or bacteria. They are not in any way, shape or form related to the urine that is secreted by mammals. The metabolites produced by mycelium of the penicillium fungus for example are used in human medicine as antibiotics to kill bacteria. The metabolites produced by mushroom mycelium serve a similar purpose.

METABOLITES - Actually, metabolites don't attract bacteria; they're a response to it. They're antibiotic. It sounds like you have some bacteria in the jar and they're being excreted by the mycelium to help fight it off. You can lay the jar on its side, and then rotate it once per day. This keeps uncolonized parts out of the liquid, helping them to finish up. The above assumes it's a grain jar. If it's a pf jar, disregard. Laying on its side and rolling can disturb the vermiculite filter leading to contaminants entering.

USES FOR MYCELIUM METABOLITES - Experiment. Put some bacteria on a Petri dish, and then put down a line of metabolite. Watch how they stop the spread of the bacteria. Without a lab, I doubt you could make your own antibiotics, but penicillin and the other common antibiotics are made from fungi metabolite. I've also found that mushroom metabolites will kill trichoderma mycelium on a Petri dish. In fact, it would probably kill off any competitor fungi, even other mushroom species.

METABOLITES - Mycelium often produces metabolites of different colors depending on what infection they're fighting. This red color was on the top of the vermiculite barrier where the mycelium had worked it's way up to where contaminants had entered through the vent hole and were laying dormant on the vermiculite barrier. When the mycelium reached that spot, it produced metabolites (antibiotic compounds) to kill the mold spores or bacteria that were present in that location.



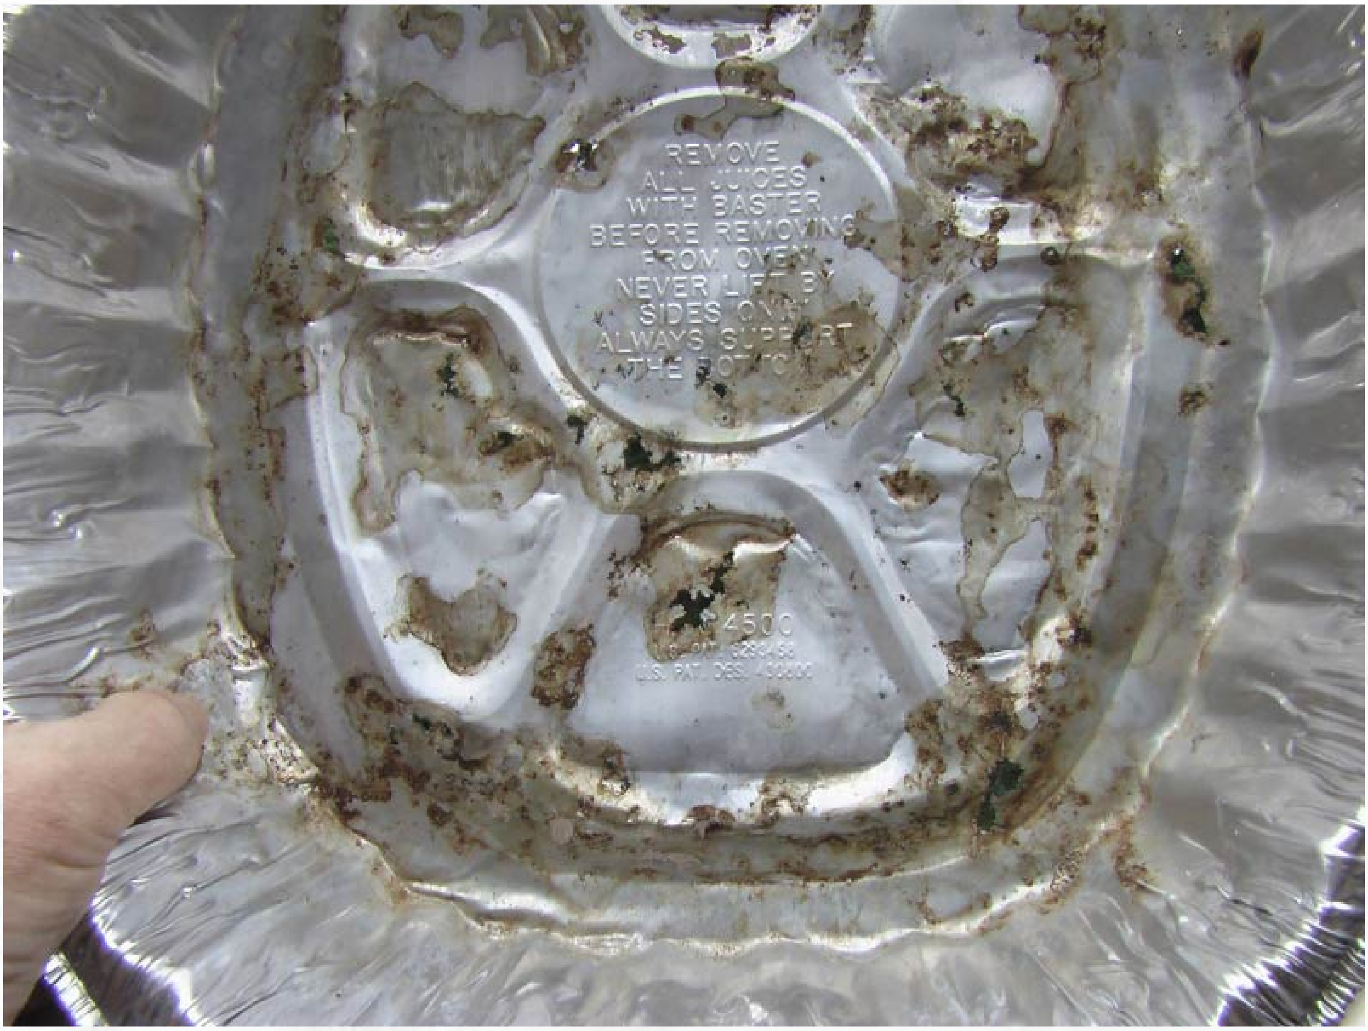
METABOLITES - The metabolites are antibiotic secretions, so when they're in large amounts, it usually means something is up. High colonization temps will also lead to metabolite production, so remember to colonize jars at room temperature. A jar with a good filter will contain any contaminants that are within, so don't toss it out. Don't use any jar with a lot of metabolites for grain-to-grain transfers, but if they colonize fine, they're good to use for spawning to bulk.

METABOLITES - Colonized poo trays sometimes emit a little honey yellow, to as dark as Tobacco juice colored metabolite type waste on the top of the tray. So long as it colonized nicely & the metabolite waste doesn't turn into a gusher. It's good to go. Been there & done that a few times, especially with big bulk trays that had a strong cow/poo mixture in them. The stuff is commonly called MYC PISS. If it's fully colonized, add a casing cover & go for it.

METABOLITES - There will be no live bacteria in the metabolites. They're acids and often ethylene based to kill bacteria and are produced in response to it. There may be bacteria in the grains, but not in the metabolites. That's why grain jars should be used at full colonization, not weeks later. The metabolites are the myceliums defense mechanism. I've used the metabolites from Hypsizygus ulmarium to kill bacteria and trichoderma on a Petri dish.

METABOLITES - It's metabolites since they're yellow. That is a sign of too much bacteria and/or excessive temperature. Is that uncased manure? I'd suggest gently dabbing the excessive off with a clean dry paper towel. The metabolites help to fight infections, but too much of a good thing isn't always good. Dry it off, and increase air exchange. You want high humidity, especially if fruiting uncased, but you also want lots of fresh air.

METABOLITES - The manure isn't eating the holes in the aluminum, the mushroom metabolites are. I have a mushroom that was sent for metals testing after harvesting from the tray pictured below. I should know within a few days if aluminum was conducted up into the fruit body. We know that heavy metals end up in the fruits, but as far as I know, nobody has ever had a fruit professionally tested for aluminum contamination.



METABOLITES - It sounds like metabolites and is often caused by excess temperature, which leads to bacterial contamination. Metabolites are antibiotic and are secreted in response to the bacteria or molds. Incubate at room temperature for best results and lowest contamination rate. I haven't even owned an incubator in ten years. They're not necessary and cause far more problems than they solve.

METABOLITES - The metabolites are generally produced in response to bacteria that are stimulated by high incubation temperatures. My rule of thumb is if you can see visible metabolites in the bottom of the jar, it's ok to spawn to bulk, but don't do a g2g with it, or the dormant bacteria will come back to life in the fresh grains. Next time, incubate your grains at room temperature.

METABOLITES - The excess moisture you see is metabolic discharges from the mycelium trying to fight off the contaminants, and/or metabolites from the molds trying to fight off the mushroom mycelium. Start over, and use a very light syringe, or better yet, prove your spores on agar, and transfer a proved, clean mycelium culture into your rye and watch it take off.

METABOLITES - A large amount of metabolites generally means a bit of bacteria in the jar. The metabolites are antibiotic secretions, so when they're in large amounts, it usually means something is up. High colonization temps will also lead to metabolite production, so remember to colonize jars at room temperature.

METABOLITES - Mycelia metabolites are not urine. They're antibiotic and much more like medicine than pee. In fact, they also help to break down the substrate for the mycelium, much like the saliva in our mouth (which is also not urine) helps break down our food, making it available to the mycelium.

CAUSES FOR METABOLITES - Elevated temperatures are a major cause of that. The high temperature stimulates bacteria, and then the mushroom mycelium must secrete antibiotic metabolites to deal with them. It's important to use room temperature for colonization, especially with larger substrates.

WHAT ARE METABOLITES - Antibiotic drugs such as penicillin are, and have been made from fungal metabolites for over fifty years. It is not a theory. I have used a syringe to draw metabolite from a grain jar and placed it on bacteria in a Petri dish. It kills the bacteria dead within hours.

METABOLITES - Antibiotics such as penicillin are made from fungi metabolites. They're a powerful anti-bacterial. They also help the mycelium to break down substrate materials. There are still a lot of unknowns to be researched, but they're not urine or feces, that's for sure.

METABOLITES - I'm convinced many growers who think they 'cut away lipstick mold' and succeeded, actually cut away harmless metabolites from their jars. Metabolites are produced by the mycelium in order to attack competitors. They're a weapon.

METABOLITES - Metabolites are a natural secretion of fungi both as a defense mechanism against competitors and to break down food sources. Molds produce as much or more metabolites than mushroom mycelium.

METABOLITES - It's just metabolites from the high temperature. NEVER use a jar with a lot of metabolites for grain-to-grain transfers, but you can use it to spawn to bulk or lay in a tray and case.

METABOLITES - They're actually antibiotic compounds used to neutralize competitor fungi and bacteria. That's why medical antibiotics are made from them.

METABOLITES - An excess of metabolites can point towards bacterial contamination, over-colonization of a substrate, or too high a temperature.

METABOLITES - Yes. Excessive heat will cause the mycelium to produce more, so if there's a lot of metabolite, try to reduce temperature.

METABOLITES - The metabolites will do no harm. You can leave the substrate soaking in it. They destroy contaminants, not cause them.

METABOLITES - A large amount of metabolites generally means a bit of bacteria in the jar.

METABOLITES - Actually, metabolites don't attract bacteria; they're a response to it.

LIGHTING

Light has absolutely NOTHING to do with telling the mycelium that it has reached the surface. The increased fresh air, with the corresponding drop in CO_2 levels sends the mycelium that message.
Light is also NOT just to establish the direction the fruits grow. In fact, air currents have a greater effect on direction of growth than light. If you doubt this, place a fan on your crop and watch.
A few seconds of light per day will NOT help to generate a good pinset. In fact, light is a secondary pinning trigger, but an important one. The difference between three or four pins, and hundreds of pins on a substrate can be directly correlated to the length, intensity, and frequency of the light applied, provided the primary pinning triggers have been fulfilled.
The light needs to be intense enough to penetrate 1/2" into the substrate. Not all pins form on the surface. Many originate from deeper in the substrate or casing layer.

Higher frequency light above a color temperature of 5,000 Kelvin will generate far more pins than a 'red' source of light such as incandescent lamps.
Fungi are a living organism that is much more closely related to mammals such as humans, than to plants. People need to quit looking at mycelium as a different kind of plant, which it isn't. Mycelium has been shown to have circadian rhythms just like mammals, and this is the reason that 12/12 light cycles work best. This planet, and all surface life on it are based on the 24-hour day. For best results, learn to work with nature rather than against it. Mycelium has an amazing ability to cope with less than optimal conditions, and will often fruit when a grower does everything wrong. However, do everything right and watch your performance go through the roof.

TMC FAULT, LIGHTING, WHY - Recent experiments (over the last 23 years) have shown the error of that statement in TMC. Many experiments have shown conclusively that fluorescent lamps in the 6500K range produce better pinsets and healthier, meatier fruits than other forms of light. Stamets himself does not repeat that 'flash of light' triggers pinning nonsense. In fact, he recommends fluorescent lamps in the 6,500-Kelvin range for 12/12 just as I do. In addition, there's a huge difference in saying something can result in 'pins', and helping to trigger a very nice flush.
Light, and the intensity/frequency of light is extremely important if one is interested in greater than mediocre performance. Many species, such as agaricus and P. cubensis, can pin in the total absence of light. That doesn't mean light isn't required for best results, especially with light sensitive species such as P. cubensis and P. ostreatus.

WHAT YOU WANT! - You want full spectrum light for best results. Indirect light from a window is fine. Hyphal knot formation is stimulated more by light at the higher end of the scale than at the lower end of the scale. A color temperature of around 6500K is just about perfect. This is the color produced by 'natural daylight fluorescent' tubes. For the geeks, I'll explain color temperature briefly. We all know when we heat a piece of metal, it first begins to glow red. We see this when we heat a syringe needle over a flame. If we continue to heat it, the metal will eventually glow white hot. As we heat it more and more the white color begins to take on a blue hue, provided the metal doesn't melt down into a puddle first. This is why tungsten in a vacuum is often used for light bulb filaments.
The Kelvin color temperature system is essentially the color a piece of dark metal will glow when heated to a specific temperature. The Kelvin scale starts at absolute zero, roughly -237C. This is Zero K. The scale follows the Celsius temperature scale and remains constant. Therefore, water freezes at 237K and boils at 337K. If you heat a piece of metal to a temperature of 4,763C, the resulting glow will have a color temperature of 5,000K. The color scale is used as 'corrected' color temperature when fluorescent or other gas type lighting fixtures are used. A 'natural daylight' fluorescent tube with a color temperature of 6500K would glow with the same color as a dark object heated to a temperature of 6,263C.
Color temperature is not an indication of the intensity of light, only its color. Mycelium forms fruits best with light at the 'blue' end of the spectrum, thus a higher color temperature is required for best performance. Look for lighting with a high color temperature such as fluorescent. Cool white fluorescent has a color temperature of 5,000K and natural daylight has a color temperature of 6,500K. Avoid UV light that is too high, and has been known to damage mycelium, as well as cause mutations, and cancer in humans.
Incandescent light bulbs by contrast, have a color temperature of around 3000K, which puts them in the 'red' end of the spectrum, and they are the worst choice for fruiting mushrooms.

LIGHTING - Many things. I've found the brightest light stimulates more pins. You need to look at pinning triggers like the instruments in a band. One instrument can be slightly off, and the band still plays the song. Often one instrument can be taken away and the music still sounds ok. However, if all are working together, it's awesome.
Perhaps the projects you remove from light after exposure are maintaining a higher humidity due to no heat from the lights. Humidity is a pinning trigger just like light. Maybe the ones you remove from the lights get better air circulation. Fresh air is a pinning trigger just like light.
For the record, light has no effect on colonizing mycelium, good or bad. The old advice of "incubate in total darkness" is bunk. Stamets wrote those words in TMC 20 years ago, and he disavows that advice today. I concur. The only real time that keeping in the dark has an advantage in my experience is during casing run, when the introduction of light after casing colonization can serve as one of the pinning triggers along with air exchange and proper humidity. Bare in mind, you want a constant rate of evaporation from your substrate to achieve the best pinset. If you're at 100% humidity, there will be little to no moisture evaporating from your

casing layer, and pinsets will suffer.
To repeat, light is a pinning trigger, but it isn't the only one, and it's greatly overrated. For the best pinsets, you have to balance several triggers at once. Screw up on any of them, and pinsets suffer, regardless of what you do with light.

LIGHTING - Normal room lighting has no effect on colonizing mycelium, either good or bad. This is one of the old myths perpetuated by stamets 'The Mushroom Cultivator', that was incorrect 20 years ago when it was written. He corrected his own mistake in GGMM, but fewer people have read that one because it centers more on edibles, than on psilocybe mushrooms. My own research says light doesn't make one whit of difference to colonizing mycelium in jars. The time to protect from light is during spawn run of bulk substrates and casing layers. During the initial colonization of grains or brf cakes, it doesn't matter. Light is required for primordia formation as well. Bulk substrate colonization is the last step prior to fruiting. The only reason for keeping a bulk substrate, and especially the casing layer dark during colonization is for the timing of the pinset initiation. It allows you to introduce all the major pinning triggers simultaneously, resulting in an explosion of pins. A bulk substrate will colonize just fine if exposed to light from day one, but then you aren't maximizing potential by synchronizing the pinning triggers.

TMC FAULTS LIGHTING - TMC is a classic and I still refer to it a lot. In the last twenty years we've learned a few things though. One, as hyphae said is the mycelium metabolites. Another is that colonizing mycelium need not be kept in total darkness. I think Paul fixed that one in GGMM, but I know at his beginners and masters seminars he points that out, and his own incubation rooms filled with hundreds of species, are under 8 to 12 hours per day of fluorescent lighting while work is being done. That has been my experience as well. Light doesn't become a significant pinning trigger prior to full colonization and the introduction of fresh air exchange. This one is probably nitpicking, but I don't like the TMC method of preparing grain jars which is add dry grain, add water and a pinch of gypsum, and PC. We now know that if you'll take the time to rinse the grains very well before cooking, they don't stick and clump up later. There's a couple of others I can't think of now. Nothing major though. It's a great reference work.

LIGHTING - While enough light to read by might give a minimum pinset, you want bright, high frequency light to induce a massive pinset. An hour or two in a window with even direct sunlight is great to kick start a pinset, but don't let the tub overheat. For the rest of the cycle, find a way to get the fluorescent to shine through the clear part of the tub. Put the light in front of or behind the tub. It doesn't have to come just from the top. The white lid will reflect side light down just fine. My entire greenhouse is lit from the back with fluorescent fixtures attached to the wall the greenhouse sits against. Cool white fluorescents produce 5000k, which is very close to natural sunlight. Incadescents are a much redder light and only produce at around 3200k, which is not nearly as effective. You want high frequency light for best results. The natural daylight fluorescents are the best, putting out light at around 7000k, but are much more expensive than cool white. Good luck.

LIGHTING FREQUENCIES, PLANT LIGHTS - Plants require much more light than mushrooms because they derive energy from the light source. In addition, most mj growers switch to a redder light at fruiting time, not the high frequency 'blue' light we get from our fluorescents. Perhaps you're confusing the Kelvin color temperature scale with intensity? My fluorescent fixture provides light to six shelves, each one eight feet long and three feet deep. That's 144 square feet, thus less than 1 watt per square foot of shelf space. The foil helps to prevent the trays in the back from being shaded by those in front. I challenge the best mj grower in the world to try to grow plants under that. Compact fluorescent bulbs work great as well for fruiting chambers and mini-greenhouses. In addition, LED technology has progressed considerably in the last few years. I'm sure it won't be long before LED fixtures are made with controllers to adjust color temperature.

LIGHTING - "Of course myc doesn't need dark but we use it to our advantage as a pinning trigger"
Exactly. After spawning the grains or brf or whatever into manure, it's a good idea to cover with foil to keep it in the dark during substrate colonization and casing colonization, and then remove the foil for light and sudden air/gas exchange to trigger pinning. However, I've found no benefit or harm from allowing the grain jars to be exposed to light from day one. If a few pins form in the grains, it is actually a good thing. Contrary to popular belief, a few pins in the grains can be spawned right into the manure or straw (or used in grain to grain transfers) and they do not rot or otherwise cause contamination. There is evidence they actually help to give a faster, more uniform pinset in the eventual flushes. Stamets believes it's the hormones or other

chemical triggers in the pins that do this.

LIGHTING - Light is very important after full colonization, when an increase in FAE is made. Enough light to 'see the tray' is absolutely NOT enough light unless you're happy with shitty pinsets. Brighter light is better. Higher frequency (blue) light such as is emitted by 'natural daylight fluorescent' tubes which produce light at 6500K are best from mine and Stamets tests. Cool white fluorescent tubes would be a second, lower cost choice and will work fine. Incandescent bulbs which emit 'red' light at 3000K are the worst choice. In addition, 24-hour light is extremely counter productive because hyphal knots form, and the fruit bodies seem to grow the most during the period of darkness. You can all prove that by simply measuring your growing mushrooms when you turn the light on, and again when you shut it off. You'll find growth is higher during the dark phase.

LIGHTING - Use full spectrum light, or a light that is in the higher frequency range. Don't use 'blue' lights or a 'blue' tub. Such is not in any way, shape, or form what the mycelium needs to perform well. The use of 'blue' led's or blue tubs is based on a misunderstanding of what Stamets was talking about in GGMM when he recommended high frequency lights, such as natural daylight fluorescent. This has all been covered ad-nauseam in previous light threads. It absolutely amazes me that people still repeat the 'any light will do' or 'if you can see, your mushrooms have enough light', or 'only a few minutes is enough' etc., etc. If one is satisfied with shitty pinsets, the above is true. If you're less than satisfied with shitty pinsets, use a light in the 6,500-Kelvin range. Incandescent grow lights are one of the worst possible choices.

LIGHTING - At full colonization, light becomes very important. The only real time you need to put your trays in the dark is during casing run. This allows the casing layer to colonize partially without the additional pinning trigger of light acting on it. At the proper time, you expose to light, increase FAE, and have full colonization all at the same time. This results in the best possible pinset. Read Hyphae's pinning strategy in his sig for more information on timing these events. There is no point in putting it into the dark now that it's already pinning. The fluoros you have will be plenty, but try to attach or hang them higher so they can give better direction to the fruits as they grow. It will also help hyphal knots to form if you'll have the light above the casing layer because it will penetrate deeper into it, thus helping to trigger knots. Good luck.

LIGHTING - Light is extremely important to good mushroom formation, and it's nothing to do with which way is up. Gravity takes care of that function. The post quoted above is only one of many times I've typed that. The problem is every time this question gets asked, people repeat the same 'stuff they've read' and thus if one of us fails to catch the misinformation, then somebody gets a grow compromised by using a desk lamp or some other less than desirable lighting source, rather than the best possible lighting. There's enough confusing points in mushroom growing to keep a board like this busy forever. Ask about things you're not sure of, or of the details you don't understand after searching. However, for the basic questions, the answers are all right here at your fingertips. Good luck to all. I'll try to be less pissy.

EXPOSING LIGHT FROM DAY ONE - In my experience, it's better to expose to light from day one. If you'll just let your bags or jars colonize on a shelf in a room of your house, they'll be exposed to normal room light. This will help to initiate pinning as soon as the substrate is ready to support fruitbodies. Colonizing your jars in the dark only delays pinning, and delay is not good in this hobby. Get light on it right away. I seriously disagree with keeping cubie mycelium in the dark at any time. I expose to light from the time the spores germinate on agar. Sometimes there are even a few pins in the jars when I break them up for the casing. That is no problem. Just mix them in and case it. If you give light from day one, your yields will go up, and you won't face overlay problems.

LIGHTING - Lighting is EXTREMELY important for a good pinset. Cubes will fruit in very low light conditions, but bright fluorescent light will help to trigger the pinsets the old timers show all the time that makes folks drool. Actually, you're probably right. The mushrooms don't care that much about light, but the mycelium sure as heck does. Lights, especially fluorescent, should be outside the terrarium, but near enough to flood the fruiting chamber in bright, high frequency light. Don't put the ballast outside and the lamps inside. The tombstones have a fairly high voltage potential across them, and wrapping a warm item in plastic in a wet environment is ...dumb. There isn't much more useless than 'blue' mood lights, especially from led's.

LIGHTING - There's a world of difference between 'blue spectrum' and what you get when a red light (incandescent) shines through blue plastic. (Dim) By 'blue' they mean high frequency light, such as would be

emitted by a metal halide bulb, or natural sunlight fluorescent. You'll want to get better lighting to get the best pinsets. It's better than nothing, but only ten percent of the electricity to run an incandescent is turned into light. The other ninety percent is turned into heat. Fluorescent fixtures are the opposite. 90% of the energy is turned into light and ten percent into heat. They're also closer to the frequency that is ideal for pinning.
http://www.shroomery.org/forums/showflat.php/Number/6611363#6611363

LIGHTING - All lights will produce heat. The light needs to be outside the fruiting chamber. Electricity and 100% humidity don't mix. Don't use blue Christmas lights. They're NOT the correct color temperature. By 'blue' we mean light at the high end of the spectrum. It will still look white to your eyes. As said, 6500 Kelvin fluorescent lights give the best bang for your buck. They're usually labeled 'natural daylight' on the package, as opposed to 'cool white' which are 5,000K and 'warm white' or 'kitchen and bath' which are 3000K, which is referred to as 'red' light, even though they still look white to our eyes. You can also simply place the terrarium in a room with a bright window and let the natural sunlight do the job.

LIGHTING - 2700K are awfully red. It might be nice for room light and for reading because it's 'warm', but you want light in the bluer end of the spectrum, so shoot for a frequency above 5,000 Kelvin. Lumens do matter to an extent. We're not deriving energy from the light, but it does need to be bright enough to penetrate into the casing layer. Bright fluorescent light from a 'daylight' type tube seems to help generate the best pinsets over a wide range of species. I have a four-tube 48" fluorescent fixture with 6500-Kelvin tubes in all four slots. This light is plenty for my mini-greenhouse. I have it hanging from the ceiling so it shines into the front of the greenhouse. Reflective foil is on the back wall of the GH.

LIGHTING - It sounds like something else growing in the area. MH is known to cause early pinning in jars because of the high frequency light output of MH. However HPS is more of a red light at the lower end of the spectrum, so it shouldn't be that bad. I'd still move the jars away from it. The heat could cause problems. There is no need to keep colonizing jars in the dark, but there is also no need to expose them to very bright lights either. When fruiting time comes, you'll probably do better to get a natural daylight fluorescent. The 6500K color temperature seems to stimulate primordia formation better than the lower color temperatures of lamps such as incandescent and HPS.

LIGHTING - You want bright light for 12 hours per day, not normal room light, which is usually at the red end of the spectrum if it's from incandescent bulbs, and is the worst possible choice. Incandescent bulbs produce light at 3000K. Cool white fluorescents are a higher frequency light and perform much better, with a color temperature of 5000K, and natural daylight fluorescent produce light at the 'blue' end of the spectrum with a color temperature of 6500K. You don't want blue lights. Light at the high (blue) end of the spectrum will look white to your eyes. You don't get high frequency light by using a bulb with a blue dye on the lens.

LIGHTING - Not at all. They will do best with 12 hours of light. I'd put them in the dark when they're about 90% colonized, then when they are at 100%, birth and begin giving them light at that time. This allows the four major pinning triggers of full colonization, steady rate of evaporation from the substrate, fresh air exchange, and light to all happen at the same time. Such has been shown to give the best pinsets. Light does not become a significant pinning trigger until the other factors have also been met. Many growers dunk at the time of birthing to pump the moisture content up for the first flush.

TMC FAULT, LIGHTING - Light has neither good nor ill effects on growing mushroom mycelium. It will not hurt, nor help, but there is no need to keep your jars in the dark. Stamets makes this clear in GGMC. He used to recommend incubation in total darkness (TMC), but he no longer recommends this. I concur. If you visit fungi perfect you will see he has 10,000 square feet of incubation space that is exposed to overhead fluorescent lights during the full workday. My jars sit on a shelf in an open room as said above and they're exposed to light from the day spores are started.

LIGHTING - The Kelvin scale refers to the color temperature of the light. Briefly stated, if you took a piece of white paper and looked at it under 2,000K such as you'd get from hps, it would look yellow. If you looked at it under 5,000K fluorescent tubes such as you'd find in an office or school classroom, it would look white. If you look at it under 7,500K fluorescent, it would have a blue tint to it. That's what is meant by 'blue' light. You can pick up an inexpensive fluorescent fixture and 7500K fluorescent tubes fairly cheaply at your local hardware store.

LIGHTING - My current setup is a larger fluorescent fixture that holds four 48" tubes, and I have it hanging vertically so it shines in from the front to bathe all five shelves in bright light. I have it about 12" from the door of the GH, so the farthest any substrate is from the light is about 36". The fruits tend to grow toward the light a bit, but that problem is fixed by rotating the trays 180 degrees every couple of days so growth is even. I'm glad to see you got the right frequency of light. 6500K are awesome. You'll never go back to silly night-lights or cool white fluorescent after using one of those. They really do make a difference in pinsets.

LIGHTING - I've still never seen a 150-watt cfl that small. At any rate, with multiple shelves or long shelves, tubes will spread the light out better, thus giving more coverage. I use 5 shelves in my mini-greenhouse, with a 48" fixture hanging vertically in front of the unit, which holds four fluorescent tubes with a color temperature of 6,500K. By hanging the light fixture vertically, the fixture lights the entire greenhouse between all shelves. With only one bulb, you're limited in coverage. They'd be great for tubs and the like, but there is no need for 250 watts. It will burn five or more times the electricity your projects require.

LIGHTING - They do care if they don't get air. You'll get a very poor pinset without several air exchanges per day at the very least. Four to five per hour are recommended. Water beads on the inside of the terrarium have NOTHING to do with humidity. They indicate a temperature differential, nothing else. You want your light outside the terrarium. Fluorescent ballasts generate a high voltage, and that doesn't go with near saturation humidity at all. In addition, a fluorescent ballast and light inside will heat your terrarium a lot. It will be over 90F in there within a few hours. Also, the heat will lower humidity, not raise it.

LIGHTING - Mushrooms grow towards the light. Very true. However, as an experiment, you can put the light above and a fan blowing from right to left. Watch what happens. In the absence of any wind, the mushrooms grow towards the light. You can also screw with your mushrooms if you're bored. Every morning, rotate your trays of pinning/fruiting mushrooms by 90 degrees, and leave them until the next morning, then rotate them an additional 90 degrees. They'll grow up in a spiral.

LIGHTING - You can't argue that light makes a big difference with growers that are happy with crappy pinsets. However, if you want the best pinset and growth you can get, and then use bright light with a color temperature of 5,000 Kelvin to 7500 Kelvin. Of course, there's other parameters that are just as important, if not more important than light. Failure to pay attention to ALL the pinning triggers is like trying to win the Indy 500 with a clogged up air filter or dirty spark plugs.

LIGHTING - It's true that they tend to grow more during the period of darkness, but that's only part of the equation. The other part is that pins for second, third, and future flushes often form during the time of first flush. If you go cheapie on the light after the first flush is set, you hinder primordia development for future flushes. Mushroom mycelium has circadian rhythms just like humans. Give them a day/night cycle and they'll be much happier over the course of several flushes.

LIGHTING - One, a 25W incandescent bulb only puts out the amount of light that a 2.5W fluorescent bulb would put out. Over 90% of the electricity used by a light bulb goes toward making heat, and only 10% of the electricity goes toward making light. With fluorescent, that ratio is reversed. In addition, incandescent bulbs put out light at the red end of the spectrum, and fluorescent lamps put out light near the blue end of the spectrum, which is much better for fungi.

LIGHTING - I've been saying for years that both light and total darkness are vastly overrated when it comes to mushroom growing. Some strains seem to be better at pinning in low light conditions, while others require much more. The other pinning triggers of full colonization, steady evaporation of moisture, and air exchange are much more critical than light. As a general rule however, pinsets will be better with bright, full spectrum lighting over dim/darker conditions.

LIGHTING - The reason intensity is important is because the light needs to penetrate the casing layer to the substrate below. Frequency is also important with light at the higher end of the spectrum, such as natural daylight fluorescent with a light temperature between 6,000K and 7,500K providing the best results. Cool white fluorescent tubes are generally in the 5,000 Kelvin range, and regular incandescent bulbs run about 3,000K, which is the worst possible choice.

LIGHTING - They need light for much more than to know which way is up. A lot has been written about this. Bright, intense light is going to stimulate a much better pinset than dim, low light. 12/12 has shown over the years to give the best performance. I don't even have my lights on a timer anymore unless I go out of town. I plug them in when I get up, and unplug them sometime in the evening. They rarely get exactly 12/12, but close.

LIGHTING - Bright, high frequency light at 12/12 will deliver the most prolific pinsets. You want maximum FAE, high humidity, and bright light, especially with cased substrates. The light needs to be bright enough to penetrate the casing layer for best results. 'Some' pins will form with low levels of light, but if you want the WOW factor, use bright fluorescent light or sunlight from a window. They do best with a period of darkness each day.

TMC FAULT, LIGHTING - Light has little to no effect on colonizing mycelium. I expose all jars to light from day one. I also incubate on a shelf in an open room at room temperature. If you visit fungi perfecti, you'll see that stamets has 10,000 square feet of incubation area, all of it exposed to fluorescent lights for 8 to 10 hours per day. He no longer recommends incubation in total darkness as he did 20 years ago when he wrote TMC. I concur.

LIGHTING - Two things. First, don't install lights inside a terrarium. Even a small light will create heat that causes other problems. Second, if it's incandescent, it's the wrong color temperature. You want a high frequency light such as natural daylight fluorescent for best results. Simply hang it above the terrarium. Bright, intense, high frequency light provides the best pinsets, so get a good one. I use four, 4' natural daylight fluorescent tubes.

LIGHTING - Many fluorescent tubes will have the light temperature stamped on them at the end. Cool white bulbs are in the neighborhood of 5000k while the kitchen and bath fluorescent tubes are warm white, and at 3000K, similar to regular light bulbs. The higher 'k' numbers will deliver better pinsets, because they match outdoor sunlight closer. Fortunately for us, cool white fluorescent which is superior, is also the least expensive.

UV LIGHTING - UV light strong enough to STERILZE will F/U your eyes, skin, cause cancer & other BS. If it is contained, as in well shielded..... it works great, but you still need filtration. Best is hepa filter run into UV light shielded in metal ductwork. Instance I refered to was UV light in metal ductwork behind filter, because it killed anything that got past the filter. The ductwork fed into a "clean" room area & it was fully sheilded.

LIGHTING - Natural Daylight fluorescent has been shown to produce the best results. Your milage will vary depending on the genetics of your strain using other types of lights. However, mushroom primordia seem to develop best in the 5,000 Kelvin to 7,500 Kelvin range which is exactly what is delivered by most fluorescent tubes. The Natural Daylight tubes are rated between 6,500 and 7,500 Kelvin depending on manufacturer.

LIGHTING - Brighter lighting will work better than dim, far away lighting. The light needs to penetrate the casing layer. Don't listen to those who say if you can see what's happening, there is enough light. That is incorrect. You can get small fluorescent fixtures intended for under kitchen cabinets for less than ten dollars. Put one a few inches above your plexiglass. Put it high enough that heat isn't transferred, but bright light is.

LIGHTING - The only reason for keeping a bulk substrate, and especially the casing layer dark during colonization is for the timing of the pinset initiation. It allows you to introduce all the major pinning triggers simultaneously, resulting in an explosion of pins. A bulk substrate will colonize just fine if exposed to light from day one, but then you aren't maximizing potential by synchronizing the pinning triggers.

LIGHTING - If you're going to use LED's, use white ones. Your mushrooms need full spectrum light, not mood light, and some evidence points to light at the higher end of the spectrum being somewhat better at setting primordia. Bright light will penetrate deeper into the casing layer, stimulating more pins than dim light. Avoid lights that produce excess heat such as incadescent or halogen.

LIGHTING - The color temperature (not light temperature) of any specialty bulb should be stamped on the package. Normal incandescents are in the 3000K range, which is too low. HPS is even worse, in the 2000K range. You want light at the other end of the spectrum. Cool white fluorescent is around 5000K and natural daylight fluorescent is 6500K, making it the best choice for the money.

LIGHTING - Use natural daylight fluorescent with a color temperature of 6,500 Kelvin for best results. I said use 6,500 Kelvin natural daylight fluorescent for best results. There is no contradiction. Mushroom cultivation was in its infancy 25 years ago. We've learned a lot since then. Lamps with a color temperature of 6,500 Kelvin are NOT low frequency-they're considered 'blue' light.

LIGHTING - Normal room light has no effect on colonizing mycelium, either good or bad. Usually, when mycelium stalls, it's due to lack of air exchange. If you have a verm filter, take the lid all the way off for a few minutes and then put it back on. If the mycelium starts to grow again, you know that was the problem. Make sure the inoculation/gas exchange holes are open.

LIGHTING - Correct. A 60 watt light bulb on the ceiling is enough to trigger a few pins. Failure to use proper lighting doesn't mean the entire project is going to fail. It simply means it will be less than what could be achieved by a tad more work. It's sort of like driving your car with one tire flat. You'll still get there, but not as fast, and people will point and giggle.

LIGHTING - Xmas lights have been used for years with poor to mediocre results. Don't put too much faith in the experiment done several years ago. Many, many tests since then have shown otherwise. Most any light will stimulate some pins to form, but the higher frequency lights in the 5,000 Kelvin to 7,500 Kelvin range will help to provide the best pinset possible.
